Preface xiii

Authors xv

1 Biomechanical topics in soft tissues 1
1.1 Introduction . . . 1
1.2 Diffusion, convection, osmosis: toward wearable artificial kidneys . . . 2
1.3 Issues in drug delivery . . . 3
1.4 Macroscopic models of tissues, interstitium and membranes . . . 4
1.5 Energy couplings, passive and active transports . . . 5
1.6 More general direct and reverse couplings . . . 6
1.7 Tissue engineering redirected to tumor tissue exploration . . . 7
1.8 From mechanics to biomechanics . . . 7
1.9 Mechanisms of injury of the knee, fracture mechanics . . . 9
1.10 Water and solid constituents of soft tissues . . . 10

I Solids and multi-species mixtures as open systems: a continuum mechanics perspective 11

---

2 Elements of continuum mechanics 13
2.1 Algebraic relations and algebraic operators . . . 13
2.2 Characteristic polynomial, eigenvalues and eigenvectors . . . 17
2.3 A few useful tensorial relations . . . 21
2.4 The differential operators of continuum mechanics . . . 25
2.5 Measures of strain . . . 36
2.6 Transports between reference and current configurations . . . 44
2.7 Time derivatives and Reynolds theorems . . . 47
2.8 Work-conjugate stress-strain pairs . . . 49
2.9 Small upon large . . . 51
2.10 Kinematical constraints and reaction stresses . . . 52
2.11 Invariance, objectivity, isotropy . . . 53
Exercises on Chapter 2 . . . 64

3 Thermodynamic properties of fluids 69
3.1 Basic thermodynamic definitions . . . 69
3.2 Phase change . . . 75
3.3 Thermodynamic functions of fluids . . . 82
3.4 Laplace's law of mechanical equilibrium at the interface between two immiscible fluids . . . 96
3.5 Henry's law and Raoult's law of chemical equilibrium between a liquid and a gas . . . 97
3.6 Composition of fluids in plasma, interstitium, cell . . . 98

4 Multi-species mixtures as thermodynamically open systems 101
4.1 The thermodynamically open system . . . 101

4.2 Chemomechanical behavior and growth of soft tissues . . . 101
4.3 General form of balance equations . . . 105
4.4 Balance of mass . . . 108
4.5 Balance of momentum . . . 110
4.6 Balance of energy . . . 113
4.7 Balance of entropy and Clausius-Duhem inequality . . . 117
4.8 Dissipation mechanisms . . . 124
4.9 General constitutive principles . . . 130
Appendices of Chapter 4 . . . 131

5 Anisotropic and conewise elasticity **133**
5.1 Hypoelasticity, elasticity and hyperelasticity . . . 133
5.2 Anisotropic linear elasticity . . . 136
5.3 Spectral analysis of the elastic matrix . . . 153
5.4 Fiber-reinforced materials: extension-contraction response . . . 155
Exercises on Chapter 5 . . . 164

6 Hyperelasticity, a purely mechanical point of view **173**
6.1 Restrictions to the strain energy function . . . 173
6.2 Properties of constitutive functions and partial differential equations . . . 175
6.3 Total potential energy . . . 181
6.4 Isotropic hyperelasticity . . . 181
6.5 Anisotropic hyperelasticity and Fung's strain energy . . . 183
6.6 Elastic potentials with the elastic-growth multiplicative decomposition . . . 187
6.7 Return to the conewise response in presence of fibers . . . 192
6.8 Elasticity and workless constitutive stress . . . 192
6.9 Use of right and left Cauchy-Green tensors . . . 193
Exercises on Chapter 6 . . . 195

7 Poroelasticity with a single porosity **197**
7.1 Geometrical, kinematical and mechanical descriptors . . . 197
7.2 Elements of mixture theory: the level/scale of the species . . . 199
7.3 Anisotropic poroelasticity: a composite material format . . . 205
7.4 Anisotropic poroelasticity: drained and undrained properties . . . 214
7.5 Unconfined compression of a poroelastic cylinder . . . 227

8 Viscoelasticity and poro-viscoelasticity **241**
8.1 Viscoelasticity, poroelasticity and poro-viscoelasticity . . . 241
8.2 Intrinsic time dependent behavior of collagen fibrils . . . 241
8.3 Complex modulus . . . 242
8.4 Relaxation spectrum . . . 251
8.5 The quasi-linear viscoelasticity QLV model of Fung . . . 254
8.6 Overall viscoelastic properties: ECM and a contractile cell . . . 255
8.7 An electrical analogy applied to the corneal endothelium . . . 256
8.8 Fluid infusion in a viscoelastic polymer gel . . . 258
8.9 Confined compression of a viscoelastic polymer gel . . . 265
8.10 Compression of a poroelastic layer: displacement control . . . 267
8.11 Visco-hyperelasticity and other memory effects . . . 269
Exercises on Chapter 8 . . . 275

9 Thermoelasticity and thermo-poroelasticity **279**
9.1 Thermomechanical properties of elastic solids . . . 279
9.2 Thermoelastic heat, stored energy and dissipated energy . . . 287
9.3 Anisotropic thermo-poroelasticity : mechanics, transport, energy . . . 291
9.4 Generalized compatibility conditions for the stress . . . 297
9.5 Heating a thermo-poroelastic medium . . . 300
Exercises on Chapter 9 . . . 312

10 Transfers of mass, momentum, and energy **313**
10.1 Summary of balance equations . . . 313
10.2 Intercompartment mass transfers . . . 314
10.3 Momentum supply in a poroelastic context . . . 317
10.4 The bioheat equation . . . 317
10.5 Mass and energy transfers between a liquid and a solid . . . 319
10.6 A porous medium with two porosities and three temperatures . . . 321
10.7 A porous medium with a single porosity and two temperatures . . . 334
10.8 Interfacial transfer coefficients and specific surface areas . . . 335
10.9 The coefficients of transfer: two scale derivation . . . 339

11 Waves in thermoelastic solids and saturated porous media **345**
11.1 Basic definitions . . . 345
11.2 Waves in elastic solids . . . 357
11.3 Acceleration waves in thermoelastic solids . . . 362
11.4 Acceleration waves and acoustic waves in fluids . . . 363
11.5 Acceleration waves in saturated porous media . . . 366
11.6 Propagation of acceleration waves in saturated porous media . . . 380
11.7 Plane motions and Helmholtz potentials in poroelasticity . . . 382
11.8 Silent poroelastic boundaries . . . 385
11.9 Surface waves in a saturated porous half-plane . . . 388
11.10 First order waves in saturated porous media . . . 406
Exercises on Chapter 11 . . . 412

II Electro-chemomechanical couplings in tissues with a fixed electrical charge **413**

12 Directional averaging for fiber-reinforced tissues **415**
12.1 Directional analysis . . . 415
12.2 A simple fiber model for the collagen network . . . 419
12.3 Directional models of tissues . . . 428
12.4 The mechanical response of individual fibers . . . 431
12.5 Fabric tensors . . . 433
12.6 Spatial homogenization over cells and ECM . . . 438

13 Electro-chemomechanical couplings **439**
13.1 Chemomechanical couplings in engineering and biology . . . 439
13.2 Molar volumes, electrostriction . . . 439
13.3 Electrokinetic processes . . . 441
13.4 Nanoscopic aspects . . . 445
13.5 Hydration, hydrolysis, complexation and solubility . . . 446
13.6 Some basic notions of electrostatics . . . 452
13.7 Semi-permeable membrane and osmotic effect . . . 454
13.8 Reverse or Inverse osmosis . . . 456
13.9 Electrical repulsion and electrical shielding . . . 457
13.10 The pore composition in materials with fixed charge . . . 457
13.11 The heart muscle and cell electrophysiology . . . 464
13.12 Reverse couplings . . . 468
13.13 A partially coupled chemo-poroelastic model . . . 471
Exercises on Chapter 13 . . . 479

14 Chemomechanical couplings in articular cartilages **485**
14.1 Overview . . . 485
14.2 Histological aspects of articular cartilages . . . 486
14.3 Pathologies, osteoarthritis, rheumatoid arthritis . . . 500

14.4 A brief review of modeling aspects . . . 501
14.5 Interpretation of laboratory experiments . . . 506
14.6 Partition of the tissue into phases . . . 508
14.7 The constitutive structure: deformation, mass transfer, diffusion . . . 519
14.8 Chemoelastic energy of the tissue . . . 520
14.9 Features of the constitutive framework . . . 524
14.10 Remarks on constitutive frameworks and constraints . . . 527
Exercises on Chapter 14 . . . 528

15 Passive transport in the interstitium and circulation **531**
15.1 Diffusion as a mode of passive transport . . . 531
15.2 Coupled flows . . . 532
15.3 Propagation, diffusion, convection . . . 534
15.4 Physico-chemical processes involving diffusion, convection and reaction . . . 547
15.5 Diffusion versus convection . . . 552
15.6 Newtonian viscous fluids and Reynolds number . . . 554
15.7 Hydraulic conductivity . . . 558
15.8 The steps of drug delivery, extravasation, transport in the interstitium . . . 568
15.9 Blood circulation . . . 572
15.10 Mechanics of vessels . . . 575
15.11 Transport of oxygen and carbon dioxide in blood . . . 576
15.12 Basics of enzymatic kinetics . . . 579
15.13 Acid-base equilibrium . . . 585
Exercises on Chapter 15 . . . 587

16 Coupled transports in tissues with a fixed electrical charge **591**
16.1 Macroscopic transports in tissues with a fixed charge . . . 591
16.2 Generalized and coupled diffusion: structure of constitutive equations . . . 597
16.3 Generalized diffusion: the membrane effect . . . 605
16.4 Generalized diffusion: ranges of the coefficients and refinements . . . 612
16.5 Generalized diffusion with thermal effects . . . 617
Exercises on Chapter 16 . . . 621

17 Effects of the pH on transport and mechanics **625**
17.1 Overview and laboratory observations . . . 626
17.2 pH agents embedded in the mixture framework . . . 629
17.3 Acid-base reactions in a thermodynamic framework . . . 631
17.4 Calcium binding in a thermodynamic framework . . . 634
17.5 Variation of the fixed electrical charge with pH . . . 637
17.6 Biochemical composition of articular cartilages . . . 637
17.7 Concentrations of ions, sites and charges . . . 640
17.8 Chemical equilibrium at the cartilage-bath interface . . . 641
17.9 Constitutive equations of generalized diffusion . . . 645
17.10 Simulations of bath-cartilage equilibria . . . 647
17.11 Constitutive mechanical framework: effects of pH and calcium binding . . . 654
17.12 Chemically induced stiffening/softening by fiber recruitment/deactivation . . . 657
17.13 Mechanical and chemical tests at varying pH . . . 661
17.14 The limit case of a conewise linear collagen response . . . 664
17.15 Comments on the mechanical model . . . 667

18 Finite element analysis of ECM couplings **669**
18.1 Overview of the finite element analysis . . . 669
18.2 Field and constitutive equations . . . 671
18.3 Finite element formulation . . . 675
18.4 Testing setup and material data . . . 679
18.5 Mechanical and chemical loadings with NaCl . . . 682
18.6 Cyclic substitution of NaCl and CaCl2 . . . 691
18.7 Improvements of the chemomechanical model . . . 692

Exercises on Chapter 18 . . . 695

19 Cornea and annulus fibrosus **701**
19.1 Function, structure and composition . . . 701
19.2 Biomechanical aspects . . . 708
19.3 Active transport in the endothelium: the cell and organ scales . . . 711
19.4 Physical data: literature review . . . 717
19.5 Scattering of light by the corneal stroma and transmittance . . . 727
19.6 Corneal surgery . . . 730
19.7 Cornea engineering . . . 730
19.8 The constitutive framework . . . 732
19.9 Biochemical composition of stroma . . . 734
19.10 The fixed electrical charge: negatively charged PGs and chloride binding . . . 735
19.11 Effects of pH and chloride binding on the fixed charge . . . 741
19.12 Global constitutive structure: mechanics and transport . . . 748
19.13 Generalized diffusion in the extrafibrillar phase . . . 752
19.14 Rest potential and active fluxes at the cell scale . . . 755
19.15 Coupled diffusion across a membrane and active transport . . . 758
19.16 Chemomechanical framework including chloride binding . . . 769
19.17 Constitutive equations of chemo-hyperelasticity . . . 771
19.18 Boundary value problems . . . 774
19.19 The purely mechanical contribution: nonlinear elasticity . . . 781
19.20 Annulus fibrosus: another lamellar tissue with two families of fibers . . . 798

III Growth of biological tissues **803**

20 Tissue Engineering **805**
20.1 Biomechanical perspectives of tissue engineering . . . 805
20.2 Basic notions of biochemistry . . . 810
20.3 Effects of hormones and growth factors . . . 819
20.4 Cell cultures . . . 821
20.5 Mechanobiology: experimental data . . . 823
20.6 Mechanobiology: models of growth of mass . . . 831
20.7 Growth and structuration of the collagen network . . . 836
20.8 Use of light for tissue fabrication . . . 843
20.9 Biochemical and mechanical factors: a synthesis . . . 844

21 Growth of soft tissues **845**
21.1 Natural growth and tissue engineering . . . 845
21.2 Residual stresses in elastic solids and material symmetries . . . 847
21.3 Kinematics of growth . . . 849
21.4 Constitutive assumptions and restrictions: the growth law . . . 861
21.5 Internal entropy production for a single solid . . . 867
21.6 Some models and their thermodynamic structure . . . 869
21.7 Boundary value problems for elastic-growing solids . . . 878
21.8 Incompatible strains and residual stresses . . . 890
Exercises on Chapter 21 . . . 896

22 Elastic-growing solids **897**
22.1 The tools: dissipation, homeostatic domain and convexity . . . 897
22.2 Relations relative to the intermediate configurations . . . 897
22.3 Growth law based on quadratic dissipation . . . 901
22.4 Bounded structure variables via convexity . . . 902
22.5 A thermodynamically consistent growth law . . . 907
22.6 Modes of mass deposition and mechanical response . . . 921
22.7 Constitutive equations for purely elastic solids . . . 926

22.8 Growth of a bar under unconfined tension/compression . . . 930
22.9 Growth of a hollow cylinder under internal pressure . . . 936
Appendices on Chapter 22 . . . 941

23 Elastic-growing mixtures **943**
23.1 Thermodynamically consistent growth laws in a mixture context . . . 943
23.2 Modes of mass deposition in an elastic-growing mixture . . . 953
23.3 The fixed charge: electro-chemomechanical couplings . . . 955
23.4 Growth equations with an evolving microstructure . . . 956
23.5 Growth equations for proteoglycans . . . 967
23.6 Summary of constitutive equations and residual . . . 969
23.7 Growth laws with evolving microstructure: simulations . . . 971
23.8 Self-healing in engineering materials . . . 983

24 Solid tumors **987**
24.1 Solid tumors: the recent intrusion of mechanics . . . 987
24.2 From DNA alteration to metastatic migration . . . 989
24.3 Oncology and molecular basis of cancer . . . 992
24.4 Mechanobiology: molecular basis and observations . . . 1002
24.5 Early mathematical models of tumor growth . . . 1004
24.6 Models of transport of fluids, nutrients and drugs . . . 1010
24.7 Mechanical boundary value problems . . . 1014
24.8 Poroelastic mixture models without growth strain . . . 1020
24.9 Poroelastic mixture models with a growth strain . . . 1034
24.10 Methods of imaging transport and mechanical properties . . . 1038

25 Units and physical constants **1043**
25.1 Units . . . 1043
25.2 Physical constants . . . 1044

Bibliography **1045**

Index **1093**

Preface

This book, devoted to the constitutive aspects of the biomechanics of soft tissues, is organized in three parts. Part I provides an in-depth description of the mechanics and thermodynamics that underlie the constitutive modeling of biological tissues in a continuum perspective. Although comments and examples are definitely aimed at soft tissues, the range of applications of this part is much larger and many of the tools that are presented apply to other fields, like mechanical engineering or civil engineering.

On the other hand, Parts II and III are solely devoted to the biomechanics of soft tissues. Part II presents a unified framework in which electro-chemo- mechanical couplings that are associated with the composition-induced function of three tissues with a fixed electric charge are exposed. As it is subjected during walking and jumping to a huge number of intense load cycles, as many as 1 million times a year, the articular cartilage that coats the knees and hips should be, mechanically speaking, endowed with a high endurance. Favored by overweight, osteoarthritis (OA) is the main pathology that affects articular cartilages. In the United States, OA affects 5% of the population and 70% of the population aged over 65, and costs $8 billion annually. Osteoarthritic cartilage leads to decreased tensile and compressive stiffness, increased tissue hydration and permeability. The intervertebral disc provides a second instance of tissue whose composition and structure are best adapted to the physiological function, which is also mostly to sustain a load. The corneal stroma is another lamellar tissue, subjected to the much smaller ocular pressure, that is yet adequate to ensure transparency.

Part III addresses the growth of biological tissues. In fact, these three tis- sues are aneural, avascular and alymphatic in adults. In the case of genetic degeneration or accidental damage, their regeneration is practically nil. One method to treat damaged cartilage consists in removing the damaged part and in implanting biodegradable cell-polymer constructs. Once in place, artificial cartilage proliferates reasonably well. However, the fact that its mechanical properties are lower than those of native cartilage is an issue. Recent studies have shown that the mechanical conditions to which chondrocytes, the cartilage cells, are subjected in vivo and in vitro affect the synthesis and degradation of the extracellular matrix (ECM). The challenge of tissue engineering is to produce implantable tissue with physical properties similar to the native car- tilage. Articular cartilages are addressed in the book from the points of view of their normal functioning and of the production of substitutes through tissue engineering.

On the other hand, tumors take advantage of the vasculature of tissues. Mechanics is seen to play a very important role here as well and tumor pressure opposes drug delivery. Tumor tissue grows abnormally fast with respect to normal cells. The process from the alteration of the first cell to the formation of tumors is usually long. Unlike normal cells whose proliferation is regulated, tumor cells proliferate without physiological control. They tend to establish their own colony, damaging the lymphatic system, and recruiting vessels to their own benefit, in order to both attract nutrients and spread metastases. It has been recently discovered that the mechanical state that is dominating inside the tumor plays an important role in the overall process. In fact, fluid pressure is high and this has two diabolic consequences: (a) metastases easily spread out of the tumors and invade normal tissues; (b) drug delivery to these zones of high pressure is virtually impossible. Tricky methods to bypass the high fluid pressure barriers opposed to therapeutic agents have been proposed but have still to prove their efficiency.

In all examples that are addressed, the structural architecture, biochemical composition and, if necessary, molecular basis, of the tissues under consideration are provided in the running chapter. In the electronic version, references to the appropriate chapters of Part I are abundantly available via hyperlinks. The bibliography is also reachable through hyperlinks. During the exposition, a number of examples taken from the literature are reviewed and adapted to the framework. Some more comprehensive problems are treated in detail so as to highlight the concepts that have been presented, and also to familiarize the reader with the analytical/computational tools that are needed to fully benefit from the book. Along the way, some particular results are moved to the end of the chapter in a section devoted to exercises that are fully documented.

Authors

Dr. Benjamin Loret is professor of mechanics and civil engineering at the University of Grenoble, France. His research addresses the constitutive responses of engineering and biological materials to static and dynamic loadings. He has especially focused on the couplings of thermal, hydraulical, electrical, chemical and mechanical natures that are ubiquitous in fluid saturated porous media. Applications target innovative energy production systems and biomechanics of soft tissues.

Fernando M. F. Simões received his Ph.D. degree in civil engineering from the Instituto Superior Técnico of the Technical University of Lisboa, Portugal, in 1997. Presently, he is assistant professor at the Department of Civil Engineering, Architecture and GeoResources, University of Lisbon. His research interests include structural mechanics and biomechanics.

Chapter 1

Biomechanical topics in soft tissues

1.1 Introduction

Biomechanics applies the laws and the techniques of mechanics in the study of biological systems and phenomena. Indeed, mechanics provides the tools for:

- the construction of models of the musculo-skeletal system with applications in ergonomics, in sports, in the study of gait and in processes of rehabilitation, or in the development of orthoses and prostheses;
- the construction of physical and mathematical models to describe, simulate and predict the behavior of soft and hard tissues of the human body, like muscles, cartilages, skin, blood vessels, and bones, with applications in areas such as orthopedics, dental medicine, medical interventions in the cardio-vascular system or tissue engineering;
- the construction of models of fluid flows like blood circulation and breathing;
- the computational modeling of tissues.

Biomechanics aims at using these mathematical and computational tools to aid in the medical diagnosis, therapeutics and surgery planning. This work targets a few topics pertaining to the biomechanics of soft tissues. The subjects that have been addressed can be grouped in three main areas:

I. Solids and multi-species mixtures as open systems: a continuum mechanics perspective;
II. Electro-chemomechanical couplings: tissues with a fixed electrical charge
III. Growth of biological tissues

Part I, including Chapters 2 to 11, presents the elements that are necessary to later consider the biomechanical issues in a porous media perspective. Basic notions of continuum mechanics that will be used throughout are collected in Chapter 2. Elements necessary to master the exchanges of mass, momentum and energy between constituents of an open mixture form the backbone of the exposition. Continuum thermodynamics of fluids and solids serves to guide the modeling attempts. The basic constitutive models that describe the mechanical response of soft tissues account for their peculiarities, namely anisotropy may be strong, deformations may be large, the solid constituents themselves may be endowed with a time dependent mechanical response. Moreover, emphasis is laid on the consequences of the interactions between the mechanical properties (elasticity, viscoelasticity), the transport properties (of biological fluids, macromolecules and ionic or neutral solutes), and the transfers of mass and energy.

Chapters 12 to 19, forming Part II, specialize in the electro-chemomechanical couplings in tissues with a fixed charge. Focus is on articular cartilages, on the corneal stroma and, in a minor mode, on the intervertebral disc. The fixed charge which is referred to sits on the solid parts of the tissues, in contrast to the mobile charges that are dissolved in the biological fluids. In that sense, the adjective "fixed" refers to space, or geometry, not to time. The change of the fixed charge associated with pH is considered at length in Chapter 17.

The presentation can be seen as macroscopic, in the sense that no formal change of scale is attempted. Still, a number of information from the lower scale, starting from the nanoscale, permeates at the scale of study. In that respect, we may mention the directional repartition of collagen fibers, the unbalanced charges in collagen and proteoglycans, the spatial organization of the lamellae in the corneal stroma and intervertebral disk.

Issues regarding growth of biological tissues are addressed in Part III, which includes Chapters 20 to 24. The perspective is on tissue engineering. Elements of biochemistry and mechanobiology are included in basic modeling

attempts. In line with earlier chapters, the analysis considers tissues as saturated porous media where several solid constituents may grow due to exchanges of nutrients through the biological fluids. In fact, the last chapter which is devoted to the growth of solid tumors follows this same perspective.

Certain chapters cover in part or entirely purely mechanical issues. Chapter 5 addresses linear elasticity but lays emphasis on the anisotropic properties of soft tissues and on their conewise constitutive response, a large part of tissues being reinforced by collagen. This fiber-reinforced aspect is further emphasized in Chapter 12 where the concept of tissue fabric is introduced. The important notions of length scale and spatial heterogeneity are unfortunately not covered. On the other hand, intrinsic time dependence of the constitutive response is the subject of Chapter 8. Some purely mechanical aspects of the growth of tissues are covered by Chapter 22.

Thermal aspects in both solid and porous media contexts are exposed in Chapters 9 and 10. Chapter 9 is devoted to heat conduction in media that are in local thermal equilibria, Chapter 10 puts emphasis on mass and heat transfer in media that are not in instantaneous equilibrium, neither hydraulically nor thermally, at time scales of interest in soft tissues. Section 16.5 is devoted to generalized diffusion in hydrated tissues with thermal effects. While the subjects considered in these chapters are preliminary, the other chapters are all devoted to issues in a porous media context where mechanics and transport are addressed in the presence of couplings of chemical, electrical, bio-energetic and thermal natures.

Even if the developments of the models are self-content, we think that it is important to perform tests in an appropriate framework, which is referred to as initial and boundary value problem (IBVP). In order to help the reader, the responses to simple tests of several pertinent constitutive models gathered from the literature are re-phrased in that perspective. In fact, a correct specification of the boundary conditions is crucial, especially when couplings are present in the constitutive models.

In order to show how this work can be used, a few problems that are not treated per se in the text have been listed in this introductory chapter. For each of them, we provide a short description and we refer to the chapters, sections or pages of the work that contain elements that are of interest to begin discovering these problems. This approach both gives the opportunity to introduce to further adjacent topics of current interest in biomechanics and it also allows to discover the issues that are considered at length in the next chapters.

1.2 Diffusion, convection, osmosis: toward wearable artificial kidneys

An artificial kidney is an example of a device that makes use of countercurrents to enhance the transfer of small molecules (urea, creatinine) through a fixed membrane (Fig. 1.2.1). The leading governing phenomena are diffusion, convection and osmosis. The basics of diffusion and convection of solutes are exposed in Chapter 15, and the concepts

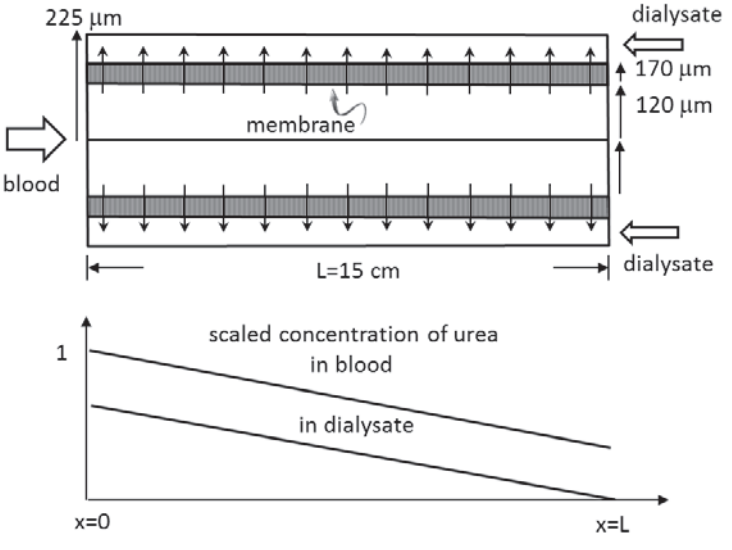

Fig. 1.2.1: Schematic of urea transfer from blood to dialysate in a hollow cylindrical fiber, according to Rambod et al. [2010].

of osmosis and semi-permeable membranes in Section 13.7. Problems of a similar nature are considered for the extravasation of drugs across the vascular wall in Section 15.8.3, for blood filtration and re-absorption by capillaries in Sections 15.9.3 and 24.8.1 and for coupled flows through electrically charged tissues in Chapter 16.

A wearable artificial kidney (WAK) is a device aimed at palliating dys- or non-functioning kidneys [Rambod et al. 2010]. It is lightweight, belt-type, battery driven, and it generates pulsatile flows of low rate since it operates around the clock. Dialysate regeneration is included.

Like a steady pump, the WAK pump pushes blood into the dialyzer but it pulls/sucks the dialysate out, which improves the filtration (a steady pump would push the dialysate out). The higher transmembranar pressure enhances filtration, convection and ultimately blood clearance. The two blood and dialysate inflows are pulsatile with the same frequency but out of phase.

The dialyzer consists of a number of long and thin hollow fibers, with a high specific surface (for filtration), where blood and the saline solution circulate in opposite directions and are separated by a membrane through which the solutes diffuse and are convected by the flow. The flow rates of blood and dialysate are controlled at the inlet and the pressures at the outlet. Maintaining a constant transmembranar pressure is crucial, given that the ultrafiltration rate depends on this pressure. This requirement is a technical challenge for conventional hemodialyzers that appears to be overcome by pulsatile flows [Rambod et al. 2010].

1.3 Issues in drug delivery

While a drug may be efficient once it has reached its target, its delivery remains a key issue. Oral and intravenous administrations of drugs are sometimes inefficient due to dilution and to physiological barriers. To reach a sufficient concentration at the targeted zone, such a high dose would need to be administered that it may induce toxic effects. When the barriers to the drugs are too tight, as in the case of blood–brain barriers, direct delivery through catheters may be the only viable issue.

Hydrogels as drug carriers and release controllers

Oral administration of a therapeutic agent is viable when it can diffuse to the targeted region. The technique consists in wrapping the active agent in a polymer network of dehydrated gel. Living bodies contain a substantial amount of water with dissolved ions. Once ingested, hydrogels[1.1] hydrate and swell. High hydration increases the diffusion coefficient of soluble drugs: water acts as a plasticizer that depresses the glass transition temperature, turning the polymer chains in the rubbery state where their mobility is higher. The active substance is released (due to concentration gradients) when the polymer network becomes sufficiently weak. Drug delivery depends on the diffusion and on the swelling of the coating polymer. The delivery process is controlled by the Deborah and swelling interface numbers which involve the characteristic time of polymer network relaxation, featured in Section 8.8, and the characteristic time of drug diffusion and liquid seepage, defined in Section 13.13.3. Hydration can be elicited by external stimuli, e.g., by an energy flux for thermosensitive polymers. Swelling of biological gels result from osmotic forces resisted by the elasticity of the network, a topic exposed in Section 13.7. In fact, each polymer presents its own peculiarities, of electrical nature (type of the electrical charges, ionic valences, electrical field, etc.), of chemical nature (ionic types, concentrations, pH, etc.) or of mechanical nature (deformations, stresses, pressures). Hydrophilic glycosaminoglycans drive swelling, and/or contraction, due to the presence of hydroxyl, carboxyl and sulfonic residues as exposed in Section 17.1. The nature of the polymer network and density of crosslinks[1.2] is an important ingredient. As a reference, we may contrast the tight organization of collagen fibers in articular cartilages aimed at minimizing strain and described in Chapter 14, from the weaker collagen interconnections in the cornea aimed at avoiding swelling and optimizing transparency reported in Section 19.1. Electro-chemomechanical couplings have been taken into account to describe the volume changes and stresses in articular cartilages and corneal stroma due to changes of the chemical composition, pH and mechanical conditions of the solution the tissues are bathed in.

The presence of crosslinks hinders dissolution of the therapeutic agent in the aqueous medium. The polymers should be able to deliver the therapeutic agent over the requested period of time. Indeed, delivery may need to be

[1.1] *Hydrogels* are crosslinked chains of swellable hydrophilic insoluble polymers. While water is the continuous phase in hydrogels, *gels* are semi-solid colloids of a solid and a liquid. In contrast to *solutions* where the solvent and the solute form a single phase, the continuous and dispersed components of a colloid form distinct phases.

[1.2] A crosslink is a covalent or ionic bond that links polymer chains. The chains of *chemical* hydrogels are crosslinked by covalent bonds while the crosslinks of *physical* hydrogels involve the much weaker hydrogen bonds or van der Waals interactions.

sustained over days/weeks/months or rest on a one-time basis. They should be biocompatible and biodegradable without toxicity. Their dissolution itself is negligible if it takes place after complete drug release.

When water seepage is slow with respect to polymer relaxation, drug diffusion obeys Fickian diffusion with a concentration depending on time t like t^α with $\alpha = 1/2$ as reported in Section 15.3.3. Semi-empirical expressions of the time dependence of drug concentration have been developed to cover more complex cases, e.g., for close characteristic times of polymer relaxation, drug diffusion and fluid seepage, for non-Fickian diffusion in the glassy state of the polymer network, or for burst release [Siepmann and Peppas 2001].

The presence of the polymer hinders diffusion of solvents and solutes: the effect is often embedded in a tortuosity factor that involves the volume fraction of the solid, an entity touched upon in Section 16.4.3. More elaborated models include some geometrical features of the diffusing species and of the polymer [Masaro and Zhu 1999]. Improving over the above models where the polymer network is seen as obstructing diffusion, hydrodynamic theories account for interactions between polymer network, solvent and solutes and are valid at higher concentrations: Sections 15.5 and 15.7.8 provide examples along this approach.

Drug delivery in the presence of strong barriers

The issue of drug delivery surfaces conspicuously for the treatments of neurodegenerative diseases and tumors of the central nervous system. Indeed, *the blood-brain barrier* in particular opposes the entrance of a number of macromolecules into the brain tissue. A new *invasive* technique termed "convection enhanced drug delivery" aims at alleviating this problem by bypassing the vasculature and introducing directly the drug into the brain tissue through an infusion catheter. With respect to the purely diffusive process described in Section 24.8.3, convection enhanced drug delivery increases the penetration depth [Linninger et al. 2008]. Infusion pressure, flow rate, catheter design, including port diameters, inter-port distance, and catheter position are unknowns to be optimized. While the hydraulic conductivity of the gray matter containing neuron cells is low and can be considered as isotropic, the white matter formed by long axons has directional physical properties. The introduction of directional properties in the permeability tensor is elaborated in Section 15.7. Some attempts to account for the heterogeneous substructure of the tissue are mentioned in Sections 15.7.8 and 19.4.5 for the stroma. In an alternative approach [Stöverud et al. 2012] use the self-diffusion tensor of water in the brain tissue obtained by magnetic resonance imaging (MRI) to infer the permeability and diffusion tensors of the tissue, the three entities being assumed to be coaxial. In fact, the brain surfaces, volumes and boundaries between regions and therefore the geometric reconstruction from MR images and the physical properties of the tissue are patient-dependent.

As the drug moves through the tissue, it can decompose via enzymatic reactions, be absorbed by cells and be released through the vasculature (blood clearance). Basics of enzyme kinetics are briefly exposed in Section 15.12. Interstitial pressure, membrane permeability and osmotic/oncotic pressures control the reaction (release/absorption) processes. These *reactive* processes are accounted for in the mass balances as thoroughly exposed in a general context in Sections 4.4, 10.2, and illustrated for fluid extravasation in solid tumors in Sections 15.8, 24.8-24.9, and for oxygen diffusion in Section 15.11.

As a routinely adopted property in this work, the brain tissue has to be considered deformable, and endowed either with an elastic or hyperelastic time-independent stress response as exposed in Chapters 5 and 6, or with a viscoelastic response, the subject of Chapter 8. In fact, changes of porosity may require a large deformation framework, a topic addressed in Chapter 6 and used for tissue growth in Chapters 22 and 23.

1.4 Macroscopic models of tissues, interstitium and membranes

Description of the components of tumor tissue in a drug delivery perspective is attempted through several porous media models in Section 24.6. Including tissue elasticity, the model in Section 24.8.2 accounts for two compartments, namely the interstitium and the capillaries, and three phases, the interstitium being composed of a solid and a pore fluid. It is used to describe the mass exchanges between the capillaries and the pores in the context of a systemic therapy.

For cryopreservation of whole organs, a cryoprotective agent CPA should be introduced in the intracellular space[1.3]. This procedure is realized by perfusion through the vascular system. A model should then include a finer description of the tissue constitution. In fact, the cell volume varies much from one tissue to the other, depending of course on the actual cellular activity: this activity is very small in adult articular cartilages, about 2 to 3% of

[1.3] A cryoprotective agent is a substance that prevents tissue damage by ice, increasing the solute concentrations in cells. Actually, the technique termed vitrification lowers the glass transition temperature and keeps the tissue in a glassy state.

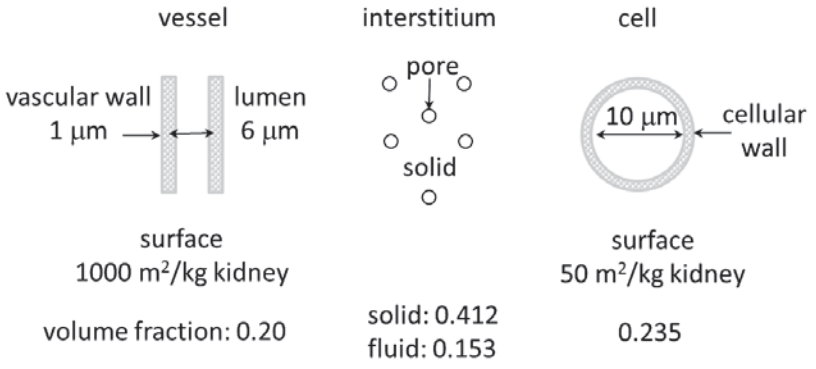

Fig. 1.4.1: Schematic of the porous media model with three compartments for rabbit kidney, each one containing species, namely CPA, ions, etc. with separate concentrations [Lachenbruch and Diller 1999].

total volume, but large in the cardiac muscle, and intermediate in kidneys, about 20% of tissue. In fact, the model of kidney considered by Lachenbruch and Diller [1999] involves the following items:

- the model includes three compartments, Fig. 1.4.1: (a) the vascular and lymphatic systems; (b) the interstitium; (c) the intracellular space. The concentrations of water, CPA and other solutes and the pressure are innate to each compartment;
- water and CPA move through the vascular membranes and cellular membranes. In developing the transport equations, attention is paid to the fact that the CPA concentration may be as high as 4 mole per liter, at variance with conventional formulations that consider dilute concentrations. As another consequence, the viscosity of the solution is expected to change with solute concentration;
- the transport of ions Na^+, Cl^-, Mg^{++}, Ca^{++}, is *passive* through the vascular membrane and interstitium as described in Chapters 15, 16 and Section 19.14. On the other hand, their transport through the cell membranes requires an energy source (*active transport*) as described for the corneal endothelium in Sections 19.3 and 19.15. At low temperature, the energy source is typically not available and transport through the membrane can take place only by diffusion and convection. Therefore, the membrane can be seen as practically impermeable to these solutes. It is also impermeable to large proteins by steric considerations;
- CPA and water diffuses through the cell membrane by coupled diffusion, a topic addressed in Chapters 15 and 16;
- the elastic response of the compartments and surrounding capsule is accounted for: Chapters 5 and 6 consider several aspects of elasticity.

Perfusion with glycerol, dimethyl sulfoxide and sucrose-based CPA results in swelling of the interstitium and shrinkage of the cells. Definite protocols for injection and removal of CPA are needed as the relative volume changes that cells can undergo without damage is known to be limited.

A large molar mass polypeptide that cannot cross the vascular membrane may be added to the perfusate to induce an osmotic pressure, see Section 15.8. The perfusate may also contain some agent that triggers active transport through the cellular membrane.

1.5 Energy couplings, passive and active transports

Energy couplings are ubiquitous in biomechanics. The basic idea of coupling requires an energy provider, an energy consumer and a device that is able to transfer the energy, with some overhead costs, between the two agents. The idea is tentatively illustrated in Fig. 4.8.2 in a restricted perspective where the provided and consumed energies are both of mechanical nature. In other examples developed in Section 4.8.3, the energy provided by a chemical reaction is used by another chemical reaction. The main biochemical energy source in living bodies is ATP. Its activation modifies the transport of solutes across cell membranes. The chemical equilibrium that would hold in absence of energy source is altered to "a dynamic equilibrium": examples described in Sections 19.3.3 and 20.2.2 show that the concentrations on the sides of the membranes depend explicitly on the energy source.

This phenomenon, termed active transport, is tied to the presence of the energy providers, the metabolic pumps, in the cell membranes. The corneal endothelium is a conspicuous instance of a cell membrane that features active transporters, refer to Section 19.3 for details. Active transport mechanisms in the corneal endothelium limits the

infinite radial swelling, which might take place due to the weak radial crosslinking between lamellae. Swelling of the stroma would be due to the absorption of water from the aqueous humor through the leaky endothelium. The dynamic equilibrium that maintains the optimal hydration regarding transparency is evidenced by decreasing the temperature just above freezing so as to silence the metabolic pumps. Then the thickness of the cornea increases but, when the temperature is returned to a physiological value, the normal thickness is progressively retrieved after a few hours.

As just alluded to, energetic coupling alters a chemical equilibrium to a dynamic equilibrium. However, at variance with the example referred to so far, the energy source may not be of biochemical origin, but rather of mechanical origin, giving rise to a phenomenon that may be called *mechanobiological coupling*.

The idea is developed for the growth of cartilage tissues in Chapter 23. Tissue growth is an irreversible process, metabolism and catabolism being associated with distinct pathways. Energy of mechanical and biochemical natures is used to grow the mass and improve the mechanical properties of the tissue constituents. Heat dissipation is in some sense minimized: the tissue recovers as much energy as possible to drive the growth and stiffening/self-healing processes. Indeed in contrast to damage, stiffening contributes negatively to the dissipation inequality. In other words, the model developed in Section 23.1 is built so that the dissipation can only be positive or zero. The idea is that mechanisms that require energy (active processes) are scaled down if the energy provided by passive processes is not sufficient. The energy available to the active processes is limited by satisfaction of the dissipation inequality.

As another instance of mechanochemical coupling and active transport, Albro et al. [2008] provide experimental evidence that strain controlled cyclic loading may enhance reversibly the uptake of a macromolecule in an agarose hydrogel.

In certain engineering materials, a chemical energy source is dispatched to potentially improve their mechanical properties in case of damage: Section 23.8 presents a brief account of this subject. This process, referred to as "self-healing" to convey the idea that energy from the surroundings in the form of heat or light is not required to repair the material, features a *chemomechanical coupling*. Both mechanical and metabolic energy sources drive tissue growth: they generate mechanochemical and chemomechanical couplings, respectively.

1.6 More general direct and reverse couplings

While the muskulo-skeletal and cardiovascular systems are not addressed here, it is of interest to provide some brief overview as they display couplings of various physical natures with both similarities and differences with respect to articular cartilages.

As an organ, the heart receives from the body various types of information (electrical, chemical, mechanical) to which it reacts. As such, it is an object of study for automation specialists. Now clearly, this interaction depends on the behavior of the heart itself. Physiologically, the cardiac muscle is very far from cartilage. Articular cartilage is avascular, aneural and alymphatic, its adult cells occupy a small percentage of the medium, they are practically inactive, and the chemomechanical activity is extracellular. The cardiac muscle on the other hand is a syncitium: cells occupy a large portion of the space and they communicate quickly through gap junctions.

Although endowed with a certain autonomy by the sinoatrial node, a natural pacemaker, the heart is subjected to the injunctions of the central nervous system. The spatio-temporal diffusion of the electrical signal produces a contraction that is optimized due to the subtle conformation of the fibrous structure of the organ (the study of its morphogenesis touched upon in Section 21.7.1 is in its infancy). The electro-chemomechanical coupling is in fact mediated by chemistry, and, in the long range, by metabolism. The electrical signal elicits a number of electric currents through the cardiomyocyte membrane that give rise to calcium cycling and muscle contraction, an area termed electrophysiology. The membrane behaves as a capacitor of fixed capacitance as described in Section 13.6.3 and p. 481. There are three types of channels through the membrane, namely ligand-gated, voltage-gated and stretch-gated channels. For the myocardiac cells, the ligand is ATP and the channels are then called *ionic pumps*, in as far as ATP allows the transport of ions across these channels against a concentration gradient.

Coupling cell electrophysiology to bioenergetics aims at obtaining a realistic control of the metabolic activities of the cardiac cells by the ATP demand of crossbridges. Indeed, the parts of the cardiac metabolism (glycolysis, TCA cycle, β-oxidation, oxidative phosphorylation) are themselves described by complex models that involve enzymatic reactions defined by various kinetics, a subject touched upon in Sections 15.12 and 20.2. β-adrenergic factors reported in Section 20.2.4 are certainly required in the modeling of the cardiac function, and especially for the simulations of ischemia and hypoxia.

The inverse *mechanoelectric coupling* is also thought to be exhibited by stretch-dependent ionic channels and by commotio cordis, a phenomenon that gives rise to cardiac arrest without tissue damage in young subjects. At variance, cardiac arrest by hypoxia or anoxia is accompanied by local tissue damage.

At the scale of the body, it is also certain that lack of exercise leads to a decrease of the mass of skeletal muscles, tendon efficiency and to bone decalcification, a mechanobiological coupling. The issue is raised in a particularly acute way for deep space explorations due to the microgravity environment. Appropriate exercises to help maintain the integrity of the muskuloskeletal and cardiovascular systems of astronauts need to be devised [White et al. 2003].

1.7 Tissue engineering redirected to tumor tissue exploration

While Chapter 20 is devoted to decipher the effects of mechanics on tissue engineering, the mechanical environment induced in a tumor tissue is considered in Chapter 24. Knowledge from these two independent expositions may advantageously be combined in the future to gain better understanding of biological and biochemical effects on the mechanical properties and of the reciprocal mechanobiological effects in both domains.

Naturally derived and artificial 3D scaffolds provide a controllable environment in which the growth of tumor cells and their interactions with the extracellular matrix (ECM) can be examined. The physical properties, in particular the density, and the mechanical properties of the ECM are significantly modified in a tumor tissue, a point stressed in Section 24.1. The shear modulus of tumor tissues may be an order of magnitude higher than in normal tissues. Their architecture and composition are also altered, including abnormal collagen density and alignment, oxygen concentration, pH and concentration of growth factors. *In vitro* cultures on biodegradable scaffolds aim at deciphering the mechanotransductive agents that mediate the dynamics of these interactions.

In fact, biochemists have realized that traditional 2D cultures do not pay enough attention to the role of the ECM in cancer metastasis and that they may gain from techniques of tissue engineering. The proliferation and spreading of cell lines differ significantly according to the stiffness of the scaffold [Helmlinger et al. 1997]a. In tumor tissues, a failing lymphatic system disorganizes the circulation of fluids and hinders drug delivery. Whether the altered ECM properties are the cause or the consequence of the tumor cell development, these properties should be understood in view of a better assessment of the elements that participate in the resistance to drug delivery.

The scaffolds should provide a porous matrix, and be proteolytically degradable to permit drug migration and cell re-structuration. They are expected to be noncytotoxic, controllable in their mechanical and diffusion properties, and susceptible to a bioactivity comparable to natural tissues. Ideally, these three properties should not be interacting to allow a full *in vitro* exploration of their effects [Gill and West 2014]. Naturally derived scaffolds, using collagen and fibrin, are endowed with the three properties but modification of one of them inevitably reflects on one or the two others. Semi-synthetic hydrogels, obtained by modifying polysaccharide alginate and hyaluronic acid, and synthetic scaffolds, based on polylactic acid and polyglycolic acid, offer the advantages of being noncytotoxic while their stiffness may be controlled during the polymerization process, a point reported in Sections 20.4 and 20.5.

Bioactivity of polyethylene glycol (PEG) hydrogel matrices can be induced through incorporation of ligands, peptides and growth factors. They are fabricated by photopolymerization, a technique[1.4] overviewed in Section 20.8. The matrix stiffness may be controlled via the PEG concentration and the molar mass of the polymer chain.

1.8 From mechanics to biomechanics

Some living tissues are submitted to severe mechanical loading conditions. During daily life, walking and jumping, articular cartilages undergo repetitive stresses ranging from 3 to 18 MPa as many as 1 million times a year. Teeth are subjected to about 1 million loading cycles per year [Bayne 2005]. While ceramics mimic natural enamel, they often contain pores that act as stress concentrators and initiators of fractures. Switching from traditional synthetic restorative dental materials to truly biological biomaterials is expected to take place in 10 to 20 years and it will require significant progresses in a chain involving 3D scaffolds, stem cells and inductive growth factors. Longevity of the substitutes necessary requires a deeper understanding of the mechanobiological interactions that take place in a polycyclic context.

Therefore, substitutes should not only provide mechanical resistance in compression, tension and/or shear as well as biological function but also be compatible with the interactions between mechanics, biochemistry and biology. Elements of this vast perspective are exposed in this book.

[1.4] Use of light for cancer therapy is briefly addressed in Section 24.3.7.4.

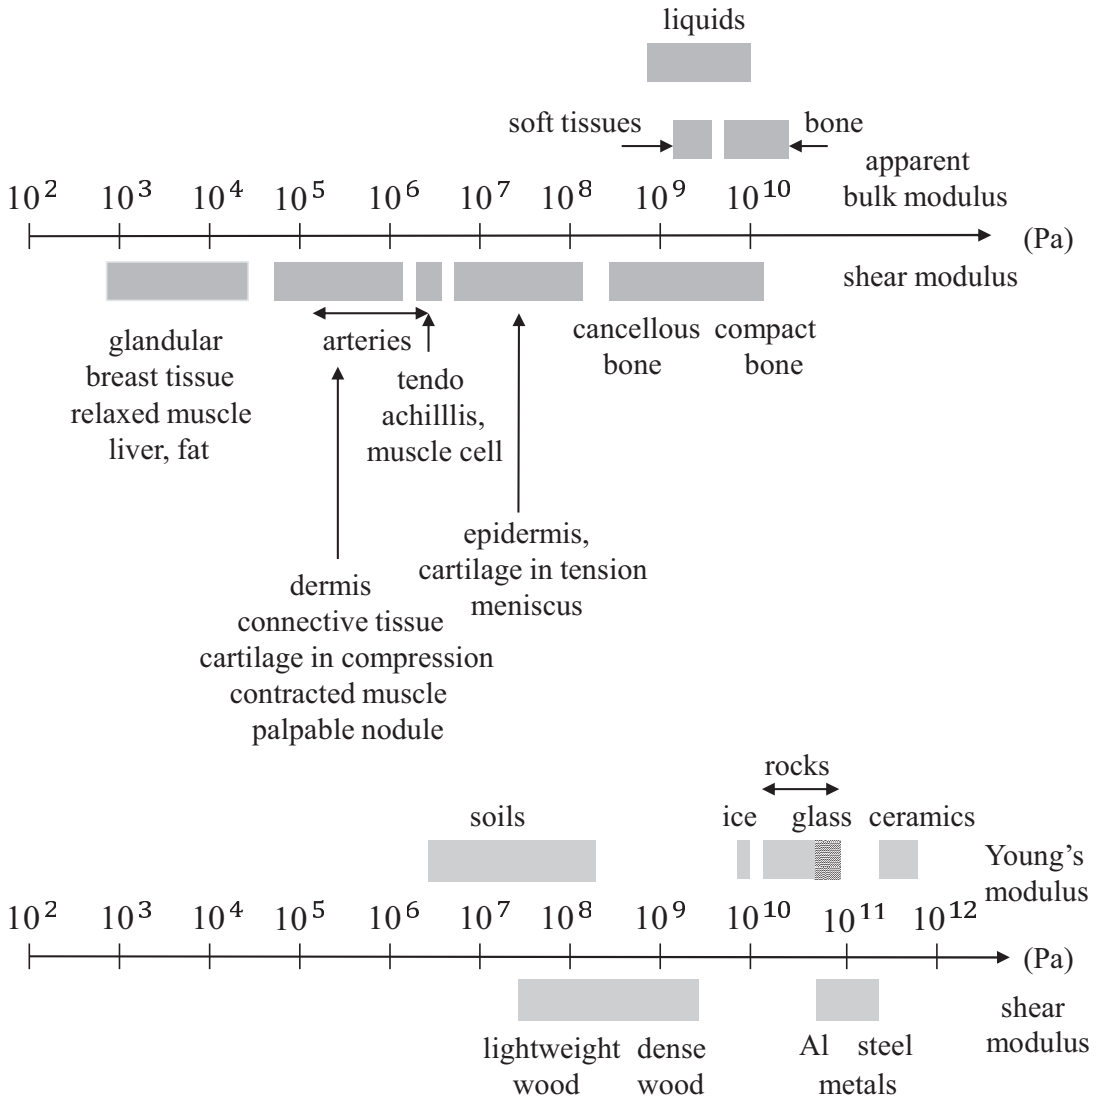

Fig. 1.8.1: Range of elastic moduli in biological tissues, compared with other engineering materials based on Sarvazyan et al. [1998], Wakatsuki et al. [2000], Gibson and Ashby [1988]. The values are to be seen as orders of magnitude, because, in fact, the moduli depend on temperature, state (glassy, transition, rubbery regimes for polymers), material density (woods, geomaterials), spatial loading direction (anisotropy), loading type (tension/compression), etc. Still, the bulk moduli are seen to range in a small interval while the shear moduli vary over seven orders of magnitude. As an implication, their pathological changes can be detected either through routine screening and more systematically and quantitatively through advanced techniques, like computer tomography, magnetic resonance elastography, etc.

That a biomechanical analysis cannot be content with a purely mechanical approach may be motivated in a number of domains, and in particular for biomaterials.

Biomaterials for orthopedic applications, namely for fixation of fractured bones, reconstruction of ligaments and tendons, and joint arthroplasty, are required to be endowed with good bio-compatibility, be corrosion-resistant and bio-degradable. Bioresorbable substitutes have attracted interest as they can be used instead of stainless steel or titanium alloys and can progressively be replaced by natural tissues.

Still, a number of difficulties have been reported when using polymer substitutes for tendon fixations, as they may be brittle, their degradation time is long, their osteo-integration is poor, and osteolysis and cyst formation may take place. The quest for biomaterials with a controllable degradation rate that allows a better tissue regeneration has attracted interest in magnesium based alloys [Farraro et al. 2014]. These biomaterials have a stiffness slightly lower than cortical bone, Fig. 1.8.1, which reduces stress shielding and therefore resorption, and their ductility reduces the

risks of fracture. Their porous structure makes them usable as scaffolds for natural tissue growth and prone to cell infiltration, and favors their degradation. Special coatings have been developed to improve their cyto-compatibility and osteo-inductivity.

1.9 Mechanisms of injury of the knee, fracture mechanics

The subject of biomechanics in relation to car occupant crash protection grew rapidly in the 1950's and 1960's as the number of road traffic accidents surged. During frontal car collisions at moderate velocity (about 50 km per hour), the contact of the knee with the instrument panel takes place early while the vehicle is still moving ahead. Therefore, the velocity of the impact knee-panel is relatively low, about a third of the vehicle initial velocity according to Mackay [1992].

Knee injury results mostly in fracture of the patella (by impact on the instrument panel) and femoral condyles, and, to a lesser extent, in knee ligament and tendon damages.

In fact, the knee is stabilized by ligaments and tendons:

- ligaments connect bones together, in this case, femur and tibia. The medial collateral and lateral collateral ligaments minimize lateral motion. The anterior cruciate ligament (ACL) inserts in the posterior face of the femur and in the upper anterior face of the tibia and the posterior cruciate ligament (PCL) joints the posterior face of the tibia and the lower face of the femur. This inclination allows for some rotation of the bones in the sagittal plane but prevents forward and backward relative translation of the tibia and femur;
- tendons attach muscles to bones. The patellar tendon links the muscles of the thigh to the patella and inserts in the front of the tibia. Similarly, the hamstring muscles attach to the back of the tibia through tendons.

Collateral ligaments are injured by excessive varus or valgus flexion, Fig. 1.9.1. Condyles may be fractured and meniscus punctured if the axial load is large during flexion. The ACL may be ruptured by shocks from the rear hitting the tibia.

Still, osteoarthritis (OA) is the main pathology that affects articular cartilages. In the United States, OA affects 5% of the population and 70% of the population aged over 65. Osteoarthritis induces a decreased tensile and compressive cartilage stiffness, and an increased tissue hydration and permeability.

A possible cause of osteoarthritis is traced to the disruption of the crosslinks between collagen fibers. According to other interpretations, osteoarthritis may not be due to a self-degradation of cartilage components, but to proteolytic

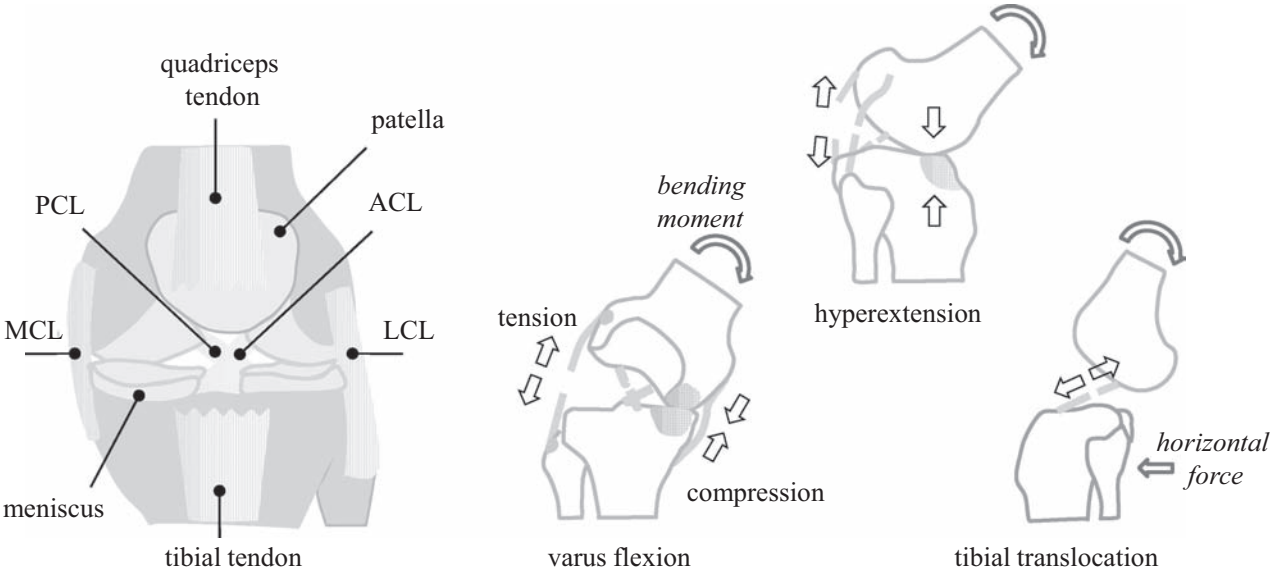

Fig. 1.9.1: (a) Sketch of ligaments in the left knee. ACL/PCL: anterior/posterior cruciate ligament; LCL/MCL: lateral/medial collateral ligament; (b) typical mechanisms of knee injury, based on Terezinsky [2005].

enzymes. These enzymes are generated by the chondrocytes themselves or diffuse into cartilage from an inflamed synovial liquid. Supra-physiological mechanical loads are also advocated to trigger osteoarthritis: as just suggested, these loads may take place during traumas due to traffic accidents or sport activities. Moreover, clinical and animal studies show that meniscectomy is often followed by osteoarthritic degeneration. In Chapter 14, which is devoted to the biomechanical analysis of articular cartilages, Section 14.3 contains a brief introduction to the subject.

Some specific sport activities contribute significantly to knee injuries, which amounts to 45% of all athletic injuries. The rupture of the ACL, medial meniscus and lateral meniscus contribute, respectively, to 20.3%, 10.8% and 3.7% [Majewski et al. 2006]. This study was performed in Switzerland and Germany and the sports leading to most injuries are skiing and soccer. In fact, the occurrence of the rupture of ACL is seven times higher for athletes. Analysis of video-taped handball matches has shown that ACL rupture was associated with a valgus knee flexion and tibia rotation. Knee braces constraining extension and modifying flexion at landing have been suggested to limit ACL rupture in skiing, basketball and handball [Yu et al. 2004].

1.10 Water and solid constituents of soft tissues

Since the chapters to follow adopt definitely the point of view that soft tissues should be regarded as mixtures of solid constituents bathed in biological fluids, it may be appropriate to provide some numbers that conform with this landscape.

For the carotid artery, water and proteoglycans contribute to 70% of wet weight [Humphrey and Rajagopal 2003]. The dry mass is composed at 50% by collagen types I, III, IV and V, at 30% by smooth muscle, at 20% by elastin, plus endothelial cells, fibroblasts, fibronectin and laminin.

Water contributes also to 60 to 70% of the weight of human skin. Collagen of type I primarily, as well as of type III, accounts for 70-80% of the dry weight, while the proportion of elastin is only about 0.5%, and that of proteoglycans 0.07-0.08% [Seehra and Silver 2006].

The proportion of water in corneal stroma ranges from 75 to 80%. The dry weight is contributed by collagen of types I and V (70%), proteoglycans and associated proteins (10%), and noncollagenous proteins (20%).

Water contributes to 60-80% of the weight of articular cartilages. Collagen of type II (50-75%) and proteoglycans (15-30%) constitute most of the dry weight. The composition evolves with age. For cartilages of distal bovine femur and humerus, the ratio of dry weight over wet weight increases progressively, 12% in third-trimester fetus, 20% in the 4-8 week old calf, 26% in the 1-2 year old animal to 32% in the 3-5 year old adult [Williamson et al. 2001].

Before entering detailed constitutive modelings, it might also be sound to keep in mind the ranges of moduli of soft and hard living tissues in comparison with common engineering materials, Fig. 1.8.1.

Part I

Solids and multi-species mixtures as open systems: a continuum mechanics perspective

Taylor & Francis
Taylor & Francis Group
http://taylorandfrancis.com

Chapter 2

Elements of continuum mechanics

Continuum mechanics concepts are used throughout this textbook. To help the reader in concentrating on the biomechanical aspects of the presentation, a number of algebraic, tensor and differential relations have been gathered in this chapter. The exposition is necessarily compact. Broader and thorough introductions to the field and constitutive equations of continuum mechanics may be found in classical textbooks, e.g., Fung [1965][1977], Mandel [1966], Malvern [1969], Bowen [1989] *inter alii*.

2.1 Algebraic relations and algebraic operators

2.1.1 Notations and conventions for tensor calculus

Cartesian coordinates are used throughout, except in specified conditions. As a general guideline, the convention of summation over mute indices applies to indices which represent the components of vectors or tensors in cartesian bases, e.g., $a_i\, b_i$ has the meaning of the sum of the products $a_i\, b_i$, the subscript i varying from 1 to 3. To avoid ambiguity, a subscript bar prevents this summation, e.g., $a_{\underline{i}}\, b_{\underline{i}}$ refers to a single product.

On the other hand, summation is a priori not implied with indices that refer to the species of a mixture, usually denoted by the generic subscript or superscript k. The conventions are stated whenever necessary.

Let $\{\mathbf{e}_i^1\}$, $\{\mathbf{e}_i^2\}$ and $\{\mathbf{e}_i\}$, $i \in [1,3]$, be three cartesian bases. Here is a list of basic definitions that are used throughout:

• scalar product of two vectors: $\mathbf{a} = a_{1i}\, \mathbf{e}_i^1 = a_i\, \mathbf{e}_i$, $\mathbf{b} = b_{2j}\, \mathbf{e}_j^2 = b_j\, \mathbf{e}_j$:

$$\mathbf{a} \cdot \mathbf{b} = \begin{cases} a_{1i}\, b_{2j}\, \mathbf{e}_i^1 \cdot \mathbf{e}_j^2, \\ a_i\, b_i\,. \end{cases} \tag{2.1.1}$$

• dot product of two second order tensors $\mathbf{A} = A_{1ij} \mathbf{e}_i^1 \otimes \mathbf{e}_j^1$, $\mathbf{B} = B_{2kl} \mathbf{e}_k^2 \otimes \mathbf{e}_l^2$:

$$\mathbf{A} \cdot \mathbf{B} = A_{1ij}\, B_{2kl}\, (\mathbf{e}_j^1 \cdot \mathbf{e}_k^2)\, \mathbf{e}_i^1 \otimes \mathbf{e}_l^2\,. \tag{2.1.2}$$

• double dot product of two second order tensors:
$\mathbf{A} = A_{1ij} \mathbf{e}_i^1 \otimes \mathbf{e}_j^1 = A_{ij} \mathbf{e}_i \otimes \mathbf{e}_j$, $\mathbf{B} = B_{2kl} \mathbf{e}_k^2 \otimes \mathbf{e}_l^2 = B_{kl} \mathbf{e}_k \otimes \mathbf{e}_l$:

$$\mathbf{A} : \mathbf{B} = \operatorname{tr} \mathbf{A}^{\mathrm{T}} \cdot \mathbf{B} = \operatorname{tr} \mathbf{A} \cdot \mathbf{B}^{\mathrm{T}} = \begin{cases} A_{1ij}\, B_{2kl}\, (\mathbf{e}_i^1 \cdot \mathbf{e}_k^2)\, (\mathbf{e}_j^1 \cdot \mathbf{e}_l^2), \\ A_{ij}\, B_{ij}\,, \end{cases} \tag{2.1.3}$$

and therefore the double product is commutative, $\mathbf{A} : \mathbf{B} = \mathbf{B} : \mathbf{A}$ and $\mathbf{A} : \mathbf{B} = \mathbf{A}^{\mathrm{T}} : \mathbf{B}^{\mathrm{T}}$. Note the following property that indicates that the double product actually decouples the symmetric and skew-symmetric parts,

$$\mathbf{A} : \mathbf{B} = \frac{\mathbf{A} + \mathbf{A}^{\mathrm{T}}}{2} : \frac{\mathbf{B} + \mathbf{B}^{\mathrm{T}}}{2} + \frac{\mathbf{A} - \mathbf{A}^{\mathrm{T}}}{2} : \frac{\mathbf{B} - \mathbf{B}^{\mathrm{T}}}{2}\,. \tag{2.1.4}$$

The double dot product of two dyads is just a particular case of the double dot product over second order tensors,

$$\big(\mathbf{a}\otimes\mathbf{b}\big) : \big(\mathbf{c}\otimes\mathbf{d}\big) = (\mathbf{a}\cdot\mathbf{c})\,(\mathbf{b}\cdot\mathbf{d})\,. \tag{2.1.5}$$

- Euclidean norm of a vector $|\mathbf{v}| = [\mathbf{v}\cdot\mathbf{v}]^{\frac{1}{2}}$.
- Euclidean norm of a second order tensor $|\mathbf{A}| = [\mathbf{A} : \mathbf{A}]^{\frac{1}{2}}$.

The reader is invited to pay attention to the very definitions of the double product and of the Euclidean norm. The rules that a norm over a linear space should satisfy are exposed in textbooks of matrix analysis, e.g., Ortega [1987], Ciarlet [1989]. The norm of any entity, vector or tensor of any order, should be either positive or zero. It can be zero if and only if the entity itself vanishes. Consider some matrix products that can be obtained from a particular nonsymmetric 2×2 matrix $\mathbf{A}$,

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \mathbf{A}^2 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad \mathbf{A}\cdot\mathbf{A}^{\mathrm{T}} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \quad \mathbf{A}^{\mathrm{T}}\cdot\mathbf{A} = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}. \tag{2.1.6}$$

Consequently, the square of a matrix $\mathbf{A}$ cannot be used to build the norm in general. Still, it can if the matrix is symmetric, and then $\operatorname{tr}\mathbf{A}^2 = |\mathbf{A}|^2$. If the matrix is skew-symmetric, then $\operatorname{tr}\mathbf{A}^2 = -|\mathbf{A}|^2$.

As a side remark, a matrix for which there exists a positive integer p such that $\mathbf{A}^p$ vanishes is called nilpotent. A matrix is nilpotent if and only if all its eigenvalues vanish, e.g., Ortega [1987].

For a second order tensor $\mathbf{A}$ with components A_{ij} in a cartesian basis, its transpose $\mathbf{A}^{\mathrm{T}}$ has components A_{ji}. $\mathbf{A}$ is said to be symmetric if $\mathbf{A} = \mathbf{A}^{\mathrm{T}}$. The transpose operator satisfies the relations $(\mathbf{A}^{\mathrm{T}})^{\mathrm{T}} = \mathbf{A}$ and $(\mathbf{A}\cdot\mathbf{B})^{\mathrm{T}} = \mathbf{B}^{\mathrm{T}}\cdot\mathbf{A}^{\mathrm{T}}$. Note the trivial but useful equivalence,

$$\mathbf{A}+\mathbf{B} \quad \text{symmetric} \quad \Leftrightarrow \quad \mathbf{A}-\mathbf{B}^{\mathrm{T}} \quad \text{symmetric}\,. \tag{2.1.7}$$

If $\mathbf{A}$ is symmetric, its inverse is symmetric if it exists, and so is any power $\mathbf{A}^n$, $n\geq 1$. The converse implication does not hold: consider the counter-example below,

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \quad \mathbf{A}^2 = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}. \tag{2.1.8}$$

Further striking differences in spectral properties between symmetric and nonsymmetric matrices are displayed in Exercise 9.1.

2.1.2 Algebraic operators

The identity over second order tensors is denoted by $\mathbf{I} = (I_{ij})$.

The permutation symbol $\mathbf{e}$, also called Levi-Civita tensor, is a third order tensor defined by

$$e_{ijk} = \begin{cases} 1 & \text{if } (i,j,k) \text{ is an even permutation of } (1,2,3)\,, \\ -1 & \text{if } (i,j,k) \text{ is an odd permutation of } (1,2,3)\,, \\ 0 & \text{otherwise}\,. \end{cases} \tag{2.1.9}$$

Some useful properties are collected below [Eringen 1967, p. 430],

$$\begin{gathered} e_{ijk}\,e_{mnp}\,A_{mnp} = A_{ijk} - A_{ikj} + A_{jki} - A_{jik} + A_{kij} - A_{kji}\,, \\ e_{ijk}\,e_{kmn} = I_{im}\,I_{jn} - I_{in}\,I_{jm}\,, \\ e_{ijk}\,e_{jkn} = 2\,I_{in}\,, \\ e_{ijk}\,e_{ijk} = 6\,. \end{gathered} \tag{2.1.10}$$

The definition of the permutation symbol can be extended to higher orders.

A one-to-one correspondence can be established between a second order skew-symmetric tensor $\mathbf{A}$, which is such that $\mathbf{A}^{\mathrm{T}} = -\mathbf{A}$ and a pseudo-vector $\vec{\mathbf{A}}$. In cartesian axes,

$$A_i = \frac{1}{2}\, e_{ijk}\, A_{jk}, \quad A_{ij} = e_{ijk}\, A_k\,, \tag{2.1.11}$$

or in matrix form,

$$\mathbf{A} = \begin{bmatrix} 0 & A_{12} & A_{13} \\ -A_{12} & 0 & A_{23} \\ -A_{13} & -A_{23} & 0 \end{bmatrix} = \begin{bmatrix} 0 & A_3 & -A_2 \\ -A_3 & 0 & A_1 \\ A_2 & -A_1 & 0 \end{bmatrix}, \quad |\mathbf{A}|^2 = 2\,|\vec{\mathbf{A}}|^2\,. \tag{2.1.12}$$

For any vector $\mathbf{b}$,

$$\mathbf{A}\cdot\mathbf{b} = -\vec{\mathbf{A}}\wedge\mathbf{b} = \mathbf{b}\wedge\vec{\mathbf{A}}\,, \tag{2.1.13}$$

where $\wedge$ is the vector product, or cross product, defined by Eqn (2.1.14). In fact $\vec{\mathbf{A}}$ is called a *pseudo*-vector because it does not follow tensor rules under change of reference frame as briefly indicated in Exercise 2.1.

The permutation symbol is instrumental to obtain the component form of a number of operators, e.g., the *vector product*,

$$(\mathbf{a}\wedge\mathbf{b})_i = e_{ijk}\, a_j\, b_k\,, \tag{2.1.14}$$

and the *determinant of a second order tensor* $\mathbf{A}$ in $\mathbb{R}^3$,

$$e_{mnp}\,\det\mathbf{A} = e_{ijk}\,A_{im}\,A_{jn}\,A_{kp} \quad \Rightarrow \quad \det\mathbf{A} = \begin{cases} e_{ijk}\,A_{i1}\,A_{j2}\,A_{k3}, \\ \frac{1}{6}\,e_{mnp}\,e_{ijk}\,A_{im}\,A_{jn}\,A_{kp}, \\ e_{mnp}\,A_{1m}\,A_{2n}\,A_{3p}\,, \end{cases} \tag{2.1.15}$$

namely, in explicit form,

$$\det\mathbf{A} = A_{11}\,A_{22}\,A_{33} - A_{11}\,A_{23}\,A_{32} - A_{22}\,A_{13}\,A_{31} - A_{33}\,A_{12}\,A_{21} + A_{12}\,A_{23}\,A_{31} + A_{13}\,A_{32}\,A_{21}\,. \tag{2.1.16}$$

These relations prove that the determinant of a second order tensor and of its transpose are the same, $\det\mathbf{A} = \det\mathbf{A}^{\mathrm{T}}$, $\forall\mathbf{A}$. Also the determinant of the product of two tensors is equal to the product of the determinants namely $\det\mathbf{A}\cdot\mathbf{B} = \det\mathbf{A}\,\det\mathbf{B}$. The proof is worthwhile just to manipulate the various pieces of Eqn (2.1.15):

$$\begin{aligned} \det\mathbf{A}\cdot\mathbf{B} &= e_{ijk}\,A_{im}\,B_{m1}\,A_{jn}\,B_{n2}\,A_{kp}\,B_{p3} \\ &= \big(e_{ijk}\,A_{im}\,A_{jn}\,A_{kp}\big)\,\big(B_{m1}\,B_{n2}\,B_{p3}\big) \\ &= e_{mnp}\,\det\mathbf{A}\,\big(B_{m1}\,B_{n2}\,B_{p3}\big) \\ &= \det\mathbf{A}\,\det\mathbf{B}\,. \end{aligned} \tag{2.1.17}$$

If a second order tensor $\mathbf{A}$ is invertible, its inverse is denoted by $\mathbf{A}^{-1}$. The transpose and inverse operators commute and therefore the shortcut notation $\mathbf{A}^{-\mathrm{T}} = (\mathbf{A}^{\mathrm{T}})^{-1} = (\mathbf{A}^{-1})^{\mathrm{T}}$ makes sense.

The following result is useful for a matrix whose components are in arbitrary order [Segel 1987, p. 19],

$$\det\begin{bmatrix} A_{ip} & A_{iq} & A_{ir} \\ A_{jp} & A_{jq} & A_{jr} \\ A_{kp} & A_{kq} & A_{kr} \end{bmatrix} = e_{ijk}\,e_{pqr}\,\det\mathbf{A}\,. \tag{2.1.18}$$

Note also the fundamental relations for the cartesian triad $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$,

$$\mathbf{e}_i\otimes\mathbf{e}_j = e_{ijk}\,\mathbf{e}_k, \quad \det(\mathbf{e}_i, \mathbf{e}_j, \mathbf{e}_k) = e_{ijk}\,, \tag{2.1.19}$$

and the additional relations for $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ and $\mathbf{d}$ arbitrary vectors,

$$\begin{aligned}
|\mathbf{a}\wedge\mathbf{b}|^2 &= |\mathbf{a}|^2\,|\mathbf{b}|^2 - |\mathbf{a}\cdot\mathbf{b}|^2,\\
(\mathbf{a}\wedge\mathbf{b})\wedge\mathbf{c} &= (\mathbf{a}\cdot\mathbf{c})\,\mathbf{b} - (\mathbf{b}\cdot\mathbf{c})\,\mathbf{a},\\
\mathbf{a}\wedge(\mathbf{b}\wedge\mathbf{c}) &= (\mathbf{a}\cdot\mathbf{c})\,\mathbf{b} - (\mathbf{a}\cdot\mathbf{b})\,\mathbf{c},\\
(\mathbf{a}\wedge\mathbf{b})\cdot\mathbf{c} &= \mathbf{a}\cdot(\mathbf{b}\wedge\mathbf{c}) = \det\,(\mathbf{a},\,\mathbf{b},\,\mathbf{c}),\\
(\mathbf{a}\wedge\mathbf{b})\cdot(\mathbf{c}\wedge\mathbf{d}) &= (\mathbf{a}\cdot\mathbf{c})\,(\mathbf{b}\cdot\mathbf{d}) - (\mathbf{a}\cdot\mathbf{d})\,(\mathbf{b}\cdot\mathbf{c}),\\
(\mathbf{a}\wedge\mathbf{b})\wedge(\mathbf{c}\wedge\mathbf{d}) &= (\mathbf{a}\cdot\mathbf{c})\,(\mathbf{b}\wedge\mathbf{d}) - (\mathbf{a}\cdot\mathbf{d})\,(\mathbf{b}\wedge\mathbf{c})\,.
\end{aligned} \tag{2.1.20}$$

The fourth relation provides the algebraic volume defined by three vectors. While the vector product is anti-commutative, $\mathbf{a}\wedge\mathbf{b} = -\mathbf{b}\wedge\mathbf{a}$, the second and third relations show that it is not associative,

$$(\mathbf{a}\wedge\mathbf{b})\wedge\mathbf{c} \neq \mathbf{a}\wedge(\mathbf{b}\wedge\mathbf{c})\,. \tag{2.1.21}$$

Another useful algebraic operator is the *trace* operator, e.g., of a second order tensor $\mathbf{A}$ expressed in cartesian axes,

$$\mathrm{tr}\,\mathbf{A} = A_{ii}\,. \tag{2.1.22}$$

A second order tensor decomposes uniquely into an isotropic or spherical part and a traceless or deviatoric part,

$$\mathbf{A} = \frac{1}{3}\,(\mathrm{tr}\,\mathbf{A})\,\mathbf{I} + \mathrm{dev}\,\mathbf{A}\,. \tag{2.1.23}$$

The following operator will be instrumental to manipulate the elasticity tensor,

$$(\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B})_{ijkl} = \frac{1}{2}\,(A_{ik}\,B_{jl} + A_{il}\,B_{jk}),\quad (\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B}) : \mathbf{X} = \mathbf{A}\cdot\tfrac{1}{2}(\mathbf{X}+\mathbf{X}^{\mathrm{T}})\cdot\mathbf{B}^{\mathrm{T}}\,, \tag{2.1.24}$$

which, for $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{X}$ symmetric second order tensors, simplifies to

$$(\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B}) : \mathbf{X} = \mathbf{A}\cdot\mathbf{X}\cdot\mathbf{B}\,. \tag{2.1.25}$$

The component form,

$$(\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I})_{ijkl} = \frac{1}{2}(I_{ik}I_{jl} + I_{il}I_{jk}),\quad (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}) : \mathbf{X} = \frac{1}{2}(\mathbf{X}+\mathbf{X}^{\mathrm{T}})\,, \tag{2.1.26}$$

shows that the operator $\overline{\underline{\otimes}}$ is the identity operator over symmetric second order tensors. Therefore $\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}$ is the fourth order identity tensor $\mathbf{I}^{(4)}$ over symmetric second order tensors. Consequently, $\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\,\mathbf{I}\otimes\mathbf{I}$, with cartesian components $\frac{1}{2}(I_{ik}I_{jl} + I_{il}I_{jk}) - \frac{1}{3}\,I_{ij}I_{kl}$, is the fourth order deviator operator over symmetric second order tensors,

$$\begin{aligned}
&(\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}) : \mathbf{X} = \mathbf{X},\quad \forall\ \mathbf{X} = \mathbf{X}^{\mathrm{T}},\\
&(\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\mathbf{I}\otimes\mathbf{I}) : \mathbf{X} = \mathrm{dev}\,\mathbf{X},\quad \forall\ \mathbf{X} = \mathbf{X}^{\mathrm{T}}\,,
\end{aligned} \tag{2.1.27}$$

and

$$\begin{aligned}
&(\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}) : (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}) = \mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I},\quad (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}) : (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\mathbf{I}\otimes\mathbf{I}) = (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\mathbf{I}\otimes\mathbf{I}),\\
&(\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\mathbf{I}\otimes\mathbf{I}) : (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\mathbf{I}\otimes\mathbf{I}) = (\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{1}{3}\mathbf{I}\otimes\mathbf{I})\,.
\end{aligned} \tag{2.1.28}$$

Note the derivatives of an arbitrary nonzero symmetric second order tensor $\mathbf{X}$,

$$\frac{\partial|\mathbf{X}|}{\partial\mathbf{X}} = \frac{\mathbf{X}}{|\mathbf{X}|}\,,\quad \frac{\partial^2|\mathbf{X}|}{\partial\mathbf{X}^2} = \frac{1}{|\mathbf{X}|}\left(\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} - \frac{\mathbf{X}}{|\mathbf{X}|}\otimes\frac{\mathbf{X}}{|\mathbf{X}|}\right),\quad \frac{\partial^2|\mathbf{X}|^2}{\partial\mathbf{X}^2} = 2\,\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}\,. \tag{2.1.29}$$

Therefore the quadratic forms associated with the second derivatives are positive (semi-)definite, namely for an arbitrary nonzero symmetric second order tensor $\mathbf{Y}$,

$$\mathbf{Y}\cdot\frac{\partial^2|\mathbf{X}|}{\partial\mathbf{X}^2}\cdot\mathbf{Y} = \frac{|\mathbf{Y}|^2}{|\mathbf{X}|}\,\sin^2(\mathbf{X},\mathbf{Y}) \geq 0,\quad \mathbf{Y}\cdot\frac{\partial^2|\mathbf{X}|^2}{\partial\mathbf{X}^2}\cdot\mathbf{Y} = 2\,|\mathbf{Y}|^2 > 0\,. \tag{2.1.30}$$

Another partial differential relation is worth mentioning. For an invertible symmetric second order tensor $\mathbf{X}$,

$$\frac{\partial(\mathbf{X}^{-1})_{ij}}{\partial\mathbf{X}_{kl}} = -\frac{1}{2}\left((\mathbf{X}^{-1})_{ik}\,(\mathbf{X}^{-1})_{jl} + (\mathbf{X}^{-1})_{il}\,(\mathbf{X}^{-1})_{jk}\right). \tag{2.1.31}$$

Therefore, if $\mathbf{X}$ is symmetric,

$$\frac{\partial\mathbf{X}^{-1}}{\partial\mathbf{X}} = -\mathbf{X}^{-1}\,\overline{\underline{\otimes}}\,\mathbf{X}^{-1}\,. \tag{2.1.32}$$

2.2 Characteristic polynomial, eigenvalues and eigenvectors

2.2.1 Eigenvalues and eigenvectors

The *eigenvalues* $\lambda = \lambda(\mathbf{A})$ of the square matrix or tensor $\mathbf{A}$ of order n are the n real, or complex, roots of the *characteristic polynomial* $P_A(\lambda) = \det(\lambda\mathbf{I}-\mathbf{A})$. At least one nonzero (right) *eigenvector* $\mathbf{v}$, such that $(\mathbf{A}-\lambda\mathbf{I})\cdot\mathbf{v} = \mathbf{0}$ is associated with each eigenvalue λ. Given an eigenvalue λ, the set of vectors such that $(\mathbf{A}-\lambda\mathbf{I})\cdot\mathbf{v} = \mathbf{0}$ is a vector space termed eigenspace associated with λ. The dimension of this eigenspace is the *geometrical multiplicity* of λ, which might be different from its *algebraic multiplicity*. As examples, let us consider the matrices in $\mathbb{R}^2$,

$$\mathbf{A} = \begin{bmatrix} a & 0 \\ 0 & b \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} a & 1 \\ 0 & b \end{bmatrix}. \tag{2.2.1}$$

The matrix $\mathbf{A}$ has the characteristic polynomial $P_A(\lambda) = (\lambda - a)(\lambda - b)$. If $a \neq b$, the eigenvalues $\lambda = a, b$ are both single, and the associated eigenspaces are spanned by the respective vectors $[1\ 0]^{\mathrm{T}}$ and $[0\ 1]^{\mathrm{T}}$ and have dimension 1. Therefore the algebraic and geometric multiplicities of the two eigenvalues are equal to 1. The eigenvalues of matrix $\mathbf{B}$ are also a and b and the associated eigenvectors are $[1\ 0]^{\mathrm{T}}$ and $[1\ b-a]^{\mathrm{T}}$.

When $a = b$, the eigenvalue $\lambda = a$ has algebraic multiplicity 2 for both matrices. Further, any vector is an eigenvector of the matrix $\mathbf{A}$ and the dimension of the eigenspace associated with the eigenvalue is equal to 2. On the other hand, the eigenspace of matrix $\mathbf{B}$ is then spanned by the single vector $\mathbf{a}_1 = [1\ 0]^{\mathrm{T}}$, so that the geometrical multiplicity of the eigenvalue is equal to 1. Such a matrix, for which the geometrical multiplicity of at least one eigenvalue is smaller than its algebraic multiplicity, is called *defective*. A generalized eigenvector $\mathbf{a}_2$ satisfies the relation $(\mathbf{B} - a\,\mathbf{I})\cdot\mathbf{a}_2 = \mathbf{a}_1$, yielding $\mathbf{a}_2 = [x\ 1]^{\mathrm{T}}$, with x arbitrary. The two vectors generate $\mathbb{R}^2$ and

$$\mathbf{P}^{-1}\cdot\mathbf{B}\cdot\mathbf{P} = \mathbf{B}, \quad \text{with} \quad \mathbf{P} = [\mathbf{a}_1\ \mathbf{a}_2]^{\mathrm{T}} = \begin{bmatrix} 1 & x \\ 0 & 1 \end{bmatrix}. \tag{2.2.2}$$

A real symmetric matrix in $\mathbb{R}^n$, $n \geq 1$, has real eigenvalues. Indeed, whatever the potential nature real or complex of the eigenvector $\mathbf{a}$ associated with the eigenvalue λ, the product $\overline{\mathbf{a}}\cdot\mathbf{A}\cdot\mathbf{a}$ is real, and therefore the eigenvalue λ which is equal to the Rayleigh quotient $\overline{\mathbf{a}}\cdot\mathbf{A}\cdot\mathbf{a}/(\overline{\mathbf{a}}\cdot\mathbf{a})$ is real. The eigenvectors of a real symmetric matrix form an orthonormal basis of $\mathbb{R}^n$ and, in this basis, the representation of the matrix, namely $\mathbf{diag}[\lambda_1\ \lambda_2\ \cdots]$, is diagonal, see, e.g., Ortega [1987]. Moreover, a positive definite symmetric matrix has strictly positive real eigenvalues.

Exercise 9.1 shows that the same properties do not hold for nonsymmetric matrices. In fact, for nonsymmetric matrices, the eigenvalues of the matrix and of its transpose are the same since $\det(\lambda\mathbf{I} - \mathbf{A}) = \det(\lambda\mathbf{I} - \mathbf{A}^{\mathrm{T}})$. On the other hand, at least one *right* eigenvector $(\mathbf{A} - \lambda\mathbf{I})\cdot\mathbf{v} = \mathbf{0}$ and one *left* eigenvector $\mathbf{w}\cdot(\mathbf{A} - \lambda\mathbf{I}) = \mathbf{0}$, which is also a right eigenvector associated with the transpose matrix, are associated with each eigenvalue λ. If $\mathbf{v}$ is a right eigenvector associated with a certain eigenvalue and $\mathbf{w}$ a left eigenvector associated with a different eigenvalue, then $\mathbf{v}\cdot\mathbf{w} = 0$ [Wilkinson 1965, Section 1.3].

The eigenvalues of (real) skew-symmetric tensors in $\mathbb{R}^3$ are all pure imaginary but one which is zero. For more details on skew-symmetric tensors in $\mathbb{R}^3$, see Section 2.5.5.1.

As for proper orthogonal tensors in $\mathbb{R}^3$, they have one eigenvalue equal to 1, and the other two are complex conjugate as indicated in Section 2.5.5.3.

Two remarkable algebraic properties that are illustrated by Figs. 2.2.1 and 2.2.2 are used to sort wave-speeds in saturated porous media in Section 11.5.4. The *separation theorem*, e.g. [Wilkinson 1965, Section 2.47], indicates that the $n-1$ eigenvalues $\lambda'(\mathbf{A}')$ of the leading principal minor $\mathbf{A}' = \mathbf{A}_{[n-1,n-1]}$ of a symmetric matrix $\mathbf{A} = \mathbf{A}_{[n,n]}$,

$$\mathbf{A}_{[n,n]} = \begin{bmatrix} \mathbf{A}_{[n-1,n-1]} & \times \\ \times & \times \end{bmatrix}, \tag{2.2.3}$$

separate the n eigenvalues $\lambda(\mathbf{A})$ of the matrix $\mathbf{A}$, namely

$$\lambda_n(\mathbf{A}) \leq \lambda'_{n-1}(\mathbf{A}') \leq \lambda_{n-1}(\mathbf{A}) \leq \quad \cdots \quad \leq \lambda_2(\mathbf{A}) \leq \lambda'_1(\mathbf{A}') \leq \lambda_1(\mathbf{A}). \tag{2.2.4}$$

Let a, $\mathbf{a}$ and $\mathbf{A}$ be an arbitrary scalar, vector and symmetric matrix, respectively. The *interlacing theorem* states that the eigenvalues of $\mathbf{A}$ and of the rank one modification $\mathbf{A}' = \mathbf{A} + a\,\mathbf{a}\otimes\mathbf{a}$ interlace, namely for $a \geq 0$,

$$\lambda_n(\mathbf{A}) \leq \lambda'_n(\mathbf{A}') \leq \lambda_{n-1}(\mathbf{A}) \leq \lambda'_{n-1}(\mathbf{A}') \quad \cdots \quad \leq \lambda_1(\mathbf{A}) \leq \lambda'_1(\mathbf{A}'). \tag{2.2.5}$$

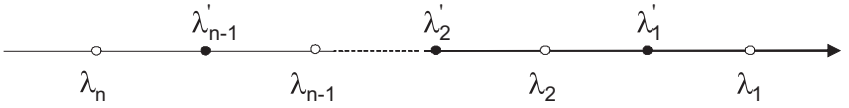

Fig. 2.2.1: Separated eigenvalues.

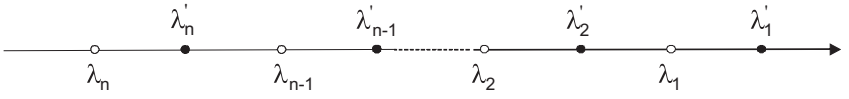

Fig. 2.2.2: Interlacing eigenvalues.

2.2.2 Characteristic polynomial of a second order tensor

For a second order tensor in $\mathbb{R}^3$, the characteristic polynomial has degree 3 in the eigenvalue λ,

$$P_A(\lambda) = \det(\lambda\,\mathbf{I} - \mathbf{A}) = \lambda^3 - I_1\,\lambda^2 + I_2\,\lambda - I_3 = 0\,, \tag{2.2.6}$$

where I_1, I_2 and I_3 are the scalar invariants,

$$I_1(\mathbf{A}) = \text{tr }\mathbf{A}, \quad I_2(\mathbf{A}) = \frac{1}{2}\left((\text{tr }\mathbf{A})^2 - \text{tr }\mathbf{A}^2\right), \quad I_3(\mathbf{A}) = \det\,\mathbf{A}\,. \tag{2.2.7}$$

The second invariant $I_2(\mathbf{A})$ is also the trace of the matrix adjoint to $\mathbf{A}$, namely

$$I_2(\mathbf{A}) = \text{tr}\,(\det\mathbf{A}\;\mathbf{A}^{-1}) = \det\mathbf{A}\,\text{tr}\,\mathbf{A}^{-1}\,. \tag{2.2.8}$$

$I_3(\mathbf{A}) = \det\,\mathbf{A}$ is given in component form by Eqn (2.1.16), and,

$$I_1(\mathbf{A}) = A_{11} + A_{22} + A_{33}, \quad I_2(\mathbf{A}) = A_{11}\,A_{22} + A_{22}\,A_{33} + A_{33}\,A_{11} - A_{23}\,A_{32} - A_{13}\,A_{31} - A_{12}\,A_{21}\,. \tag{2.2.9}$$

The definition extends to tensors of higher order. Let $\mathbf{A}$ be an arbitrary tensor and $\mathbf{I}$ the identity tensor, both of order n. The characteristic polynomial $P_A(\lambda)$ associated with $\mathbf{A}$ is the polynomial of degree n defined by the relation, p. 440 in Eringen [1967],

$$P_A(\lambda) = \det(\lambda\,\mathbf{I} - \mathbf{A}) = \lambda^n + \alpha_1\,\lambda^{n-1} + \alpha_2\,\lambda^{n-2} + \cdots + \alpha_{n-1}\,\lambda^1 + \alpha_n\,, \tag{2.2.10}$$

where

$$\begin{aligned}
\alpha_1 &= -\text{tr }\mathbf{A},\\
\alpha_2 &= -\frac{1}{2}\,(\alpha_1\,\text{tr }\mathbf{A} + \text{tr }\mathbf{A}^2),\\
\alpha_3 &= -\frac{1}{3}\,(\alpha_2\,\text{tr }\mathbf{A} + \alpha_1\,\text{tr }\mathbf{A}^2 + \text{tr }\mathbf{A}^3),\\
&\vdots\\
\alpha_n &= -\frac{1}{n}\,(\alpha_{n-1}\,\text{tr }\mathbf{A} + \alpha_{n-2}\,\text{tr }\mathbf{A}^2 + \cdots + \alpha_1\,\text{tr }\mathbf{A}^{n-1} + \text{tr }\mathbf{A}^n)\,.
\end{aligned} \tag{2.2.11}$$

In terms of the eigenvalues $\lambda_i(\mathbf{A})$, $i \in [1, n]$, of $\mathbf{A}$, the above formulas become

$$P_A(\lambda) = \prod_{i=1}^{n}\,(\lambda - \lambda_i)\,, \tag{2.2.12}$$

and, for $n = 3$,

$$I_1(\mathbf{A}) = -\alpha_1 = \lambda_1 + \lambda_2 + \lambda_3, \quad I_2(\mathbf{A}) = \alpha_2 = \lambda_1\,\lambda_2 + \lambda_2\,\lambda_3 + \lambda_3\,\lambda_1, \quad I_3(\mathbf{A}) = -\alpha_3 = \lambda_1\,\lambda_2\,\lambda_3\,. \tag{2.2.13}$$

The isotropic scalar invariants of second order tensors satisfy some interesting inequalities, as already touched upon in Section 2.5.7. For instance, let $\mathbf{A}$ be an arbitrary *second order tensor with real positive eigenvalues*. Then, by a direct calculation or using Eqn (2.2.8),

$$(I_1(\mathbf{A}))^2 \geq 3\,I_2(\mathbf{A}), \quad I_1(\mathbf{A})\,I_2(\mathbf{A}) - I_3(\mathbf{A}) = I_3(\mathbf{A})\left(I_1(\mathbf{A})\,I_1(\mathbf{A}^{-1}) - 1\right) > 0\,, \tag{2.2.14}$$

since, according to Eqn (2.5.60), $I_1(\mathbf{A})\,I_1(\mathbf{A}^{-1}) \geq 9$. In fact, according to Eqn (2.5.60) and Eqn (2.2.8),

$$\frac{1}{3}\,I_1(\mathbf{A}) \geq (I_3(\mathbf{A}))^{\frac{1}{3}} \geq \frac{3}{I_1(\mathbf{A}^{-1})} = 3\,\frac{I_3(\mathbf{A})}{I_2(\mathbf{A})}\,, \tag{2.2.15}$$

whence, with equalities only if the three eigenvalues are equal,

$$I_1(\mathbf{A}) \geq 3\,(I_3(\mathbf{A}))^{\frac{1}{3}}, \quad I_1(\mathbf{A})\,I_2(\mathbf{A}) \geq 9\,I_3(\mathbf{A}), \quad I_2(\mathbf{A}) \geq 3\,(I_3(\mathbf{A}))^{\frac{2}{3}}\,. \tag{2.2.16}$$

2.2.3 Scalar invariants of the stress deviator

2.2.3.1 Spectral decomposition of a unit deviator

For the record, let us note the spectral decomposition of the unit deviator $\hat{\mathbf{S}}$,

$$\hat{\mathbf{S}} = \sum_{i=1}^{3} \hat{S}_i \, \mathbf{e}_i \otimes \mathbf{e}_i, \quad \hat{S}_1 \geq \hat{S}_2 \geq \hat{S}_3 \,, \tag{2.2.17}$$

where the eigenvectors $\mathbf{e}_i$, $i \in [1,3]$, are of unit norm and the eigenvalues can be defined in terms of a single scalar $\ell \in [0, \pi/3]$, referred to as Lode angle,

$$\hat{S}_i = \sqrt{\frac{2}{3}} \cos \ell_i \,, \quad \ell_i = \ell - \frac{2\pi}{3}\,(i-1), \quad i \in [1,3] \,. \tag{2.2.18}$$

Note the properties of the unit deviator [Loret and Harireche 1991, Loret 1992],

$$\begin{aligned} &\hat{S}_1 + \hat{S}_2 + \hat{S}_3 = 0, \quad \hat{S}_1^2 + \hat{S}_2^2 + \hat{S}_3^2 = 1 \quad \hat{S}_j \, \hat{S}_k = \hat{S}_i^2 - \tfrac{1}{2}, \quad i \neq j \neq k, \\ &\hat{S}_1^3 + \hat{S}_2^3 + \hat{S}_3^3 = 3 \, \hat{S}_1 \, \hat{S}_2 \, \hat{S}_3, \quad \hat{S}_1^4 + \hat{S}_2^4 + \hat{S}_3^4 = \tfrac{1}{2} \,. \end{aligned} \tag{2.2.19}$$

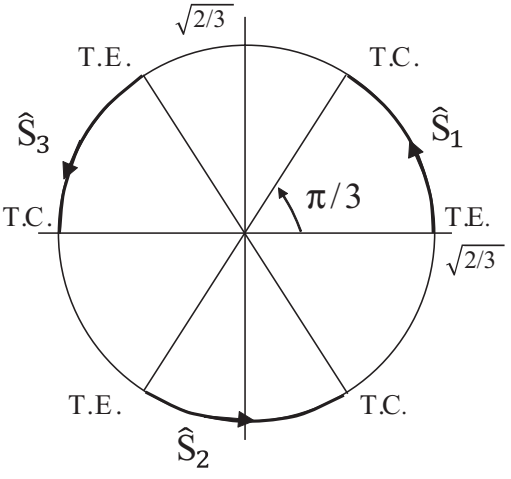

Fig. 2.2.3: Range of the eigenvalues of the unit deviator $\hat{\mathbf{S}}$.

For triaxial extension (T.E.), ℓ=0°, and $\hat{S}_1 > \hat{S}_2 = \hat{S}_3$, while for triaxial compression (T.C.), ℓ=60°, and $\hat{S}_1 = \hat{S}_2 > \hat{S}_3$. The three eigenvalues range in the following interval, see Fig. 2.2.3,

$$\hat{S}_1 \in \Big[\frac{1}{2}\sqrt{\frac{2}{3}}, \sqrt{\frac{2}{3}}\Big], \quad \hat{S}_2 \in \Big[-\frac{1}{2}\sqrt{\frac{2}{3}}, \frac{1}{2}\sqrt{\frac{2}{3}}\Big], \quad \hat{S}_3 \in \Big[-\sqrt{\frac{2}{3}}, -\frac{1}{2}\sqrt{\frac{2}{3}}\Big], \tag{2.2.20}$$

and satisfy the inequalities,

$$\hat{S}_1 + 2\,\hat{S}_3 \leq 0, \quad \hat{S}_3 + 2\,\hat{S}_1 \geq 0 \,. \tag{2.2.21}$$

As an addition, two compact nonaligned perturbations with respect to a unit deviator are provided below. Indeed, consider the nonaligned unit deviators $\hat{\mathbf{S}}_P$ and $\hat{\mathbf{S}}_Q$. They can be cast in the following form [Loret 1992]:

$$\hat{\mathbf{S}}_P = \cos\alpha \; \hat{\mathbf{S}} - \sin\alpha \; \Delta\hat{\mathbf{S}} \,, \quad \hat{\mathbf{S}}_Q = \cos\alpha \; \hat{\mathbf{S}} + \sin\alpha \; \Delta\hat{\mathbf{S}} \,, \tag{2.2.22}$$

where we introduce the unit deviators $\hat{\mathbf{S}}$ and $\Delta\hat{\mathbf{S}}$ which are orthogonal and the angle $\alpha \in \,]\,0, \pi/2\,[$:

$$\hat{\mathbf{S}} = \frac{\hat{\mathbf{S}}_Q + \hat{\mathbf{S}}_P}{|\hat{\mathbf{S}}_Q + \hat{\mathbf{S}}_P|} \,, \quad \Delta\hat{\mathbf{S}} = \frac{\hat{\mathbf{S}}_Q - \hat{\mathbf{S}}_P}{|\hat{\mathbf{S}}_Q - \hat{\mathbf{S}}_P|} \,, \quad \tan\alpha = \frac{|\hat{\mathbf{S}}_Q - \hat{\mathbf{S}}_P|}{|\hat{\mathbf{S}}_Q + \hat{\mathbf{S}}_P|} \,, \tag{2.2.23}$$

and

$$|\hat{\mathbf{S}}| = 1, \quad |\Delta\hat{\mathbf{S}}| = 1, \quad \hat{\mathbf{S}} : \Delta\hat{\mathbf{S}} = 0\,. \tag{2.2.24}$$

Due to the orthogonality condition, the unit deviator $\Delta\hat{\mathbf{S}}$ may be defined by the angle $\ell - \pi/2 + k\,\pi$, where k is an integer,

$$\Delta\hat{S}_i = (-1)^k \sqrt{\frac{2}{3}} \sin\Big(\ell - \frac{2\pi}{3}\,(i-1)\Big)\,, \;\; i \in [1,3]\,. \tag{2.2.25}$$

Consequently the non collinear unit deviators $\hat{\mathbf{S}}_P$ and $\hat{\mathbf{S}}_Q$ are defined by the Lode angles $\ell + (-1)^k\,\alpha$ and $\ell - (-1)^k\,\alpha$,

$$\begin{aligned}
(\hat{S}_P)_i &= (-1)^k \sqrt{\frac{2}{3}} \cos\Big(\ell + (-1)^k\,\alpha - \frac{2\pi}{3}\,(i-1)\Big)\,, \\
(\hat{S}_Q)_i &= (-1)^k \sqrt{\frac{2}{3}} \cos\Big(\ell - (-1)^k\,\alpha - \frac{2\pi}{3}\,(i-1)\Big), \;\; i \in [1,3]\,.
\end{aligned} \tag{2.2.26}$$

2.2.3.2 The Lode angle: eigenvalues in terms of isotropic scalar invariants

Let $\mathbf{s}$ be the stress deviator. Its characteristic polynomial (2.2.6),

$$P_s(\lambda) = \det(\lambda\,\mathbf{I} - \mathbf{s}) = \lambda^3 + I_2\,\lambda - I_3 = 0\,, \tag{2.2.27}$$

expresses in terms of the scalar invariants I_2 and I_3,

$$I_2 = -\frac{1}{2}\,\mathrm{tr}\;\mathbf{s}^2, \quad I_3 = \det\,\mathbf{s} = \frac{1}{3}\,\mathrm{tr}\;\mathbf{s}^3\,. \tag{2.2.28}$$

The last relation is due to (2.2.33). The solution of this cubic equation for λ is obtained by introducing the Lode angle ℓ,

$$\lambda = \sqrt{\frac{2}{3}\,\mathrm{tr}\,\mathbf{s}^2}\,\cos\ell\,, \tag{2.2.29}$$

which transforms (2.2.27) to

$$4\,\cos^3\ell - 3\,\cos\ell = \cos 3\ell = \sqrt{6}\,\frac{\mathrm{tr}\;\mathbf{s}^3}{(\mathrm{tr}\;\mathbf{s}^2)^{\frac{3}{2}}}\,, \tag{2.2.30}$$

which has three independent solutions,

$$\ell_i = \ell - \frac{2\,\pi}{3}(i-1), \quad i = 1,2,3, \quad \text{with } \ell = \frac{1}{3}\cos^{-1}\Big[\sqrt{6}\,\frac{\mathrm{tr}\;\mathbf{s}^3}{(\mathrm{tr}\;\mathbf{s}^2)^{\frac{3}{2}}}\Big] \in [0, \frac{\pi}{3}]\,. \tag{2.2.31}$$

Incidentally, as a complement to the previous section, we have proved that the three eigenvalues of the stress can be expressed analytically as

$$\sigma_i = \frac{1}{3}\,\mathrm{tr}\;\boldsymbol{\sigma} + \sqrt{\frac{2}{3}\,\mathrm{tr}\,\mathbf{s}^2}\,\cos\ell_i, \quad i = 1,2,3\,. \tag{2.2.32}$$

2.2.3.3 Some relations between isotropic scalar invariants

Let $\mathbf{A}$ and $\mathbf{B}$ be two arbitrary second order tensors. Here are some interesting relations involving the isotropic scalar invariants I_1, $I_2\,I_3$ of a second order tensor, the isotropic scalar invariants of its deviatoric part, its determinant and the trace of its cubic power,

$$\begin{aligned}
&\mathbf{A} = \mathrm{tr}\,\mathbf{A}\,\frac{\mathbf{I}}{3} + \mathrm{dev}\,\mathbf{A}, \quad \mathbf{B} = \mathrm{tr}\,\mathbf{B}\,\frac{\mathbf{I}}{3} + \mathrm{dev}\,\mathbf{B}, \\
&\mathbf{A} : \mathbf{B} = \frac{1}{3}\mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{B} + \mathrm{dev}\,\mathbf{A} : \mathrm{dev}\,\mathbf{B}, \\
&I_2(\mathrm{dev}\,\mathbf{A}) = I_2(\mathbf{A}) - \frac{1}{3}\,I_1(\mathbf{A})^2 = -\frac{1}{2}\,\mathrm{tr}\,(\mathrm{dev}\,\mathbf{A})^2\,, \\
&J_3(\mathbf{A}) \equiv \mathrm{tr}\,\mathbf{A}^3\,, \\
&J_3(\mathrm{dev}\,\mathbf{A}) = \mathrm{tr}\;(\mathrm{dev}\,\mathbf{A})^3 = \mathrm{tr}\,\mathbf{A}^3 - \mathrm{tr}\,\mathbf{A}^2\,\mathrm{tr}\,\mathbf{A} + \frac{2}{9}\,(\mathrm{tr}\,\mathbf{A})^3, \\
&I_3(\mathbf{A}) \equiv \det\,\mathbf{A} = \frac{1}{3}\,\mathrm{tr}\;\mathbf{A}^3 - \frac{1}{2}\,\mathrm{tr}\;\mathbf{A}\,\mathrm{tr}\;\mathbf{A}^2 + \frac{1}{6}\,(\mathrm{tr}\;\mathbf{A})^3, \\
&I_3(\mathrm{dev}\,\mathbf{A}) = \det\,(\mathrm{dev}\,\mathbf{A}) = \frac{1}{3}\,\mathrm{tr}\;(\mathrm{dev}\,\mathbf{A})^3 = \frac{1}{3}\,\mathrm{tr}\,\mathbf{A}^3 - \frac{1}{3}\,\mathrm{tr}\,\mathbf{A}^2\,\mathrm{tr}\,\mathbf{A} + \frac{2}{27}\,(\mathrm{tr}\,\mathbf{A})^3\,.
\end{aligned} \tag{2.2.33}$$

Also, for $\mathbf{A}$ dimensionless, setting $\lambda = -1$ in the characteristic polynomial,

$$\det(\mathbf{I}+\mathbf{A}) = 1 + I_1(\mathbf{A}) + I_2(\mathbf{A}) + I_3(\mathbf{A}) \tag{2.2.34}$$

and more generally for any scalar a and second order tensor $\mathbf{A}$,

$$\begin{aligned} I_1(a\,\mathbf{I}+\mathbf{A}) &= 3\,a + I_1(\mathbf{A}), \\ I_2(a\,\mathbf{I}+\mathbf{A}) &= 3\,a^2 + 2\,a\,I_1(\mathbf{A}) + I_2(\mathbf{A}) \\ I_3(a\,\mathbf{I}+\mathbf{A}) &= a^3 + a^2\,I_1(\mathbf{A}) + a\,I_2(\mathbf{A}) + I_3(\mathbf{A})\,. \end{aligned} \tag{2.2.35}$$

2.2.4 Spectral analysis of a symmetrized dyadic product of two vectors

The symmetrized dyadic second order tensor $\boldsymbol{\epsilon}^{\otimes}$

$$\boldsymbol{\epsilon}^{\otimes} = \frac{1}{2}\,(\mathbf{n}\otimes\mathbf{g} + \mathbf{g}\otimes\mathbf{n})\,, \qquad \mathbf{n}\cdot\mathbf{n} = \mathbf{g}\cdot\mathbf{g} = 1 \tag{2.2.36}$$

has peculiar spectral properties [Loret and Rizzi 1997]. If $\mathbf{g} \neq \mathbf{n}$, the three eigenvalues ξ_i and orthogonal eigenvectors $\mathbf{v}_i$, $i \in$[1,3], are

$$\begin{aligned} &\xi_1 = \frac{1}{2}\,(\mathbf{g}\cdot\mathbf{n} - 1) < 0\,, && \mathbf{v}_1 = \frac{1}{2\sqrt{-\xi_1}}\,(\mathbf{g}-\mathbf{n})\,; \\ &\xi_3 = \frac{1}{2}\,(\mathbf{g}\cdot\mathbf{n} + 1) > 0\,, && \mathbf{v}_3 = \frac{1}{2\sqrt{\ \xi_3}}\,(\mathbf{g}+\mathbf{n})\,; \\ &\xi_2 = 0\,, && \mathbf{v}_2 = \mathbf{v}_3 \wedge \mathbf{v}_1\,. \end{aligned} \tag{2.2.37}$$

Conversely, for a symmetric second order tensor $\boldsymbol{\epsilon}$ to be of the dyadic form (2.2.36), its eigenvalues ξ_i, $i\in$[1,3], $\xi_1 \leq \xi_2 \leq \xi_3$, must satisfy $\xi_1 \leq 0 = \xi_2 \leq \xi_3$. Moreover,

- if $\xi_1 = \xi_2 = 0$, one necessarily has $\mathbf{g} = \mathbf{n}$, and so $\boldsymbol{\epsilon} = \mathbf{n}\otimes\mathbf{n}$, $\xi_3 = 1$, $\mathbf{v}_3 = \mathbf{n}$, $\mathbf{v}_1 =$ any unit vector $\perp \mathbf{n}$;
- if $\xi_2 = \xi_3 = 0$, $\mathbf{g} = -\mathbf{n}$ and so $\boldsymbol{\epsilon} = -\mathbf{n}\otimes\mathbf{n}$, $\xi_1 = -1$, $\mathbf{v}_1 = \mathbf{n}$, $\mathbf{v}_3 =$ any unit vector $\perp \mathbf{n}$;
- if $\xi_1 < 0 = \xi_2 < \xi_3$, there exist two directions $\mathbf{n}$ and $\mathbf{g}$ such that $\boldsymbol{\epsilon}$ has the dyadic form $\boldsymbol{\epsilon}^{\otimes}$, namely

$$\frac{1}{\sqrt{\xi_3 - \xi_1}}\,\left(\sqrt{\xi_3}\,\mathbf{v}_3 + \sqrt{-\xi_1}\,\mathbf{v}_1\right) \quad \text{and} \quad \frac{1}{\sqrt{\xi_3 - \xi_1}}\,\left(\sqrt{\xi_3}\,\mathbf{v}_3 - \sqrt{-\xi_1}\,\mathbf{v}_1\right) \tag{2.2.38}$$

where the $\mathbf{v}_i$, i=1,3, are the unit eigenvectors of $\boldsymbol{\epsilon}$ associated with its eigenvalues ξ_i.

2.3 A few useful tensorial relations

2.3.1 Cayley-Hamilton theorem

The Cayley-Hamilton theorem states that a second order tensor satisfies its own characteristic polynomial. Indeed, for an arbitrary second order tensor $\mathbf{A}$ in $\mathbb{R}^3$,

$$\mathbf{CH}(\mathbf{A}) = \mathbf{A}^3 - I_1\,\mathbf{A}^2 + I_2\,\mathbf{A} - I_3\,\mathbf{I} = \mathbf{0}\,, \tag{2.3.1}$$

where, in accordance with (2.2.7) and (2.2.11) for $n = 3$, I_1, I_2 and I_3 are the scalar invariants of $\mathbf{A}$ defined by

$$I_1 = \text{tr}\ \mathbf{A}, \quad I_2 = \frac{1}{2}\,((\text{tr}\ \mathbf{A})^2 - \text{tr}\ \mathbf{A}^2), \quad I_3 = \det\ \mathbf{A} = \frac{1}{3}\,\text{tr}\ \mathbf{A}^3 - \frac{1}{2}\,\text{tr}\ \mathbf{A}\,\text{tr}\ \mathbf{A}^2 + \frac{1}{6}\,(\text{tr}\ \mathbf{A})^3\,. \tag{2.3.2}$$

If $\mathbf{A}$ has three distinct eigenvalues, the proof is trivial: just write the characteristic polynomial for the three eigenvalues. For a general proof, see, e.g., Bowen [1989], p. 235.

As an application, let $\mathbf{A}$ be an invertible second order tensor, and $a \geq 0$ a positive scalar. The inverse of $\mathbf{A} + a\,\mathbf{I}$ is sought as a linear combination of $\mathbf{I}$, $\mathbf{A}$ and $\mathbf{A}^2$ and by use of Cayley-Hamilton theorem [Hoger and Carlson 1984]a,

$$\big(a\,\big(a\,(a + I_1) + I_2\big) + I_3\big)\,(\mathbf{A} + a\,\mathbf{I})^{-1} = \mathbf{A}^2 - \,(a + I_1)\,\mathbf{A} + \big(a\,(a + I_1) + I_2\big)\,\mathbf{I}\,. \tag{2.3.3}$$

Alternatively apply the Cayley-Hamilton theorem to $\mathbf{A} + a\,\mathbf{I}$ using (2.2.35).

2.3.2 Application to the polar decomposition $\mathbf{F} = \mathbf{Q} \cdot \mathbf{U}$

Consider the polar decomposition of the deformation gradient $\mathbf{F} = \mathbf{Q} \cdot \mathbf{U}$ detailed in Section 2.5.1. The scalar invariants of the associated right Cauchy-Green tensor $\mathbf{C} = \mathbf{F}^{\mathrm{T}} \cdot \mathbf{F} = \mathbf{U}^2$ express in terms of the scalar invariants of $\mathbf{U}$,

$$I_1(\mathbf{C}) = (I_1(\mathbf{U}))^2 - 2\, I_2(\mathbf{U}), \quad I_2(\mathbf{C}) = (I_2(\mathbf{U}))^2 - 2\, I_1(\mathbf{U})\, I_3(\mathbf{U}), \quad I_3(\mathbf{C}) = (I_3(\mathbf{U}))^2 \,. \tag{2.3.4}$$

To prove these relations, just express the invariants in terms of the eigenvalues $\lambda_i(\mathbf{U})$ and $\lambda_i(\mathbf{C}) = (\lambda_i(\mathbf{U}))^2$, $i \in [1, 3]$, as indicated by (2.2.13).

The converse relations which provide the scalar invariants of $\mathbf{U}$ in terms of the scalar invariants of $\mathbf{C}$ may be obtained through the following process. First obtain the eigenvalues $\lambda_i(\mathbf{C})$ of $\mathbf{C}$ using the procedure outlined in Section 2.2.3.2. Since these eigenvalues are positive, take their (positive) square-roots $\sqrt{\lambda_i(\mathbf{C})}$ to obtain the eigenvalues and invariants of $\mathbf{U}$. A different procedure suggested in Hoger and Carlson [1984]a is critized by Sawyers [1986].

As another application of the Cayley-Hamilton theorem, the pure deformation $\mathbf{U}$ and its inverse $\mathbf{U}^{-1}$ may be brought in the formats,

$$\mathbf{U} = I_1(\mathbf{U}) \left(\mathbf{C} + I_2(\mathbf{U})\, \mathbf{I}\right)^{-1} \cdot \left(\mathbf{C} + \frac{I_3(\mathbf{U})}{I_1(\mathbf{U})}\, \mathbf{I}\right), \quad \mathbf{U}^{-1} = \frac{1}{I_1(\mathbf{U})} \left(\mathbf{C} + \frac{I_3(\mathbf{U})}{I_1(\mathbf{U})}\, \mathbf{I}\right)^{-1} \cdot \left(\mathbf{C} + I_2(\mathbf{U})\, \mathbf{I}\right). \tag{2.3.5}$$

With help of (2.3.3), (2.3.4) and (2.3.5) and another use of Cayley-Hamilton theorem, $\mathbf{U}$ and $\mathbf{U}^{-1}$ can be expressed as linear combinations of $\mathbf{I}$, $\mathbf{C}$ and $\mathbf{C}^2$, with coefficients involving the invariants of $\mathbf{U}$ only,

$$\Big(I_1(\mathbf{U})\, I_2(\mathbf{U}) - I_3(\mathbf{U})\Big)\, \mathbf{U} = -\mathbf{C}^2 + \left(I_1^2(\mathbf{U}) - I_2(\mathbf{U})\right)\, \mathbf{C} + I_1(\mathbf{U})\, I_3(\mathbf{U})\, \mathbf{I}\,, \tag{2.3.6}$$

and

$$\begin{aligned} I_3(\mathbf{U}) \Big(I_1(\mathbf{U})\, I_2(\mathbf{U}) - I_3(\mathbf{U})\Big)\, \mathbf{U}^{-1} &= I_1(\mathbf{U})\, \mathbf{C}^2 - \left(I_1(\mathbf{U})\, (I_1^2(\mathbf{U}) - 2\, I_2(\mathbf{U})) + I_3(\mathbf{U})\right)\, \mathbf{C} \\ &+ \left((I_1(\mathbf{U})\, I_2(\mathbf{U}) - I_3(\mathbf{U}))\, I_2(\mathbf{U}) - I_1^2(\mathbf{U})\, I_3(\mathbf{U})\right)\, \mathbf{I}\,. \end{aligned} \tag{2.3.7}$$

Moreover, the invariants of $\mathbf{U}$ may be expressed in terms of the invariants of $\mathbf{C}$ via algebraic manipulations, as indicated just above. The results (2.3.6) and (2.3.7) are meaningful because $I_1(\mathbf{U})\, I_2(\mathbf{U}) - I_3(\mathbf{U})$ does not vanish, as shown by (2.2.14).

2.3.3 Generalized Cayley-Hamilton relation

Rivlin [1955] has generalized the Cayley-Hamilton theorem to three arbitrary second order tensors $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ in $\mathbb{R}^3$,

$$\begin{aligned} &\mathbf{GCH}(\mathbf{A}, \mathbf{B}, \mathbf{C}) = \\ &\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{C} + \mathbf{A}\cdot\mathbf{C}\cdot\mathbf{B} + \mathbf{B}\cdot\mathbf{A}\cdot\mathbf{C} + \mathbf{B}\cdot\mathbf{C}\cdot\mathbf{A} + \mathbf{C}\cdot\mathbf{A}\cdot\mathbf{B} + \mathbf{C}\cdot\mathbf{B}\cdot\mathbf{A} \\ &-\mathrm{tr}\,\mathbf{A}\,(\mathbf{B}\cdot\mathbf{C} + \mathbf{C}\cdot\mathbf{B}) - \mathrm{tr}\,\mathbf{B}\,(\mathbf{C}\cdot\mathbf{A} + \mathbf{A}\cdot\mathbf{C}) - \mathrm{tr}\,\mathbf{C}\,(\mathbf{A}\cdot\mathbf{B} + \mathbf{B}\cdot\mathbf{A}) \\ &+(\mathrm{tr}\,\mathbf{B}\,\mathrm{tr}\,\mathbf{C} - \mathrm{tr}\,\mathbf{B}\cdot\mathbf{C})\,\mathbf{A} + (\mathrm{tr}\,\mathbf{C}\,\mathrm{tr}\,\mathbf{A} - \mathrm{tr}\,\mathbf{C}\cdot\mathbf{A})\,\mathbf{B} + (\mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{B} - \mathrm{tr}\,\mathbf{A}\cdot\mathbf{B})\,\mathbf{C} \\ &-(\mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{B}\,\mathrm{tr}\,\mathbf{C} - \mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{B}\cdot\mathbf{C} - \mathrm{tr}\,\mathbf{B}\,\mathrm{tr}\,\mathbf{A}\cdot\mathbf{C} - \mathrm{tr}\,\mathbf{C}\,\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B} + \mathrm{tr}\,\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{C} + \mathrm{tr}\,\mathbf{C}\cdot\mathbf{B}\cdot\mathbf{A})\,\mathbf{I} = \mathbf{0}\,. \end{aligned} \tag{2.3.8}$$

A sketch of the proof is suggested in Exercise 2.5.

With $\mathbf{C} = \mathbf{A}$, the generalized Cayley-Hamilton theorem specializes to

$$\begin{aligned} \mathbf{SCH}(\mathbf{A}, \mathbf{B}) \;=\; & \mathbf{A}^2\cdot\mathbf{B} + \mathbf{B}\cdot\mathbf{A}^2 + \mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} \\ & - \mathrm{tr}\,\mathbf{A}\,(\mathbf{A}\cdot\mathbf{B} + \mathbf{B}\cdot\mathbf{A}) - \mathrm{tr}\,\mathbf{B}\,\mathbf{A}^2 \\ & - (\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B} - \mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{B})\,\mathbf{A} + \tfrac{1}{2}\left((\mathrm{tr}\,\mathbf{A})^2 - \mathrm{tr}\,\mathbf{A}^2\right)\mathbf{B} \\ & - \Big(\mathrm{tr}\,\mathbf{A}^2\cdot\mathbf{B} - \mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B} + \tfrac{1}{2}\,\mathrm{tr}\,\mathbf{B}\left((\mathrm{tr}\,\mathbf{A})^2 - \mathrm{tr}\,\mathbf{A}^2\right)\Big)\,\mathbf{I} = \mathbf{0}\,. \end{aligned} \tag{2.3.9}$$

Two further algebraic manipulations provide two other useful linear dependence relations [Rivlin 1955]

$$\begin{aligned} \mathbf{A}^2\cdot\mathbf{B}\cdot\mathbf{A} + \mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A}^2 - \mathrm{tr}\,\mathbf{A}\;\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} \;=\; & (\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B})\;\mathbf{A}^2 + \Big(\mathrm{tr}\,\mathbf{A}^2\cdot\mathbf{B} - \mathrm{tr}\,\mathbf{A}\,\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B}\Big)\;\mathbf{A} \\ & - \det\mathbf{A}\;\mathbf{B} + \det\mathbf{A}\,\mathrm{tr}\,\mathbf{B}\;\mathbf{I}\,; \\ \mathbf{A}^2\cdot\mathbf{B}\cdot\mathbf{A}^2 - \tfrac{1}{2}\left((\mathrm{tr}\,\mathbf{A})^2 - \mathrm{tr}\,\mathbf{A}^2\right)\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} \;=\; & -\det\mathbf{A}\;(\mathbf{A}\cdot\mathbf{B} + \mathbf{B}\cdot\mathbf{A}) + (\mathrm{tr}\,\mathbf{A}^2\cdot\mathbf{B})\;\mathbf{A}^2 \\ & + \Big((\det\mathbf{A}\,\mathrm{tr}\,\mathbf{B} - \tfrac{1}{2}\left((\mathrm{tr}\,\mathbf{A})^2 - \mathrm{tr}\,\mathbf{A}^2\right)\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B}\Big)\;\mathbf{A} \\ & + \det\mathbf{A}\,(\mathrm{tr}\,\mathbf{A}\cdot\mathbf{B})\;\mathbf{I}\,. \end{aligned} \tag{2.3.10}$$

In view of future use, we record the special case where $\mathbf{A}$ is symmetric and $\mathbf{B}$ skew-symmetric,

$$\begin{aligned}
\mathbf{A}^2\cdot\mathbf{B}+\mathbf{B}\cdot\mathbf{A}^2+\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} &= \operatorname{tr}\mathbf{A}\,(\mathbf{A}\cdot\mathbf{B}+\mathbf{B}\cdot\mathbf{A})-\tfrac{1}{2}\left((\operatorname{tr}\mathbf{A})^2-\operatorname{tr}\mathbf{A}^2\right)\mathbf{B};\\
\mathbf{A}^2\cdot\mathbf{B}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A}^2-\operatorname{tr}\mathbf{A}\;\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} &= -\det\mathbf{A}\;\mathbf{B}\,;\\
\mathbf{A}^2\cdot\mathbf{B}\cdot\mathbf{A}^2-\tfrac{1}{2}\left((\operatorname{tr}\mathbf{A})^2-\operatorname{tr}\mathbf{A}^2\right)\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} &= -\det\mathbf{A}\;(\mathbf{A}\cdot\mathbf{B}+\mathbf{B}\cdot\mathbf{A})\,.
\end{aligned}\tag{2.3.11}$$

Rivlin [1955] also provides a number of additional interesting relations for matrices, or tensors, in $\mathbb{R}^2$.

2.3.4 The tensor equation $\mathbf{X}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{X}=2\,\mathbf{S}$

Here are other instances where the use of the Cayley-Hamilton theorem combines with the theorems of representation of isotropic second order tensors.

Differentiating the polar decomposition yields the velocity gradient $\mathbf{L}=d\mathbf{R}/dt\cdot\mathbf{R}^{\mathrm{T}}+\mathbf{R}\cdot d\mathbf{U}/dt\cdot\mathbf{U}^{-1}\cdot\mathbf{R}^{\mathrm{T}}$. Taking the symmetric part provides an equation for the rate of the pure deformation

$$\frac{d\mathbf{U}}{dt}\cdot\mathbf{U}^{-1}+\mathbf{U}^{-1}\cdot\frac{d\mathbf{U}}{dt}=2\,\mathbf{D}_*=2\,\mathbf{R}^{\mathrm{T}}\cdot\mathbf{D}\cdot\mathbf{R}\,.\tag{2.3.12}$$

An equation for the rotation,

$$\left(\frac{d\mathbf{R}}{dt}\cdot\mathbf{R}^{\mathrm{T}}\right)\cdot\mathbf{V}+\mathbf{V}\cdot\left(\frac{d\mathbf{R}}{dt}\cdot\mathbf{R}^{\mathrm{T}}\right)\cdot\mathbf{V}=\mathbf{L}\cdot\mathbf{V}-\mathbf{V}\cdot\mathbf{L}^{\mathrm{T}}\,,\tag{2.3.13}$$

derives by forming the rhs of this expression and use of the polar decomposition in the form $\mathbf{F}=\mathbf{V}\cdot\mathbf{R}$.

The solution of these equations has been addressed in a number of papers, e.g., Sidoroff [1978], Guo [1984], Hoger and Carlson [1984]b. The presentation below follows their main idea, although it considers two sub-problems so as to minimize the algebras.

For $\mathbf{A}$ a positive definite second order tensor, and $\mathbf{S}$ and $\mathbf{T}$ two arbitrary second order (rate) tensors, we shall consider the two equations for the unknown second order tensors $\mathbf{X}$ and $\mathbf{Y}$,

$$\mathbf{X}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{X}=2\,\mathbf{S},\quad \mathbf{Y}\cdot\mathbf{A}^{-1}+\mathbf{A}^{-1}\cdot\mathbf{Y}=2\,\mathbf{T}\,.\tag{2.3.14}$$

The idea is to view the solution $\mathbf{Y}$ (a rate) as an isotropic function of $\mathbf{A}$ and $\mathbf{T}$, linear in the rate $\mathbf{T}$. Section 2.11.3.5 provides generators of two symmetric second order tensors. The symmetry is not assumed here, but we proceed heuristically and use this basis,

$$\mathbf{I},\ \mathbf{A},\ \mathbf{A}^2,\ \mathbf{T},\ \mathbf{T}^2,\ \mathbf{A}\cdot\mathbf{T}+\mathbf{T}\cdot\mathbf{A},\ \mathbf{A}\cdot\mathbf{T}^2+\mathbf{T}^2\cdot\mathbf{A},\ \mathbf{A}^2\cdot\mathbf{T}+\mathbf{T}\cdot\mathbf{A}^2\,,\tag{2.3.15}$$

from which we first eliminate the two terms which involve $\mathbf{T}^2$ and, second, with an eye toward (2.3.10) which holds for arbitrary tensors, we replace the three terms $\mathbf{I}$, $\mathbf{A}$, $\mathbf{A}^2$ by terms linear in $\mathbf{T}$ and build the solution on the set

$$\mathbf{A}^2\cdot\mathbf{T}\cdot\mathbf{A}^2,\ \mathbf{A}^2\cdot\mathbf{T}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{T}\cdot\mathbf{A}^2,\ \mathbf{A}^2\cdot\mathbf{T}+\mathbf{T}\cdot\mathbf{A}^2,\ \mathbf{A}\cdot\mathbf{T}\cdot\mathbf{A},\ \mathbf{A}\cdot\mathbf{T}+\mathbf{T}\cdot\mathbf{A},\ \mathbf{T}\,.\tag{2.3.16}$$

Backsubstituting the linear combination in Eqn $(2.3.14)_2$ and using the Cayley-Hamilton theorem provides readily the coefficients, yielding

$$\begin{aligned}
&(I_1\,I_2-I_3)\,\mathbf{Y}=\\
&\mathbf{A}^2\cdot\mathbf{T}\cdot\mathbf{A}^2-I_1\,(\mathbf{A}^2\cdot\mathbf{T}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{T}\cdot\mathbf{A}^2)+(I_1^2+I_2)\,\mathbf{A}\cdot\mathbf{T}\cdot\mathbf{A}-I_3\,(\mathbf{T}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{T})+I_1\,I_3\,\mathbf{T}\,,
\end{aligned}\tag{2.3.17}$$

with I_1, I_2 and I_3 isotropic scalar invariants of $\mathbf{A}$. The solution $\mathbf{X}$ to Eqn $(2.3.14)_1$ deduces by setting $\mathbf{T}=\mathbf{A}^{-1}\cdot\mathbf{S}\cdot\mathbf{A}^{-1}$ and further use of the Cayley-Hamilton theorem,

$$\begin{aligned}
&(I_1\,I_2-I_3)\,I_3\,\mathbf{X}=\\
&I_1\,\mathbf{A}^2\cdot\mathbf{S}\cdot\mathbf{A}^2-I_1^2\,(\mathbf{A}^2\cdot\mathbf{S}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{S}\cdot\mathbf{A}^2)+(I_1\,I_2-I_3)\,(\mathbf{A}^2\cdot\mathbf{S}+\mathbf{S}\cdot\mathbf{A}^2)+(I_1^3+I_3)\,\mathbf{A}\cdot\mathbf{S}\cdot\mathbf{A}\\
&-I_1^2\,I_2\,(\mathbf{S}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{S})+\left((I_1^2-I_2)\,I_3+I_1\,I_2^2\right)\mathbf{S}\,.
\end{aligned}\tag{2.3.18}$$

Alternative, but equivalent, expressions may be obtained by use of the relations (2.3.10), e.g., Hoger and Carlson [1984]b. In the special case where $\mathbf{A}$ is symmetric and $\mathbf{S}$ skew-symmetric, we recover via (2.3.11) the solution of Guo [1984],

$$(I_1\,I_2-I_3)\,\mathbf{X}=-2\,(\mathbf{A}^2\cdot\mathbf{S}+\mathbf{S}\cdot\mathbf{A}^2)+2\,(I_1^2-I_2)\,\mathbf{S}\,.\tag{2.3.19}$$

Incidentally, this result indicates that the construction holds for both symmetric and skew-symmetric tensors, and therefore, by superposition, for arbitrary tensors $\mathbf{S}$ and $\mathbf{T}$.

So far, so good. But is the solution unique? Guo [1984] has proved that it is indeed unique if $\mathbf{A}$ is symmetric positive definite. Indeed then, he showed that the equation $\mathbf{X}\cdot\mathbf{A}+\mathbf{A}\cdot\mathbf{X}=\mathbf{0}$ has only the trivial solution $\mathbf{X}=\mathbf{0}$, by writing this equation in component form on the eigenaxes of $\mathbf{A}$. This result shows that the denominator $I_1\,I_2-I_3$ does not vanish, but this we knew already from (2.2.14).

2.3.5 Rank one and rank two modifications of the identity

Let $\mathbf{a}$ and $\mathbf{b}$ be two arbitrary vectors. If

$$\Delta = \det\big(\mathbf{I} + \mathbf{a}\otimes\mathbf{b}\big) = 1 + \mathbf{a}\cdot\mathbf{b} \neq 0\,, \tag{2.3.20}$$

the inverse of this rank one modification of the identity keeps exactly its structure, namely

$$\text{Sherman}-\text{Morrison formula:}\quad \big(\mathbf{I} + \mathbf{a}\otimes\mathbf{b}\big)^{-1} = \mathbf{I} - \frac{\mathbf{a}\otimes\mathbf{b}}{1+\mathbf{a}\cdot\mathbf{b}}\,. \tag{2.3.21}$$

Symmetric rank one modifications of the identity enjoy interesting properties. Let $\mathbf{n}$ be a unit vector, and x an arbitrary real number. The symmetric matrices,

$$\mathbf{I}(x) = \mathbf{I} + (x-1)\,\mathbf{n}\otimes\mathbf{n}\,, \tag{2.3.22}$$

are form-invariant under multiplication, e.g., for x and y arbitrary real numbers,

$$\mathbf{I}(x)\cdot\mathbf{I}(y) = \mathbf{I}(y)\cdot\mathbf{I}(x) = \mathbf{I}(x\,y) = \mathbf{I} + (x\,y-1)\,\mathbf{n}\otimes\mathbf{n}\,, \tag{2.3.23}$$

and, for $x>0$, when raised to an arbitrary real exponent a,

$$\det\mathbf{I}(x) = x\,;\quad \mathbf{I}^a(x) = \mathbf{I}(x^a) = \mathbf{I} + (x^a-1)\,\mathbf{n}\otimes\mathbf{n}\,. \tag{2.3.24}$$

They enjoy the following spectral properties:

$$\mathbf{I}(x)\cdot\mathbf{n} = x\,\mathbf{n},\quad \mathbf{I}(x)\cdot\mathbf{n}^\perp = \mathbf{n}^\perp,\quad \text{with}\quad \mathbf{n}^\perp\cdot\mathbf{n} = 0\,. \tag{2.3.25}$$

A useful extension of the Sherman-Morrison formula is obtained by replacing the identity $\mathbf{I}$ by an invertible second order tensor $\mathbf{A}$. Namely if

$$\det\big(\mathbf{A} + \mathbf{a}\otimes\mathbf{b}\big) = \det\mathbf{A} + \det\mathbf{A}\,(\mathbf{A}^{-1}\cdot\mathbf{a})\cdot\mathbf{b} \neq 0\,, \tag{2.3.26}$$

then

$$\big(\mathbf{A} + \mathbf{a}\otimes\mathbf{b}\big)^{-1} = \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\cdot\mathbf{a}\otimes\mathbf{b}\cdot\mathbf{A}^{-1}}{1+(\mathbf{A}^{-1}\cdot\mathbf{a})\cdot\mathbf{b}}\,. \tag{2.3.27}$$

Another extension to rank two modifications of the identity can be recorded. Let $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ and $\mathbf{d}$ be four arbitrary vectors. If

$$\Delta = \det\big(\mathbf{I} + \mathbf{a}\otimes\mathbf{b} + \mathbf{c}\otimes\mathbf{d}\big) = (1+\mathbf{a}\cdot\mathbf{b})\,(1+\mathbf{c}\cdot\mathbf{d}) - (\mathbf{a}\cdot\mathbf{d})\,(\mathbf{b}\cdot\mathbf{c}) \neq 0\,, \tag{2.3.28}$$

the inverse of this rank two modification of the identity keeps formally its structure, namely

$$\big(\mathbf{I} + \mathbf{a}\otimes\mathbf{b} + \mathbf{c}\otimes\mathbf{d}\big)^{-1} = \mathbf{I} + \mathbf{a}\otimes\mathbf{b}' + \mathbf{c}\otimes\mathbf{d}'\,, \tag{2.3.29}$$

with

$$\Delta\,\mathbf{b}' = -(1+\mathbf{c}\cdot\mathbf{d})\,\mathbf{b} + (\mathbf{b}\cdot\mathbf{c})\,\mathbf{d},\quad \Delta\,\mathbf{d}' = -(1+\mathbf{a}\cdot\mathbf{b})\,\mathbf{d} + (\mathbf{a}\cdot\mathbf{d})\,\mathbf{b}\,. \tag{2.3.30}$$

The proof of these formulas proceeds by simple inspection, Exercise 2.6.

2.3.6 Square-root of a positive definite symmetric second order tensor

Let $\mathbf{B}$ be a positive definite symmetric second order tensor. If $\mathbf{B} = \sum_{i=1}^{3}\; b_i\,\mathbf{b}_i\otimes\mathbf{b}_i$ is its spectral decomposition, then of course its square root $\mathbf{B}^{\frac{1}{2}}$ is equal to $\sum_{i=1}^{3}\; b_i^{\frac{1}{2}}\,\mathbf{b}_i\otimes\mathbf{b}_i$. However this formula requires the eigenvectors. Morman [1986] has provided an expression of the square root that requires only the eigenvalues.

First, $\mathbf{B}$ satisfies its characteristic polynomial $\mathbf{B}^3 - I_1(\mathbf{B})\,\mathbf{B}^2 + I_2(\mathbf{B})\,\mathbf{B} - I_3(\mathbf{B})\,\mathbf{I} = \mathbf{0}$ where $I_1(\mathbf{B}) = \operatorname{tr}\mathbf{B}$, $I_2(\mathbf{B}) = (\operatorname{tr}^2\mathbf{B} - \operatorname{tr}\mathbf{B}^2)/2$, $I_3(\mathbf{B}) = \det\mathbf{B}$ are the three isotropic scalar invariants of $\mathbf{B}$.

Second, the square root is an isotropic function of $\mathbf{B}$, Section 2.11.3.2, and, third, representation theorems indicate that an isotropic function of the second order tensor $\mathbf{B}$ can be expressed as a linear combination of $\mathbf{I}$, $\mathbf{B}$ and $\mathbf{B}^2$,

namely $\mathbf{B}^{\frac{1}{2}} = \alpha_0\,\mathbf{I} + \alpha_1\,\mathbf{B} + \alpha_2\,\mathbf{B}^2$. The three coefficients α_i, $i \in [0,2]$, are calculated from the set of three equations (some details are provided in Exercise 2.10),

$$b_j^{\frac{1}{2}} = \alpha_0 + \alpha_1\,b_j + \alpha_2\,b_j^2\,, \quad j \in [1,3]\,. \tag{2.3.31}$$

The eigenvalues,

$$b_j = \frac{I_1}{3} + \frac{2}{3}\,(I_1^2 - 3\,I_2)^{\frac{1}{2}}\cos\ell_j, \quad j \in [1,3]\,, \tag{2.3.32}$$

can be expressed in terms of the Lode angles defined in (2.2.31) if the tensor $\mathbf{B}$ is not isotropic. Then, with help of (2.2.33), $I_2(\mathrm{dev}\,\mathbf{B}) = -\frac{1}{2}\,\mathrm{tr}\,(\mathrm{dev}\,\mathbf{B})^2$ is equal to $I_2(\mathbf{B}) - \frac{1}{3}\,I_1(\mathbf{B})^2$. The Lode angles may be calculated via the invariants of the tensor itself instead of the invariants of its deviator, namely

$$\ell_j = \ell - \frac{2\pi}{3}\,(j-1),\ j \in [1,3],\ \text{with}\ \cos 3\,\ell = \frac{2\,I_1^3 - 9\,I_1\,I_2 + 27\,I_3}{2\,(I_1^2 - 3\,I_2)^{3/2}}\,. \tag{2.3.33}$$

Finally,

$$\begin{aligned}
&1.\ b_1 \neq b_2 \neq b_3: \quad \mathbf{B}^{\frac{1}{2}} = \sum_{i=1}^{3} b_i^{\frac{1}{2}}\,\frac{\mathbf{B}^2 - (I_1 - b_i)\,\mathbf{B} + I_3\,b_i^{-1}\mathbf{I}}{2\,b_i^2 - I_1\,b_i + I_3\,b_i^{-1}};\\
&2.\ b_i = b_j \neq b_k: \quad \mathbf{B}^{\frac{1}{2}} = b_i^{\frac{1}{2}}\,\mathbf{I} + (b_k^{\frac{1}{2}} - b_i^{\frac{1}{2}})\,\frac{\mathbf{B}^2 - (I_1 - b_k)\,\mathbf{B} + I_3\,b_k^{-1}\mathbf{I}}{2\,b_k^2 - I_1\,b_k + I_3\,b_k^{-1}};\\
&3.\ b_1 = b_2 = b_3: \quad \mathbf{B}^{\frac{1}{2}} = b_1^{\frac{1}{2}}\,\mathbf{I}\,.
\end{aligned} \tag{2.3.34}$$

2.4 The differential operators of continuum mechanics

Differential operators are needed to express the local forms of the balance equations. They are also used to define the kinematics of the continuum.

2.4.1 Definitions of the differential operators

We start by defining operators over scalars, vectors and tensors so as to be able to list a number of fundamental results that allow switching from volume to surface integrals and conversely. Next, we define these operators over tensors of various orders. We will interpret these first formulas as providing their left version in noncartesian axes and we will also define their right versions.

2.4.1.1 Standard differential operators

Let $\mathbf{x} = x_i\,\mathbf{e}_i$ be the coordinates of a point $\mathbf{x}$ in the cartesian axes $\mathbf{e}_i$, $i \in [1,3]$. In a first step, the basic operators *gradient* $\boldsymbol{\nabla}$, *divergence* denoted by div or $\boldsymbol{\nabla}\cdot$, and *rotational* denoted by curl or $\boldsymbol{\nabla}\wedge$ may be defined componentwise,

$$\boldsymbol{\nabla}\boldsymbol{\Phi} = \mathbf{e}_k\,\frac{\partial\boldsymbol{\Phi}}{\partial x_k}, \quad \mathrm{div}\,\boldsymbol{\Phi} = \boldsymbol{\nabla}\cdot\boldsymbol{\Phi} = \mathbf{e}_k\cdot\frac{\partial\boldsymbol{\Phi}}{\partial x_k}, \quad \mathrm{curl}\,\boldsymbol{\Phi} = \boldsymbol{\nabla}\wedge\boldsymbol{\Phi} = \mathbf{e}_k\wedge\frac{\partial\boldsymbol{\Phi}}{\partial x_k}\,, \tag{2.4.1}$$

for the smooth field $\boldsymbol{\Phi}$, whether vector or tensor. The first relation also defines the gradient of a scalar Φ. A field which is divergence free is said to be *solenoidal*. A field whose rotational vanishes is said to be *irrotational*.

It is useful to record the component forms in cartesian axes of the gradient, divergence and rotational of a vector,

$$(\boldsymbol{\nabla}\boldsymbol{\Phi})_{ij} = \frac{\partial\Phi_j}{\partial x_i}, \quad \boldsymbol{\nabla}\cdot\boldsymbol{\Phi} = \frac{\partial\Phi_j}{\partial x_j}, \quad (\boldsymbol{\nabla}\wedge\boldsymbol{\Phi})_i = e_{ijk}\,\frac{\partial\Phi_k}{\partial x_j}\,. \tag{2.4.2}$$

The divergence and the rotational of a second order tensor $\boldsymbol{\Phi}$ will be defined componentwise as

$$(\mathrm{div}\ \boldsymbol{\Phi})_i = \frac{\partial\Phi_{ji}}{\partial x_j}, \quad (\boldsymbol{\nabla}\wedge\ \boldsymbol{\Phi})_{ij} = e_{ikl}\,\frac{\partial\Phi_{lj}}{\partial x_k}\,. \tag{2.4.3}$$

The relations for Φ scalar,

$$\boldsymbol{\nabla}\wedge(\boldsymbol{\nabla}\Phi) = \mathbf{0}\,, \tag{2.4.4}$$

for $\mathbf{\Phi}$ vector,

$$\operatorname{div}(\boldsymbol{\nabla}\wedge\mathbf{\Phi})=\mathbf{0},$$

$$\boldsymbol{\Delta}\mathbf{\Phi}=\boldsymbol{\nabla}\operatorname{div}\mathbf{\Phi}-\boldsymbol{\nabla}\wedge(\boldsymbol{\nabla}\wedge\mathbf{\Phi}), \tag{2.4.5}$$

$$\mathbf{\Phi}\wedge(\boldsymbol{\nabla}\wedge\mathbf{\Phi})=\boldsymbol{\nabla}(\tfrac{1}{2}\mathbf{\Phi}^2)-\mathbf{\Phi}\cdot\boldsymbol{\nabla}\mathbf{\Phi}\,,$$

for Φ scalar and $\mathbf{\Psi}$ vector,

$$\boldsymbol{\nabla}\wedge(\Phi\,\mathbf{\Psi})=\boldsymbol{\nabla}\Phi\wedge\mathbf{\Psi}+\Phi\,\boldsymbol{\nabla}\wedge\mathbf{\Psi}\,, \tag{2.4.6}$$

and for $\mathbf{\Phi}$ and $\mathbf{\Psi}$ vectors,

$$\operatorname{div}(\mathbf{\Phi}\wedge\mathbf{\Psi})=\mathbf{\Psi}\cdot\boldsymbol{\nabla}\wedge\mathbf{\Phi}-\mathbf{\Phi}\cdot\boldsymbol{\nabla}\wedge\mathbf{\Psi}\,, \tag{2.4.7}$$

follow from (2.1.10) and the definitions of the divergence and rotational operators. Eqn (2.4.5) involves the Laplacian of a vector which is built from the gradients, namely $\Delta\mathbf{\Phi}=\boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}\mathbf{\Phi})$.

• **Green's theorem** or **Gauss's theorem** or **divergence theorem**:

The divergence theorem transforms a surface integral into a volume integral or conversely. Let $\mathbf{n}$ be the unit outward normal to the surface $S=\partial V$ of the volume V which does not need to be simply connected. If the volume V is not simply connected, the surface S includes both the outer and the inner boundaries of V and $\mathbf{n}$ denotes always the outward normal. Therefore, the main condition on the domain V is that one should be able to define an interior and an exterior, excluding nonorientable surfaces like the Klein surface or the Möbius strip. In the formulas below, whatever its tensorial nature, the integrand considered is assumed sufficiently smooth so that there is no *discontinuity surface* of the gradient $\partial\Phi/\partial\mathbf{x}$ crossing the volume. Otherwise, the formulas should be restricted to the volumes where the integrand is smooth: summation over these volumes will display the contributions due to the lack of smoothness, e.g., [Bowen 1989, p. 248].

For a proof of the divergence theorem, refer to a textbook of vector analysis.

For Φ scalar,

$$\int_{\partial V} n_k\,\Phi\;dS=\int_V\frac{\partial\Phi}{\partial x_k}\;dV,\quad i\in[1,3]\,, \tag{2.4.8}$$

for $\mathbf{\Phi}$ vector,

$$\int_{\partial V}\mathbf{n}\cdot\mathbf{\Phi}\;dS=\int_V\operatorname{div}\mathbf{\Phi}\;dV,\quad \int_{\partial V}n_k\Phi_k\;dS=\int_V\frac{\partial\Phi_k}{\partial x_k}\;dV\,, \tag{2.4.9}$$

and

$$\int_{\partial V}\mathbf{n}\wedge\mathbf{\Phi}\,dS=\int_V\boldsymbol{\nabla}\wedge\mathbf{\Phi}\,dV,\quad \int_{\partial V}e_{ijk}\,n_j\Phi_k\;dS=\int_V e_{ijk}\,\frac{\partial\Phi_k}{\partial x_j}\;dV\,, \tag{2.4.10}$$

for $\mathbf{\Phi}$ tensor,

$$\int_{\partial V}\mathbf{n}\cdot\mathbf{\Phi}\;dS=\int_V\operatorname{div}\mathbf{\Phi}\;dV,\quad \int_{\partial V}n_k\,\Phi_{k\cdots}\;dS=\int_V\frac{\partial\Phi_{k\cdots}}{\partial x_k}\;dV\,. \tag{2.4.11}$$

The formula (2.4.10) deduces from (2.4.9) simply by use of the definition of the vector product (2.1.14) and of the rotational (2.4.2).

Analogous theorems transform an integral over a closed curve $\mathcal{C}=\partial S$ into an integral over the surface S it encloses and conversely, namely for Φ scalar,

$$\oint_{\mathcal{C}=\partial S}\mathbf{n}\,\Phi\;ds=\int_S\frac{\partial\Phi}{\partial\mathbf{x}}\,dS,\quad \oint_{\mathcal{C}=\partial S}n_k\,\Phi\;ds=\int_S\frac{\partial\Phi}{\partial x_k}\,dS\,, \tag{2.4.12}$$

and for $\mathbf{\Phi}$ vector or tensor of arbitrary order,

$$\begin{aligned}\oint_{\mathcal{C}=\partial S}\mathbf{n}\cdot\mathbf{\Phi}\,ds&=\int_S\operatorname{div}\mathbf{\Phi}\,dS,\\ \oint_{\mathcal{C}=\partial S}\mathbf{t}\cdot\mathbf{\Phi}\,ds&=\int_S\mathbf{e}\cdot(\boldsymbol{\nabla}\wedge\mathbf{\Phi})\;dS\,.\end{aligned} \tag{2.4.13}$$

The last formula is known as **Stokes theorem** in $\mathbb{R}^3$ with $\mathbf{e}\,dS$ the oriented elementary surface. For a vector of the plane $(\mathbf{e}_1,\,\mathbf{e}_2)$ endowed with cartesian coordinates $(x_1,\,x_2)$, the theorem reads (see [Mei 1995, p. 448], for a simple proof),

$$\oint_{\mathcal{C}=\partial S}\Phi_1\,dx_1+\Phi_2\,dx_2=\int_S\Big(\frac{\partial\Phi_2}{\partial x_1}-\frac{\partial\Phi_1}{\partial x_2}\Big)\,dx_1\,dx_2\,. \tag{2.4.14}$$

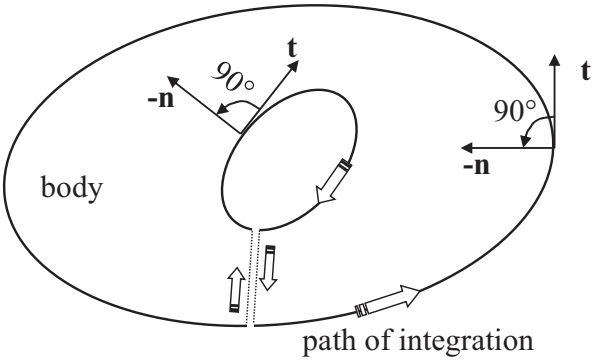

Fig. 2.4.1: Direct sense of integration for a body which is not simply connected. The inner and outer surfaces are connected by a branch cut, made by two arbitrarily close segments, which are run in the appropriate direction.

The curvilinear abscissa along the curve $\mathcal{C}$ is denoted by s. The symbol $\oint$ means integration over a closed curve in the *direct sense*, that is, the normal $-\mathbf{n}$ deduced from the tangent $\mathbf{t}$ by rotation of $+90°$ points to the interior of the surface. This definition serves also to define the sense of integration on inner boundaries if the surface is not simply connected, Fig. 2.4.1. Note that a similar notation might be used for the surface integration in the divergence theorem since the latter assumes the normal $\mathbf{n}$ to point to the exterior of the body. However the special integration symbol is used here only in the plane (x_1, x_2) where the tangent vector $\mathbf{t}\,ds$ and the normal $\mathbf{n}\,ds$ have components (dx_1, dx_2) and $(dx_2, -dx_1)$, respectively. These relations follow from (2.4.2) and (2.4.12).

• **Green's first and second identities**:

For Φ and Ψ twice differentiable scalars in the volume V, bounded by the surface $S = \partial V$ of incremental area $d\mathbf{S} = \mathbf{n}\,dS$,

$$\begin{aligned} \int_V \boldsymbol{\nabla}\Phi \cdot \boldsymbol{\nabla}\Psi \; dV &= \int_{\partial V} \Phi\, \boldsymbol{\nabla}\Psi \cdot d\mathbf{S} - \int_V \Phi\, \Delta\Psi \; dV \\ \int_V \left(\Phi\, \Delta\Psi - \Psi\, \Delta\Phi\right) dV &= \int_{\partial V} \left(\Phi\, \boldsymbol{\nabla}\Psi - \Psi\, \boldsymbol{\nabla}\Phi\right) \cdot d\mathbf{S}\,. \end{aligned} \tag{2.4.15}$$

Green's first identity follows from the divergence theorem. The second identity is obtained by subtracting the first identities associated with Φ and Ψ and Ψ and Φ, respectively. Green's identities are key ingredients for the study of potential flows and constitute the starting point of boundary integral methods.

• **Representation theorems based on differential operators**:

We have seen in (2.4.4) and (2.4.5) that the rotational of a gradient and the divergence of a rotational vanish. The converses of these results are most useful in a number of applications:

Representation of a solenoidal displacement field:

There exists a twice differentiable solenoidal field $\boldsymbol{\psi}$, such that

$$\mathbf{u} = \boldsymbol{\nabla} \wedge \boldsymbol{\psi}, \quad u_i = e_{ijk}\, \frac{\partial \psi_k}{\partial x_j}\,, \tag{2.4.16}$$

if and only if $\operatorname{div} \mathbf{u} = \mathbf{0}$.

Representation of an irrotational displacement field:

In a simply connected domain, there exists a twice differentiable scalar field ϕ such that

$$\mathbf{u} = \boldsymbol{\nabla}\phi, \quad u_i = \frac{\partial \phi}{\partial x_i}\,, \tag{2.4.17}$$

if and only if the sufficiently smooth field $\mathbf{u}$ is irrotational, namely $\boldsymbol{\nabla} \wedge \mathbf{u} = \mathbf{0}$.

Helmholtz representation of a displacement field:

If $\mathbf{u}$ is a displacement field which is continuously differentiable, bounded, and bounded at infinity, there exist a differentiable scalar field ϕ, and a solenoidal field $\boldsymbol{\psi}$ such that

$$\mathbf{u} = \boldsymbol{\nabla}\phi + \boldsymbol{\nabla} \wedge \boldsymbol{\psi}\,, \quad u_i = \frac{\partial \phi}{\partial x_i} + e_{ijk}\, \frac{\partial \psi_k}{\partial x_j}\,. \tag{2.4.18}$$

Note that, due to (2.4.4) and (2.4.5), $\operatorname{div}\mathbf{u} = \Delta\phi$ and $\boldsymbol{\nabla}\wedge\mathbf{u} = -\boldsymbol{\Delta}\boldsymbol{\psi}$.

The condition that $\boldsymbol{\psi}$ should be divergence free is intended to reduce to three the number of independent scalar fields of the representation. The completeness of this representation is discussed in textbooks on dynamic elasticity where it is a most useful tool, e.g., Fung [1965], p. 184, or Achenbach [1975].

• **Conservative field**:

If $\int_C \boldsymbol{\Phi}(\mathbf{x})\cdot d\mathbf{x}$ vanishes for any closed curve C in a domain, then there exists a differentiable field $\Phi = \Phi(\mathbf{x})$, that serves as a potential to $\boldsymbol{\Phi} = \boldsymbol{\Phi}(\mathbf{x})$ in this domain,

$$\boldsymbol{\Phi} = -\frac{\partial\Phi}{\partial\mathbf{x}}\,. \tag{2.4.19}$$

The theorem holds also when the integrand depends on variables that are not the space coordinates.

2.4.1.2 Scaling factors, left and right differential operators

The operators defined in the preceding section can be seen as *left* operators, in the sense that they operate on entities on their *right*. Their *right* counterparts which operate on entities on their *left* are provided here, in the context of curvilinear coordinates with which are associated the set of unit orthogonal vectors $\hat{\mathbf{e}}_i$ and the scaling factors h_i, $i \in [1,3]$. Arrows are superimposed over the operators to indicate if they operate to the right or to the left. If the coordinates are expressed in the format

$$\mathbf{x} = x_k\,\hat{\mathbf{e}}_k\,, \tag{2.4.20}$$

the scaling factors are defined by the relations

$$d\mathbf{x} = h_k\,\hat{\mathbf{e}}_k\,dx_k\,. \tag{2.4.21}$$

Starting from the left operators (2.4.1), their right counterparts follow through a *de visu* representation, for Φ scalar,

$$\vec{\boldsymbol{\nabla}}\Phi = \frac{\hat{\mathbf{e}}_k}{h_k}\frac{\vec{\partial}}{\partial x_k}\Phi, \quad \Phi\frac{\overleftarrow{\partial}}{\partial x_k}\frac{\hat{\mathbf{e}}_k}{h_k} = \Phi\overleftarrow{\boldsymbol{\nabla}}\,, \tag{2.4.22}$$

and for $\boldsymbol{\Phi}$ vector or tensor,

$$\begin{aligned}
\vec{\boldsymbol{\nabla}}\boldsymbol{\Phi} &= \frac{\hat{\mathbf{e}}_k}{h_k}\frac{\vec{\partial}}{\partial x_k}\boldsymbol{\Phi}, \quad \boldsymbol{\Phi}\frac{\overleftarrow{\partial}}{\partial x_k}\frac{\hat{\mathbf{e}}_k}{h_k} = \boldsymbol{\Phi}\overleftarrow{\boldsymbol{\nabla}}\\
\vec{\boldsymbol{\nabla}}\cdot\boldsymbol{\Phi} &= \frac{\hat{\mathbf{e}}_k}{h_k}\cdot\frac{\vec{\partial}}{\partial x_k}\boldsymbol{\Phi}, \quad \boldsymbol{\Phi}\frac{\overleftarrow{\partial}}{\partial x_k}\cdot\frac{\hat{\mathbf{e}}_k}{h_k} = \boldsymbol{\Phi}\cdot\overleftarrow{\boldsymbol{\nabla}}\\
\vec{\boldsymbol{\nabla}}\wedge\boldsymbol{\Phi} &= \frac{\hat{\mathbf{e}}_k}{h_k}\wedge\frac{\vec{\partial}}{\partial x_k}\boldsymbol{\Phi}, \quad \boldsymbol{\Phi}\frac{\overleftarrow{\partial}}{\partial x_k}\wedge\frac{\hat{\mathbf{e}}_k}{h_k} = \boldsymbol{\Phi}\wedge\overleftarrow{\boldsymbol{\nabla}}\ .
\end{aligned} \tag{2.4.23}$$

The definition of the gradient operators stems from the differentials,

$$d\Phi = d\mathbf{x}\cdot(\vec{\boldsymbol{\nabla}}\Phi) = (\Phi\overleftarrow{\boldsymbol{\nabla}})\cdot d\mathbf{x}, \quad d\boldsymbol{\Phi} = d\mathbf{x}\cdot(\vec{\boldsymbol{\nabla}}\boldsymbol{\Phi}) = (\boldsymbol{\Phi}\overleftarrow{\boldsymbol{\nabla}})\cdot d\mathbf{x}\,. \tag{2.4.24}$$

Therefore, the left and right gradients of a scalar are one and the same vector,

$$\vec{\boldsymbol{\nabla}}\Phi = \frac{\hat{\mathbf{e}}_k}{h_k}\frac{\vec{\partial}}{\partial x_k}\Phi = \Phi\overleftarrow{\boldsymbol{\nabla}} = \Phi\frac{\overleftarrow{\partial}}{\partial x_k}\frac{\hat{\mathbf{e}}_k}{h_k}\,. \tag{2.4.25}$$

The Laplacian of a scalar is built from the gradients,

$$\Delta\Phi = \vec{\boldsymbol{\nabla}}\cdot(\vec{\boldsymbol{\nabla}}\Phi) = \vec{\boldsymbol{\nabla}}\cdot(\Phi\overleftarrow{\boldsymbol{\nabla}}) = (\Phi\overleftarrow{\boldsymbol{\nabla}})\cdot\overleftarrow{\boldsymbol{\nabla}} = (\vec{\boldsymbol{\nabla}}\Phi)\cdot\overleftarrow{\boldsymbol{\nabla}}\,, \tag{2.4.26}$$

namely, in cartesian coordinates ($h_k = 1$, $k \in [1,3]$),

$$\Delta\Phi = \frac{\partial^2\Phi}{\partial x_k\partial x_k}\,. \tag{2.4.27}$$

The Laplacian of a vector $\mathbf{\Phi}$ is defined similarly, namely $\Delta\mathbf{\Phi} = \overrightarrow{\boldsymbol{\nabla}}\cdot(\overrightarrow{\boldsymbol{\nabla}}\mathbf{\Phi}) = (\mathbf{\Phi}\overleftarrow{\boldsymbol{\nabla}})\cdot\overleftarrow{\boldsymbol{\nabla}}$.

For a vector, the left and right gradients are the transpose of one another, the left and right divergences are one and the same scalar, and the left and right rotationals are opposite to one another,

$$\mathbf{\Phi}\overleftarrow{\boldsymbol{\nabla}} = \big(\overrightarrow{\boldsymbol{\nabla}}\mathbf{\Phi}\big)^{\mathrm{T}}, \quad \mathbf{\Phi}\cdot\overleftarrow{\boldsymbol{\nabla}} = \overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{\Phi}, \quad \mathbf{\Phi}\wedge\overleftarrow{\boldsymbol{\nabla}} = -\,\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{\Phi}\,, \tag{2.4.28}$$

and, in cartesian coordinates,

$$\begin{aligned} (\overrightarrow{\boldsymbol{\nabla}}\mathbf{\Phi})_{ij} &= \frac{\partial\Phi_j}{\partial x_i}; \quad (\mathbf{\Phi}\overleftarrow{\boldsymbol{\nabla}})_{ij} = \frac{\partial\Phi_i}{\partial x_j}; \\ \mathbf{\Phi}\cdot\overleftarrow{\boldsymbol{\nabla}} &= \frac{\partial\Phi_k}{\partial x_k} = \overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{\Phi}\,; \\ (\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{\Phi})_i &= e_{ijk}\,\frac{\partial\Phi_k}{\partial x_j} = -(\mathbf{\Phi}\wedge\overleftarrow{\boldsymbol{\nabla}})_i\,. \end{aligned} \tag{2.4.29}$$

For a 2nd order tensor, the left and right divergences are the transpose of one another, and the left rotational is equal to the negative of the transpose of the right rotational of the transpose tensor, easier to write than to say,

$$\mathbf{\Phi}\cdot\overleftarrow{\boldsymbol{\nabla}} = (\overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{\Phi})^{\mathrm{T}}, \quad \mathbf{\Phi}\wedge\overleftarrow{\boldsymbol{\nabla}} = -\big(\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{\Phi}^{\mathrm{T}}\big)^{\mathrm{T}}\,, \tag{2.4.30}$$

and, in cartesian coordinates,

$$\begin{aligned} (\overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{\Phi})_i &= \frac{\partial\Phi_{ji}}{\partial x_j}, \quad (\mathbf{\Phi}\cdot\overleftarrow{\boldsymbol{\nabla}})_i = \frac{\partial\Phi_{ij}}{\partial x_j}\,; \\ (\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{\Phi})_{ij} &= e_{ikl}\,\frac{\partial\Phi_{lj}}{\partial x_k}, \quad (\mathbf{\Phi}\wedge\overleftarrow{\boldsymbol{\nabla}})_{ij} = -e_{jkl}\,\frac{\partial\Phi_{il}}{\partial x_k}\,. \end{aligned} \tag{2.4.31}$$

We may now rewrite two versions of the divergence theorem (2.4.11) for 2nd order tensors,

$$\int_{\partial V}\mathbf{n}\cdot\mathbf{\Phi}\;dS = \int_V \overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{\Phi}\;dV, \quad \int_{\partial V} n_j\,\Phi_{ji}\;dS = \int_V \frac{\partial\Phi_{ji}}{\partial x_j}\;dV\,, \tag{2.4.32}$$

and

$$\int_{\partial V}\mathbf{\Phi}\cdot\mathbf{n}\;dS = \int_V \mathbf{\Phi}\cdot\overleftarrow{\boldsymbol{\nabla}}\;dV, \quad \int_{\partial V}\Phi_{ij}\,n_j\;dS = \int_V \frac{\partial\Phi_{ij}}{\partial x_j}\;dV\,. \tag{2.4.33}$$

2.4.2 Application to kinematics

The motion which associates with a point $\underline{\mathbf{x}}$ another unique point $\mathbf{x} = \underline{\mathbf{x}} + \mathbf{u}$ is thus defined by the displacement vector $\mathbf{u}$. The latter can be seen as a function of time t and of the reference point $\underline{\mathbf{x}}$, or of the current point $\mathbf{x}$[2.1]. The gradients corresponding to these two points of view use the following notations:

$$\underline{\overleftarrow{\boldsymbol{\nabla}}} = \frac{\overleftarrow{\partial}}{\partial\underline{\mathbf{x}}}, \quad \underline{\overrightarrow{\boldsymbol{\nabla}}} = \frac{\overrightarrow{\partial}}{\partial\underline{\mathbf{x}}}, \quad \overleftarrow{\boldsymbol{\nabla}} = \frac{\overleftarrow{\partial}}{\partial\mathbf{x}}, \quad \overrightarrow{\boldsymbol{\nabla}} = \frac{\overrightarrow{\partial}}{\partial\mathbf{x}}\,. \tag{2.4.34}$$

Let us recall the component form of the left and right gradients with respect to the current configuration,

$$(\overrightarrow{\boldsymbol{\nabla}}\mathbf{u})_{ij} = \frac{\partial u_j}{\partial x_i}, \quad (\mathbf{u}\overleftarrow{\boldsymbol{\nabla}})_{ij} = \frac{\partial u_i}{\partial x_j}\,. \tag{2.4.35}$$

The deformation gradient $\mathbf{F}$ is defined through the relations,

$$\begin{aligned} d\mathbf{x} &= (\mathbf{x}\underline{\overleftarrow{\boldsymbol{\nabla}}})\cdot d\underline{\mathbf{x}} &&= d\underline{\mathbf{x}}\cdot(\underline{\overrightarrow{\boldsymbol{\nabla}}}\mathbf{x}) \\ &= \mathbf{F}\cdot d\underline{\mathbf{x}} &&= d\underline{\mathbf{x}}\cdot\mathbf{F}^{\mathrm{T}}\,, \end{aligned} \tag{2.4.36}$$

[2.1] To the exception of this chapter, which of the left or right differential operators is used is usually not indicated explicitly. To avoid ambiguity, the relations are provided in terms of operators and in component form.

and componentwise in terms of the scaling factors defined by (2.4.21) in the reference and current configurations,

$$F_{iJ} = \frac{h_i}{\underline{h}_J}\frac{\partial x_i}{\partial \underline{x}_J}, \quad (i,J) \in [1,3] \text{ (no sum on i, J)}\,. \tag{2.4.37}$$

In cartesian axes,

$$d\mathbf{x} = dx_i\,\mathbf{e}_i = \mathbf{F}\cdot d\underline{\mathbf{x}} = (F_{iJ}\,\mathbf{e}_i \otimes \underline{\mathbf{e}}_J)\cdot(d\underline{x}_K\underline{\mathbf{e}}_K) = F_{iJ}\,\mathbf{e}_i\,d\underline{x}_J\,, \tag{2.4.38}$$

the component form of the deformation gradient simplifies to,

$$F_{iJ} = \frac{\partial x_i}{\partial \underline{x}_J}, \quad (i,J) \in [1,3]\,. \tag{2.4.39}$$

The symmetric and skew-symmetric 2nd order tensors associated with the displacement vector,

$$\begin{aligned}
\boldsymbol{\epsilon}(\mathbf{u}) &= \tfrac{1}{2}\big(\mathbf{u}\overleftarrow{\boldsymbol{\nabla}} + (\mathbf{u}\overleftarrow{\boldsymbol{\nabla}})^{\mathrm{T}}\big) = \tfrac{1}{2}\big(\mathbf{u}\overleftarrow{\boldsymbol{\nabla}} + \overrightarrow{\boldsymbol{\nabla}}\mathbf{u}\big)\,, \quad \epsilon_{ij} = \frac{1}{2}\,(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i});\\
\boldsymbol{\omega}(\mathbf{u}) &= \tfrac{1}{2}\big(\mathbf{u}\overleftarrow{\boldsymbol{\nabla}} - (\mathbf{u}\overleftarrow{\boldsymbol{\nabla}})^{\mathrm{T}}\big) = \tfrac{1}{2}\big(\mathbf{u}\overleftarrow{\boldsymbol{\nabla}} - \overrightarrow{\boldsymbol{\nabla}}\mathbf{u}\big)\,, \quad \omega_{ij} = \frac{1}{2}\,(\frac{\partial u_i}{\partial x_j} - \frac{\partial u_j}{\partial x_i})\,,
\end{aligned} \tag{2.4.40}$$

are termed *infinitesimal strain* and *rotation tensor*, respectively (the matter is elaborated in Section 2.5.6). Equivalently, the displacement gradients decompose uniquely into a symmetric part and a skew-symmetric part,

$$\overrightarrow{\boldsymbol{\nabla}}\mathbf{u} = \boldsymbol{\epsilon} - \boldsymbol{\omega}, \quad \mathbf{u}\overleftarrow{\boldsymbol{\nabla}} = \boldsymbol{\epsilon} + \boldsymbol{\omega}\,. \tag{2.4.41}$$

The left rotational of a vector is defined componentwise in cartesian axes through the permutation symbol,

$$(\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{u})_i = e_{ijk}\,\frac{\partial u_k}{\partial x_j}\,, \quad i \in [1,3]\,. \tag{2.4.42}$$

Via (2.1.11), it is the pseudo-vector associated with the skew-symmetric tensor $-2\,\boldsymbol{\omega}(\mathbf{u})$. If $\vec{\boldsymbol{\omega}}$ is the pseudo-vector associated with the skew-symmetric tensor $-\boldsymbol{\omega}$, then

$$\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{u} = 2\,\vec{\boldsymbol{\omega}}, \quad (\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{u})_i = -e_{ijk}\,\omega_{jk} = 2\,\vec{\omega}_i\,, \quad i \in [1,3]\,. \tag{2.4.43}$$

Consequently

$$\overrightarrow{\boldsymbol{\nabla}}\wedge\boldsymbol{\epsilon}(\mathbf{u}) = \frac{1}{2}\,\big(\,\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{u}\big)\overleftarrow{\boldsymbol{\nabla}} = (\vec{\boldsymbol{\omega}}(\mathbf{u}))\overleftarrow{\boldsymbol{\nabla}}\,. \tag{2.4.44}$$

Note also, with help of $(2.1.10)_2$,

$$\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon}(\mathbf{u}) = \overrightarrow{\boldsymbol{\nabla}}(\overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{u}) - \frac{1}{2}\;\overrightarrow{\boldsymbol{\nabla}}\wedge\overrightarrow{\boldsymbol{\nabla}}\wedge\mathbf{u}\,. \tag{2.4.45}$$

2.4.3 Spherical, cylindrical and polar coordinates

2.4.3.1 Spherical coordinates

The definitions of left and right differential operators stated in Section 2.4.1.2 are used to obtain the entities that characterize the kinematics in curvilinear coordinates.

Let $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ be a reference cartesian triad. The spherical triad of unit orthogonal vectors shown in Fig. 2.4.2,

$$\begin{aligned}
\hat{\mathbf{e}}_r &= \sin\theta\,\mathbf{e}_* + \cos\theta\,\mathbf{e}_3\,,\\
\hat{\mathbf{e}}_\theta &= \cos\theta\,\mathbf{e}_* - \sin\theta\,\mathbf{e}_3\,,\\
\hat{\mathbf{e}}_\phi &= \hat{\mathbf{e}}_r\wedge\hat{\mathbf{e}}_\theta = \mathbf{e}_*^{\perp}\,,
\end{aligned} \tag{2.4.46}$$

is built from the cartesian triad and from the two vectors,

$$\mathbf{e}_* = \cos\phi\,\mathbf{e}_1 + \sin\phi\,\mathbf{e}_2\,, \quad \mathbf{e}_*^{\perp} = -\sin\phi\,\mathbf{e}_1 + \cos\phi\,\mathbf{e}_2\,. \tag{2.4.47}$$

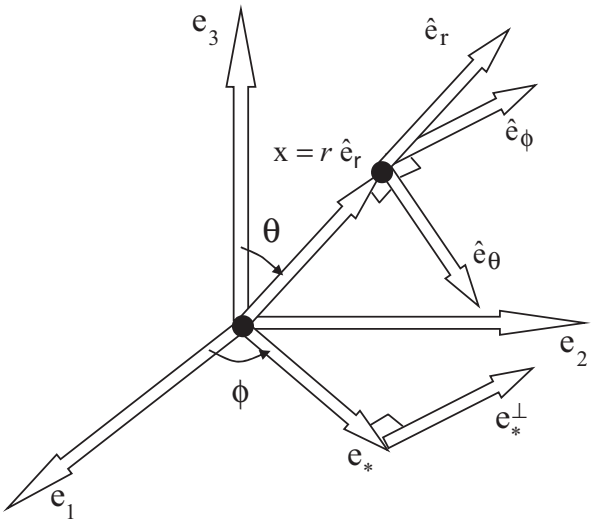

Fig. 2.4.2: Spherical coordinates. Starting from a cartesian triad $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$, the spherical triad $(\hat{\mathbf{e}}_\theta, \hat{\mathbf{e}}_\phi, \hat{\mathbf{e}}_r)$ is deduced by applying first a rotation of angle ϕ about $\mathbf{e}_3$ and next a rotation of angle θ about $\mathbf{e}_2$.

Its differentials read

$$\begin{aligned} d\hat{\mathbf{e}}_r &= d\theta\, \hat{\mathbf{e}}_\theta + \sin\theta\, d\phi\, \hat{\mathbf{e}}_\phi\,, \\ d\hat{\mathbf{e}}_\theta &= -d\theta\, \hat{\mathbf{e}}_r + \cos\theta\, d\phi\, \hat{\mathbf{e}}_\phi\,, \\ d\hat{\mathbf{e}}_\phi &= -d\phi\, (\sin\theta\, \hat{\mathbf{e}}_r + \cos\theta\, \hat{\mathbf{e}}_\theta)\,. \end{aligned} \tag{2.4.48}$$

The rotation matrix $\mathbf{R}$ that brings the cartesian axes $\mathbf{e}$ to the spherical axes $\hat{\mathbf{e}}$ has the form

$$\begin{bmatrix} \hat{\mathbf{e}}_\theta \\ \hat{\mathbf{e}}_\phi \\ \hat{\mathbf{e}}_r \end{bmatrix} = \mathbf{R}(\theta,\phi) \begin{bmatrix} \mathbf{e}_1 \\ \mathbf{e}_2 \\ \mathbf{e}_3 \end{bmatrix}, \quad \mathbf{R}(\theta,\phi) = \begin{bmatrix} \cos\theta\,\cos\phi & \cos\theta\,\sin\phi & -\sin\theta \\ -\sin\phi & \cos\phi & 0 \\ \sin\theta\,\cos\phi & \sin\theta\,\sin\phi & \cos\theta \end{bmatrix}. \tag{2.4.49}$$

Let $\mathbf{R}(0,\phi)$ be the rotation about $\mathbf{e}_3$ and $\mathbf{R}(\theta,0)$ be the rotation about $\mathbf{e}_2$,

$$\mathbf{R}(0,\phi) = \begin{bmatrix} \cos\phi & \sin\phi & 0 \\ -\sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{R}(\theta,0) = \begin{bmatrix} \cos\theta & 0 & -\sin\theta \\ 0 & 1 & 0 \\ \sin\theta & 0 & \cos\theta \end{bmatrix}. \tag{2.4.50}$$

Note that the rotation $\mathbf{R}(\theta,\phi)$ consists in applying first the rotation $\mathbf{R}(0,\phi)$ and next the rotation $\mathbf{R}(\theta,0)$. In fact, since the inverse and transpose of $\mathbf{R}(0,\phi)$ are equal to $\mathbf{R}(0,-\phi)$, and similarly the inverse and transpose of $\mathbf{R}(\theta,0)$ are equal to $\mathbf{R}(-\theta,0)$, one may check the relations,

$$\begin{aligned} \mathbf{R}(\theta,\phi) &= \mathbf{R}(\theta,0)\cdot\mathbf{R}(0,\phi), \\ \mathbf{R}^{-1}(\theta,\phi) &= \mathbf{R}^{\mathrm{T}}(\theta,\phi) = \mathbf{R}^{\mathrm{T}}(0,\phi)\cdot\mathbf{R}^{\mathrm{T}}(\theta,0) = \mathbf{R}(0,-\phi)\cdot\mathbf{R}(-\theta,0) \\ \mathbf{R}(0,\phi)\cdot\mathbf{R}(\theta,0) &= \mathbf{R}^{-1}(-\theta,-\phi)\,. \end{aligned} \tag{2.4.51}$$

As expected, the rotation inverse to $\mathbf{R}(\theta,\phi)$ consists in applying first the rotation $\mathbf{R}(-\theta,0)$ followed by the rotation $\mathbf{R}(0,-\phi)$. The two rotations $\mathbf{R}(\theta,0)$ and $\mathbf{R}(0,\phi)$ do not commute since they involve distinct axes.

The motion associates the point $\mathbf{x}$ with a reference point $\underline{\mathbf{x}}$,

$$\underline{\mathbf{x}} = \underline{r}\,\underline{\hat{\mathbf{e}}}_r \longmapsto \mathbf{x} = r\,\hat{\mathbf{e}}_r\,, \tag{2.4.52}$$

with differentials

$$d\underline{\mathbf{x}} = d\underline{r}\,\hat{\underline{\mathbf{e}}}_r + \underline{r}\,d\underline{\theta}\,\hat{\underline{\mathbf{e}}}_\theta + \underline{r}\,\sin\underline{\theta}\,d\underline{\phi}\,\hat{\underline{\mathbf{e}}}_\phi, \quad d\mathbf{x} = dr\,\hat{\mathbf{e}}_r + r\,d\theta\,\hat{\mathbf{e}}_\theta + r\,\sin\theta\,d\phi\,\hat{\mathbf{e}}_\phi\,. \tag{2.4.53}$$

Comparison of (2.4.53) and (2.4.21) yields the scaling factors in the reference and current configurations,

$$\begin{aligned} &\underline{h}_r = 1, \quad \underline{h}_\theta = \underline{r}, \quad \underline{h}_\phi = \underline{r}\,\sin\underline{\theta}; \\ &h_r = 1, \quad h_\theta = r, \quad h_\phi = r\,\sin\theta\,. \end{aligned} \tag{2.4.54}$$

Formally, the left and right gradients are defined through the relations, e.g., Malvern [1969], p. 652,

$$\overset{\rightarrow}{\boldsymbol{\nabla}} = \frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\overset{\rightarrow}{\partial}}{\partial x_k}, \quad \overset{\leftarrow}{\boldsymbol{\nabla}} = \frac{\overset{\leftarrow}{\partial}}{\partial x_k}\,\frac{\hat{\mathbf{e}}_k}{h_k}\,. \tag{2.4.55}$$

These operators can be used directly to obtain the gradient of a scalar u,

$$\overset{\rightarrow}{\boldsymbol{\nabla}} u = \Big(\frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\overset{\rightarrow}{\partial}}{\partial x_k}\Big)\,u = u\overset{\leftarrow}{\boldsymbol{\nabla}} = u\,\Big(\frac{\overset{\leftarrow}{\partial}}{\partial x_k}\,\frac{\hat{\mathbf{e}}_k}{h_k}\Big)\,, \tag{2.4.56}$$

namely

$$\overset{\rightarrow}{\boldsymbol{\nabla}} u = u\overset{\leftarrow}{\boldsymbol{\nabla}} = \frac{\partial u}{\partial r}\,\hat{\mathbf{e}}_r + \frac{1}{r}\,\frac{\partial u}{\partial \theta}\,\hat{\mathbf{e}}_\theta + \frac{1}{r\,\sin\theta}\,\frac{\partial u}{\partial \phi}\,\hat{\mathbf{e}}_\phi\,, \tag{2.4.57}$$

the gradients of a vector $\mathbf{u}$,

$$\overset{\rightarrow}{\boldsymbol{\nabla}}\mathbf{u} = \Big(\frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\overset{\rightarrow}{\partial}}{\partial x_k}\Big)\,\mathbf{u}, \quad \mathbf{u}\,\overset{\leftarrow}{\boldsymbol{\nabla}} = \mathbf{u}\,\Big(\frac{\overset{\leftarrow}{\partial}}{\partial x_k}\,\frac{\hat{\mathbf{e}}_k}{h_k}\Big)\,, \tag{2.4.58}$$

its rotationals,

$$\overset{\rightarrow}{\boldsymbol{\nabla}}\wedge\mathbf{u} = \Big(\frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\overset{\rightarrow}{\partial}}{\partial x_k}\Big)\wedge\mathbf{u} = -\mathbf{u}\wedge\overset{\leftarrow}{\boldsymbol{\nabla}}\,, \tag{2.4.59}$$

and its divergence $\operatorname{div}\mathbf{u} = \operatorname{tr}(\overset{\rightarrow}{\boldsymbol{\nabla}}\mathbf{u}) = \operatorname{tr}(\mathbf{u}\overset{\leftarrow}{\boldsymbol{\nabla}})$.

The right and left gradients of a vector $\mathbf{u}$, $\overset{\rightarrow}{\boldsymbol{\nabla}}\mathbf{u}$ and $\mathbf{u}\overset{\leftarrow}{\boldsymbol{\nabla}} = (\overset{\rightarrow}{\boldsymbol{\nabla}}\mathbf{u})^{\mathrm{T}}$, respectively, are also defined through the relation

$$d\mathbf{u} = (\mathbf{u}\overset{\leftarrow}{\boldsymbol{\nabla}})\cdot d\mathbf{x} = d\mathbf{x}\cdot\overset{\rightarrow}{\boldsymbol{\nabla}}\mathbf{u}\,. \tag{2.4.60}$$

In the axes $(\hat{\mathbf{e}}_r, \hat{\mathbf{e}}_\theta, \hat{\mathbf{e}}_\phi)$,

$$\mathbf{x} = r\,\hat{\mathbf{e}}_r\,, \quad \mathbf{u} = u_r\,\hat{\mathbf{e}}_r + u_\theta\,\hat{\mathbf{e}}_\theta + u_\phi\,\hat{\mathbf{e}}_\phi\,, \tag{2.4.61}$$

and the differentials $d\mathbf{u}$ and $d\mathbf{x}$ are obtained via (2.4.48) and (2.4.53). Hence

∘ the right gradient $\mathbf{u}\overset{\leftarrow}{\boldsymbol{\nabla}}$ of the vector $\mathbf{u}$ is read from the matrix format,

$$d\mathbf{u} = \begin{bmatrix} \dfrac{\partial u_r}{\partial r} & \dfrac{1}{r}\dfrac{\partial u_r}{\partial \theta} - \dfrac{u_\theta}{r} & \dfrac{1}{r\,\sin\theta}\dfrac{\partial u_r}{\partial \phi} - \dfrac{u_\phi}{r} \\ \dfrac{\partial u_\theta}{\partial r} & \dfrac{1}{r}\dfrac{\partial u_\theta}{\partial \theta} + \dfrac{u_r}{r} & \dfrac{1}{r\,\sin\theta}\dfrac{\partial u_\theta}{\partial \phi} - \dfrac{u_\phi}{r}\,\cot\theta \\ \dfrac{\partial u_\phi}{\partial r} & \dfrac{1}{r}\dfrac{\partial u_\phi}{\partial \theta} & \dfrac{1}{r\,\sin\theta}\dfrac{\partial u_\phi}{\partial \phi} + \dfrac{u_r}{r} + \dfrac{u_\theta}{r}\,\cot\theta \end{bmatrix} \begin{bmatrix} dr \\ r\,d\theta \\ r\,\sin\theta\,d\phi \end{bmatrix}. \tag{2.4.62}$$

For the special case of radial motions,

$$r = r(\underline{r}, t),\ \theta = \underline{\theta},\ \phi = \underline{\phi}\,, \tag{2.4.63}$$

the only nonzero components of the deformation gradient (2.4.37) are

$$F_{rr} = \frac{dr}{d\underline{r}}, \quad F_{\theta\theta} = F_{\phi\phi} = \frac{r}{\underline{r}}\,. \tag{2.4.64}$$

∘ the divergence $\operatorname{div}\mathbf{u}$ of a vector $\mathbf{u}$ is the trace of its gradient,

$$\operatorname{div}\mathbf{u} = \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\, u_r) + \frac{1}{r\sin\theta}\frac{\partial}{\partial\theta}(u_\theta\,\sin\theta) + \frac{1}{r\sin\theta}\frac{\partial u_\phi}{\partial\phi}\,. \tag{2.4.65}$$

∘ the Laplacian $\Delta u = \operatorname{div}(\overrightarrow{\boldsymbol{\nabla}}u) = \operatorname{tr}((\overrightarrow{\boldsymbol{\nabla}}u)\overleftarrow{\boldsymbol{\nabla}})$ of a scalar (2.4.26) follows from (2.4.57) and (2.4.58),

$$\Delta u = \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\,\frac{\partial u}{\partial r}) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}(\sin\theta\,\frac{\partial u}{\partial\theta}) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2 u}{\partial\phi^2}\,. \tag{2.4.66}$$

∘ the left and right divergences of a second order tensor $\boldsymbol{\sigma}$,

$$\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma} = \Big(\frac{\hat{\mathbf{e}}_k}{h_k}\frac{\overrightarrow{\partial}}{\partial x_k}\Big)\cdot\boldsymbol{\sigma}, \quad \boldsymbol{\sigma}\cdot\overleftarrow{\boldsymbol{\nabla}} = \boldsymbol{\sigma}\cdot\Big(\frac{\overleftarrow{\partial}}{\partial x_k}\frac{\hat{\mathbf{e}}_k}{h_k}\Big)\,, \tag{2.4.67}$$

are identical on symmetric tensors, $\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma} = \boldsymbol{\sigma}\cdot\overleftarrow{\boldsymbol{\nabla}}$ if $\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\mathrm{T}}$. In explicit form,

$$\begin{aligned}
\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma} &= \Big(\frac{\hat{\mathbf{e}}_k}{h_k}\frac{\overrightarrow{\partial}}{\partial x_k}\Big)\cdot\boldsymbol{\sigma}\\
&= \frac{\hat{\mathbf{e}}_k}{h_k}\frac{\overrightarrow{\partial}}{\partial x_k}\cdot(\sigma_{ij}\,\hat{\mathbf{e}}_i\otimes\hat{\mathbf{e}}_j)\\
&= \frac{1}{h_k}\frac{\partial\sigma_{kj}}{\partial x_k}\hat{\mathbf{e}}_j + \frac{1}{h_k}\Big(\frac{\partial\hat{\mathbf{e}}_i}{\partial x_k}\cdot\hat{\mathbf{e}}_k\Big)\,\sigma_{ij}\,\hat{\mathbf{e}}_j + \frac{\sigma_{kj}}{h_k}\frac{\partial\hat{\mathbf{e}}_j}{\partial x_k}\\
&= \Big(\frac{1}{h_k}\frac{\partial\sigma_{kj}}{\partial x_k} + \frac{\sigma_{rj}}{h_\theta} + \frac{1}{h_\phi}\,(\sin\theta\,\sigma_{rj} + \cos\theta\,\sigma_{\theta j})\Big)\,\hat{\mathbf{e}}_j\\
&- \Big(\frac{\sigma_{\theta\theta}}{h_\theta} + \sin\theta\,\frac{\sigma_{\phi\phi}}{h_\phi}\Big)\,\hat{\mathbf{e}}_r + \Big(\frac{\sigma_{\theta r}}{h_\theta} - \cos\theta\,\frac{\sigma_{\phi\phi}}{h_\phi}\Big)\,\hat{\mathbf{e}}_\theta + \Big(\sin\theta\,\frac{\sigma_{\phi r}}{h_\theta} + \cos\theta\,\frac{\sigma_{\phi\theta}}{h_\phi}\Big)\,\hat{\mathbf{e}}_\phi\,,
\end{aligned} \tag{2.4.68}$$

whence the component form of the left divergence of the tensor $\boldsymbol{\sigma}$,

$$[\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}] = \begin{bmatrix}
\dfrac{\partial\sigma_{rr}}{\partial r} + \dfrac{1}{r}\dfrac{\partial\sigma_{\theta r}}{\partial\theta} + \dfrac{1}{r\,\sin\theta}\dfrac{\partial\sigma_{\phi r}}{\partial\phi} + \dfrac{\cot\theta}{r}\,\sigma_{\theta r} + \dfrac{1}{r}\,(2\,\sigma_{rr} - \sigma_{\theta\theta} - \sigma_{\phi\phi})\\
\dfrac{\partial\sigma_{r\theta}}{\partial r} + \dfrac{1}{r}\dfrac{\partial\sigma_{\theta\theta}}{\partial\theta} + \dfrac{1}{r\,\sin\theta}\dfrac{\partial\sigma_{\phi\theta}}{\partial\phi} + \dfrac{\cot\theta}{r}\,(\sigma_{\theta\theta} - \sigma_{\phi\phi}) + 2\,\dfrac{\sigma_{r\theta}}{r} + \dfrac{\sigma_{\theta r}}{r}\\
\dfrac{\partial\sigma_{r\phi}}{\partial r} + \dfrac{1}{r}\dfrac{\partial\sigma_{\theta\phi}}{\partial\theta} + \dfrac{1}{r\,\sin\theta}\dfrac{\partial\sigma_{\phi\phi}}{\partial\phi} + \dfrac{\cot\theta}{r}\,(\sigma_{\theta\phi} + \sigma_{\phi\theta}) + 2\,\dfrac{\sigma_{r\phi}}{r} + \dfrac{\sigma_{\phi r}}{r}
\end{bmatrix}. \tag{2.4.69}$$

2.4.3.2 Cylindrical coordinates

The cylindrical unit vectors shown in Fig. 2.4.3 built from the reference cartesian triad $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$,

$$\begin{aligned}
\hat{\mathbf{e}}_r &= \cos\theta\,\mathbf{e}_1 + \sin\theta\,\mathbf{e}_2\,,\\
\hat{\mathbf{e}}_\theta &= -\sin\theta\,\mathbf{e}_1 + \cos\theta\,\mathbf{e}_2\,,\\
\hat{\mathbf{e}}_z &= \mathbf{e}_3\,,
\end{aligned} \tag{2.4.70}$$

have differentials,

$$d\hat{\mathbf{e}}_r = d\theta\,\hat{\mathbf{e}}_\theta, \quad d\hat{\mathbf{e}}_\theta = -d\theta\,\hat{\mathbf{e}}_r, \quad d\hat{\mathbf{e}}_z = \mathbf{0}\,. \tag{2.4.71}$$

The motion associates the point $\mathbf{x}$ with a reference point $\underline{\mathbf{x}}$,

$$\underline{\mathbf{x}} = \underline{r}\,\hat{\underline{\mathbf{e}}}_r + \underline{z}\,\hat{\underline{\mathbf{e}}}_z \longmapsto \mathbf{x} = r\,\hat{\mathbf{e}}_r + z\,\hat{\mathbf{e}}_z\,. \tag{2.4.72}$$

These points vary with the reference and current coordinates,

$$d\underline{\mathbf{x}} = d\underline{r}\,\hat{\underline{\mathbf{e}}}_r + \underline{r}\,d\underline{\theta}\,\hat{\underline{\mathbf{e}}}_\theta + d\underline{z}\,\hat{\underline{\mathbf{e}}}_z, \quad d\mathbf{x} = dr\,\hat{\mathbf{e}}_r + r\,d\theta\,\hat{\mathbf{e}}_\theta + dz\,\hat{\mathbf{e}}_z\,. \tag{2.4.73}$$

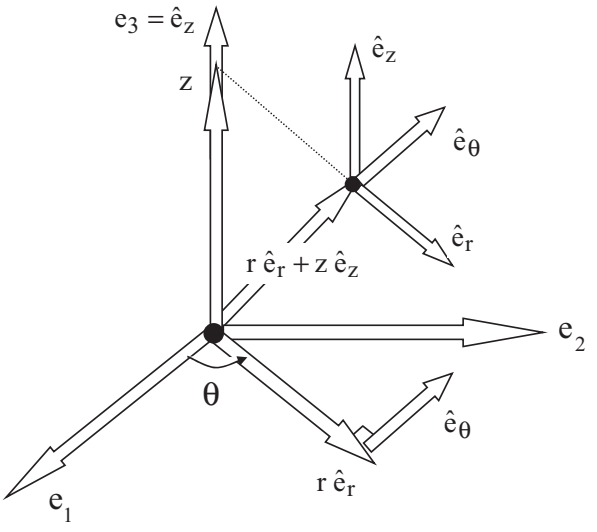

Fig. 2.4.3: Cylindrical coordinates.

The scaling factors (2.4.21) in the current configurations are therefore,

$$h_r = 1, \quad h_\theta = r, \quad h_z = 1\,. \tag{2.4.74}$$

The differential operators can now be made explicit in the cylindrical coordinate axes, namely

∘ the gradient $\vec{\boldsymbol{\nabla}} u$ of the scalar u:

$$\vec{\boldsymbol{\nabla}} u = u \overleftarrow{\boldsymbol{\nabla}} = \frac{\partial u}{\partial r}\,\hat{\mathbf{e}}_r + \frac{1}{r}\,\frac{\partial u}{\partial \theta}\,\hat{\mathbf{e}}_\theta + \frac{\partial u}{\partial z}\,\hat{\mathbf{e}}_z\,. \tag{2.4.75}$$

∘ the Laplacian Δu of the scalar u:

$$\Delta u = \frac{1}{r}\frac{\partial}{\partial r}(r\,\frac{\partial u}{\partial r}) + \frac{1}{r^2}\frac{\partial^2 u}{\partial \theta^2} + \frac{\partial^2 u}{\partial z^2}\,. \tag{2.4.76}$$

∘ the right gradient $\mathbf{u}\overleftarrow{\boldsymbol{\nabla}}$ of a vector:

$$d\mathbf{u} = \begin{bmatrix} \dfrac{\partial u_r}{\partial r} & \dfrac{1}{r}\dfrac{\partial u_r}{\partial \theta} - \dfrac{u_\theta}{r} & \dfrac{\partial u_r}{\partial z} \\[2ex] \dfrac{\partial u_\theta}{\partial r} & \dfrac{1}{r}\dfrac{\partial u_\theta}{\partial \theta} + \dfrac{u_r}{r} & \dfrac{\partial u_\theta}{\partial z} \\[2ex] \dfrac{\partial u_z}{\partial r} & \dfrac{1}{r}\dfrac{\partial u_z}{\partial \theta} & \dfrac{\partial u_z}{\partial z} \end{bmatrix} \begin{bmatrix} dr \\ \\ r\,d\theta \\ \\ dz \end{bmatrix}\,. \tag{2.4.77}$$

∘ the divergence $\operatorname{div}\mathbf{u}$ of a vector:

$$\operatorname{div}\mathbf{u} = \frac{1}{r}\frac{\partial}{\partial r}(r\,u_r) + \frac{1}{r}\frac{\partial u_\theta}{\partial \theta} + \frac{\partial u_z}{\partial z}\,. \tag{2.4.78}$$

∘ the left divergence $\vec{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}$ of a second order tensor $\boldsymbol{\sigma}$:

$$[\vec{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}] = \begin{bmatrix} \dfrac{\partial \sigma_{rr}}{\partial r} + \dfrac{1}{r}\dfrac{\partial \sigma_{\theta r}}{\partial \theta} + \dfrac{\partial \sigma_{zr}}{\partial z} + \dfrac{1}{r}\,(\sigma_{rr} - \sigma_{\theta\theta}) \\[2ex] \dfrac{\partial \sigma_{r\theta}}{\partial r} + \dfrac{1}{r}\dfrac{\partial \sigma_{\theta\theta}}{\partial \theta} + \dfrac{\partial \sigma_{z\theta}}{\partial z} + \dfrac{\sigma_{r\theta}}{r} + \dfrac{\sigma_{\theta r}}{r} \\[2ex] \dfrac{\partial \sigma_{rz}}{\partial r} + \dfrac{1}{r}\dfrac{\partial \sigma_{\theta z}}{\partial \theta} + \dfrac{\partial \sigma_{zz}}{\partial z} + \dfrac{\sigma_{rz}}{r} \end{bmatrix}\,. \tag{2.4.79}$$

For the special case of radial and axial motions,

$$r = r(\underline{r}, t),\ \theta = \underline{\theta},\ z = z(\underline{z}, t)\,, \tag{2.4.80}$$

then the only nonzero components of the deformation gradient (2.4.37) are the diagonal terms,

$$F_{rr} = \frac{dr}{d\underline{r}}, \quad F_{\theta\theta} = \frac{r}{\underline{r}}, \quad F_{zz} = \frac{dz}{d\underline{z}}\,. \tag{2.4.81}$$

2.4.3.3 Polar coordinates

Let $(\mathbf{e}_1, \mathbf{e}_2)$ be cartesian axes, and $\hat{\mathbf{e}}_r = \cos\theta\,\mathbf{e}_1 + \sin\theta\,\mathbf{e}_2$ and $\hat{\mathbf{e}}_\theta = -\sin\theta\,\mathbf{e}_1 + \cos\theta\,\mathbf{e}_2$ be the polar axes deduced by a direct rotation of angle θ as in (2.4.70).

Let us record the polar components of the displacement vector $\mathbf{u} = u_1\,\mathbf{e}_1 + u_2\,\mathbf{e}_2$, namely

$$\begin{array}{l} u_r = \cos\theta\,u_1 + \sin\theta\,u_2, \\ u_\theta = -\sin\theta\,u_1 + \cos\theta\,u_2, \end{array} \quad . \tag{2.4.82}$$

as well as the polar components of the symmetric stress $\boldsymbol{\sigma} = \sigma_{11}\,\mathbf{e}_1 \otimes \mathbf{e}_1 + \sigma_{22}\,\mathbf{e}_2 \otimes \mathbf{e}_2 + \sigma_{12}\,(\mathbf{e}_1 \otimes \mathbf{e}_2 + \mathbf{e}_2 \otimes \mathbf{e}_1)$, namely

$$\begin{array}{l} \sigma_{rr} = \cos^2\theta\,\sigma_{11} + \sin^2\theta\,\sigma_{22} + 2\,\sin\theta\,\cos\theta\,\sigma_{12}, \\ \sigma_{\theta\theta} = \sin^2\theta\,\sigma_{11} + \cos^2\theta\,\sigma_{22} - 2\,\sin\theta\,\cos\theta\,\sigma_{12}, \\ \sigma_{r\theta} = -\sin\theta\,\cos\theta\,(\sigma_{11} - \sigma_{22}) + (\cos^2\theta - \sin^2\theta)\,\sigma_{12}\,. \end{array} \tag{2.4.83}$$

In the case where $\sigma_{zr} = 0$, $\sigma_{z\theta} = \sigma_{z\theta}(r)$ and $\sigma_{zz} = \sigma_{zz}(r,\theta)$, the component of the left divergence $\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}$ defined by (2.4.79) along z vanishes and the divergence adopts the format of polar coordinates,

$$[\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}] = \left[\begin{array}{l} \dfrac{\partial\sigma_{rr}}{\partial r} + \dfrac{1}{r}\,\dfrac{\partial\sigma_{\theta r}}{\partial\theta} + \dfrac{1}{r}\,(\sigma_{rr} - \sigma_{\theta\theta}) \\ \dfrac{\partial\sigma_{r\theta}}{\partial r} + \dfrac{1}{r}\,\dfrac{\partial\sigma_{\theta\theta}}{\partial\theta} + \dfrac{\sigma_{r\theta}}{r} + \dfrac{\sigma_{\theta r}}{r} \end{array}\right] . \tag{2.4.84}$$

2.4.4 Convective acceleration

A particle located at position $\underline{\mathbf{x}}$ at a reference time, say $t = 0$, moves to the position $\mathbf{x} = \mathbf{x}(\underline{\mathbf{x}}, t)$ at time t. We may also take a picture of the particle positions at an arbitrary time t: this picture will not tell us where the particle located at position $\mathbf{x}$ was at time $t = 0$. To cover these different points of view, we adapt the arguments of the field Φ (although we should also change the notation for the field itself),

$$\Phi(\underline{\mathbf{x}}, t) = \Phi(\mathbf{x}, t) = \Phi(\mathbf{x}(\underline{\mathbf{x}}, t), t)\,. \tag{2.4.85}$$

The derivatives with respect to time will reflect these differences,

$$\underbrace{\frac{\partial\Phi}{\partial t}_{|\underline{\mathbf{x}}}}_{\substack{\text{material} \\ \text{time derivative}}} = \underbrace{\frac{\partial\Phi}{\partial t}_{|\mathbf{x}}}_{\substack{\text{local time derivative} \\ \text{vanishes in steady flow}}} + \underbrace{\frac{\partial\Phi}{\partial\mathbf{x}}_{|\underline{\mathbf{x}}} \cdot \frac{\partial\mathbf{x}}{\partial t}}_{\substack{\text{convective rate of change} \\ \text{vanishes in spatially} \\ \text{uniform flow}}} \quad . \tag{2.4.86}$$

The convective rate of change is due to the fact that the particle is moving in a landscape where the field Φ is not uniform.

In order to avoid the notation being more cumbersome than necessary, we will write

$$\begin{array}{rcl} \dfrac{d\Phi}{dt} & = & \dfrac{\partial\Phi}{\partial t} + \mathbf{v}\cdot\,\overrightarrow{\boldsymbol{\nabla}}\Phi \\ & = & \dfrac{\partial\Phi}{\partial t} + \Phi\,\overleftarrow{\boldsymbol{\nabla}}\cdot\mathbf{v} \\ \dfrac{d\Phi_{\ldots}}{dt} & = & \dfrac{\partial\Phi_{\ldots}}{\partial t} + v_l\,\dfrac{\partial\Phi_{\ldots}}{\partial x_l}\,, \end{array} \tag{2.4.87}$$

where $\mathbf{v}$ is the velocity,

$$\mathbf{v}(\underline{\mathbf{x}}, t) = \frac{\partial\mathbf{x}}{\partial t}_{|\underline{\mathbf{x}}} = \frac{\partial\mathbf{u}}{\partial t}_{|\underline{\mathbf{x}}}\,. \tag{2.4.88}$$

These relations apply to any field and to the position $\mathbf{x}$ and displacement $\mathbf{u} = \mathbf{x} - \underline{\mathbf{x}}$ in particular. Similarly the formulas apply to the velocity itself and the acceleration may be cast in two equivalent formats:

$$\begin{aligned} \mathbf{a} = \frac{d\mathbf{v}}{dt} &= \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v}\cdot \vec{\boldsymbol{\nabla}}\mathbf{v} \\ &= \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v}\overleftarrow{\boldsymbol{\nabla}} \cdot \mathbf{v} \\ a_k = \frac{dv_k}{dt} &= \frac{\partial v_k}{\partial t} + v_l \, \frac{\partial v_k}{\partial x_l} \, . \end{aligned} \tag{2.4.89}$$

The acceleration components follow, for example, from the right gradient (2.4.62) in spherical axes,

$$\begin{aligned} a_r &= \frac{\partial v_r}{\partial t} + v_r \, \frac{\partial v_r}{\partial r} + \frac{v_\theta}{r} \, \frac{\partial v_r}{\partial \theta} + \frac{v_\phi}{r \sin\theta} \, \frac{\partial v_r}{\partial \phi} - \frac{1}{r} \, (v_\theta^2 + v_\phi^2) \\ a_\theta &= \frac{\partial v_\theta}{\partial t} + v_r \, \frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} \, \frac{\partial v_\theta}{\partial \theta} + \frac{v_\phi}{r \sin\theta} \, \frac{\partial v_\theta}{\partial \phi} + \frac{1}{r} \, v_r \, v_\theta - \frac{1}{r} \, v_\phi^2 \, \cot\theta \\ a_\phi &= \frac{\partial v_\phi}{\partial t} + v_r \, \frac{\partial v_\phi}{\partial r} + \frac{v_\theta}{r} \, \frac{\partial v_\phi}{\partial \theta} + \frac{v_\phi}{r \sin\theta} \, \frac{\partial v_\phi}{\partial \phi} + \frac{1}{r} \, v_r \, v_\phi + \frac{1}{r} \, v_\theta \, v_\phi \, \cot\theta \, , \end{aligned} \tag{2.4.90}$$

and from the right gradient (2.4.77) in cylindrical axes,

$$\begin{aligned} a_r &= \frac{\partial v_r}{\partial t} + v_r \, \frac{\partial v_r}{\partial r} + \frac{v_\theta}{r} \, \frac{\partial v_r}{\partial \theta} + v_z \, \frac{\partial v_r}{\partial z} - \frac{1}{r} \, v_\theta^2 \\ a_\theta &= \frac{\partial v_\theta}{\partial t} + v_r \, \frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} \, \frac{\partial v_\theta}{\partial \theta} + v_z \, \frac{\partial v_\theta}{\partial z} + \frac{1}{r} \, v_r \, v_\theta \\ a_z &= \frac{\partial v_z}{\partial t} + v_r \, \frac{\partial v_z}{\partial r} + \frac{v_\theta}{r} \, \frac{\partial v_z}{\partial \theta} + v_z \, \frac{\partial v_z}{\partial z} \, . \end{aligned} \tag{2.4.91}$$

A rewriting of the convective term of the acceleration using the identity $(2.4.5)_3$,

$$\frac{d\mathbf{v}}{dt} = \frac{\partial \mathbf{v}}{\partial t} + (\vec{\boldsymbol{\nabla}} \wedge \mathbf{v}) \wedge \mathbf{v} + \vec{\boldsymbol{\nabla}}(\tfrac{1}{2}\mathbf{v}^2) \, , \tag{2.4.92}$$

will be useful to derive a simple scalar condition for steady irrotational flow of inviscid fluids, termed Bernoulli equation. Still an alternative and equivalent form may be derived. According to (2.4.43), $\vec{\boldsymbol{\nabla}} \wedge \mathbf{v}$ is equal to $2\,\vec{\mathbf{W}}$ where $\vec{\mathbf{W}}$ is the pseudo-vector associated with the negative of the spin $\mathbf{W}(\mathbf{v})$ defined by (2.5.13). Then with the help of (2.1.13),

$$\frac{d\mathbf{v}}{dt} = \frac{\partial \mathbf{v}}{\partial t} + 2\,\vec{\mathbf{W}} \wedge \mathbf{v} + \vec{\boldsymbol{\nabla}}(\tfrac{1}{2}\mathbf{v}^2) = \frac{\partial \mathbf{v}}{\partial t} + 2\,\mathbf{W} \cdot \mathbf{v} + \vec{\boldsymbol{\nabla}}(\tfrac{1}{2}\mathbf{v}^2) \, . \tag{2.4.93}$$

2.5 Measures of strain

2.5.1 Polar decomposition of the deformation gradient

The invertible deformation gradient $\mathbf{F}$ can be decomposed uniquely into a product of a proper orthogonal tensor $\mathbf{Q}$ and of a pure deformation $\mathbf{U}$ or $\mathbf{V}$, namely

$$\mathbf{F} = \mathbf{Q} \cdot \mathbf{U} = \mathbf{V} \cdot \mathbf{Q} \, , \tag{2.5.1}$$

with $\mathbf{Q} \cdot \mathbf{Q}^{\mathrm{T}} = \mathbf{Q}^{\mathrm{T}} \cdot \mathbf{Q} = \mathbf{I}$, $\det \mathbf{Q} = 1$, and $\mathbf{U}$ and $\mathbf{V}$ symmetric definite positive tensors referred to as right and left stretch tensors, respectively. For a proof of the existence and uniqueness of the decomposition, see, e.g., Bowen [1989], p. 237. As an example, Exercise 2.3 proposes the decomposition of a motion describing a simple shear.

Incidentally note that the tensor $d\mathbf{Q}/dt \cdot \mathbf{Q}^{\mathrm{T}}$ is skew-symmetric: this result simply follows by derivation of the relation $\mathbf{Q} \cdot \mathbf{Q}^{\mathrm{T}} = \mathbf{I}$. Indeed

$$\mathbf{Q} \cdot \mathbf{Q}^{\mathrm{T}} = \mathbf{I} \Rightarrow \frac{d\mathbf{Q}}{dt} \cdot \mathbf{Q}^{\mathrm{T}} + \mathbf{Q} \cdot \frac{d\mathbf{Q}^{\mathrm{T}}}{dt} = \mathbf{0} \Rightarrow \frac{d\mathbf{Q}}{dt} \cdot \mathbf{Q}^{\mathrm{T}} = -\mathbf{Q} \cdot \Big(\frac{d\mathbf{Q}}{dt}\Big)^{\mathrm{T}} = -(\frac{d\mathbf{Q}}{dt} \cdot \mathbf{Q}^{\mathrm{T}})^{\mathrm{T}} \, . \tag{2.5.2}$$

The right and left Cauchy-Green tensors are defined, respectively, as

$$\mathbf{C} = \mathbf{F}^{\mathrm{T}} \cdot \mathbf{F} = \mathbf{U}^2 \,, \quad \mathbf{B} = \mathbf{F} \cdot \mathbf{F}^{\mathrm{T}} = \mathbf{V}^2 \,. \tag{2.5.3}$$

Thus $\mathbf{U} = \mathbf{C}^{\frac{1}{2}}$ and $\mathbf{V} = \mathbf{B}^{\frac{1}{2}}$.

Let $\mathbf{v}$ be an eigenvector of $\mathbf{C}$ associated with the eigenvalue λ, namely $\mathbf{C} \cdot \mathbf{v} = \lambda \, \mathbf{v}$. Multiplication of the two terms of the equation by $\mathbf{F}$ yields $(\mathbf{F} \cdot \mathbf{F}^{\mathrm{T}}) \cdot (\mathbf{F} \cdot \mathbf{v}) = \lambda \, (\mathbf{F} \cdot \mathbf{v})$. Consequently the eigenvalues of the left and right Cauchy-Green tensors are identical and, if $\mathbf{v}$ is an eigenvector of $\mathbf{C}$ associated with the eigenvalue λ, $\mathbf{F} \cdot \mathbf{v}$ is the eigenvector of $\mathbf{B}$ associated with the same eigenvalue.

Explicit expressions of the right and left stretches require taking the square-root of a symmetric second order tensor. One possibility is to use the spectral decomposition, including eigenvalues and eigenvectors. The approach of Section 2.3.6 makes use only of the eigenvalues. An alternative method based on repeated use of Cayley-Hamilton theorem has been devised by Hoger and Carlson [1984]a, Section 2.3.2.

2.5.2 Spectral decomposition of the right and left Cauchy-Green tensors

Since they are symmetric, the right and left stretches have a real spectrum[2.2]: the eigenvalues referred to as principal stretches are identical and remain strictly positive while the eigenvectors of the left stretch are rotated with respect to those of the right stretch through the rotation $\mathbf{Q}$:

$$\mathbf{U} = \sum_{i=1,3} \lambda_i \, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_i, \quad \mathbf{V} = \sum_{i=1,3} \lambda_i \, \mathbf{e}_i \otimes \mathbf{e}_i, \quad \mathbf{Q} = \sum_{i=1,3} \mathbf{e}_i \otimes \underline{\mathbf{e}}_i \,, \tag{2.5.4}$$

with, for $i \in [1,3]$,

$$\mathbf{e}_i = \mathbf{Q} \cdot \underline{\mathbf{e}}_i = \sum_{j=1,3} Q_{ji} \, \underline{\mathbf{e}}_j, \quad \underline{\mathbf{e}}_i = \mathbf{Q}^{\mathrm{T}} \cdot \mathbf{e}_i = \sum_{j=1,3} Q_{ij} \, \mathbf{e}_j \,, \tag{2.5.5}$$

using the decomposition of $\mathbf{Q}$ on the two triads, $\mathbf{Q} = \sum_{i,j} Q_{ij} \, \mathbf{e}_i \otimes \mathbf{e}_j = \sum_{i,j} Q_{ij} \, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j$.

Consequently, the eigenvalues of the right and left Cauchy-Green tensors are identical, while their eigenspaces are equal to those of the right and left stretches, respectively,

$$\begin{aligned} \mathbf{C} = \mathbf{F}^{\mathrm{T}} \cdot \mathbf{F} = \mathbf{U}^2 &= \sum_{i=1,3} \lambda_i^2 \, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_i, \\ \mathbf{B} = \mathbf{F} \cdot \mathbf{F}^{\mathrm{T}} = \underbrace{\mathbf{V}^2}_{\mathbf{Q} \cdot \mathbf{U}^2 \cdot \mathbf{Q}^{\mathrm{T}}} &= \sum_{i=1,3} \lambda_i^2 \, \mathbf{e}_i \otimes \mathbf{e}_i \,. \end{aligned} \tag{2.5.6}$$

The spectral decomposition of the deformation gradient itself is implied by the spectral properties of the right and left stretches or of the Cauchy-Green tensors, namely,

$$\mathbf{F} = \sum_{i=1,3} \lambda_i \, \mathbf{e}_i \otimes \underline{\mathbf{e}}_i \,. \tag{2.5.7}$$

2.5.3 Lagrangian and Eulerian strain measures

A family of Lagrangian (right) and Eulerian (left) strain measures associated with the integer n and defined in terms of the right and left stretches is attributed to Seth [1964],

$$\begin{aligned} \mathbf{E}^{\mathrm{L}}_{(n)} &= \frac{1}{n} \, (\mathbf{U}^n - \mathbf{I}) = \sum_{i=1,3} \frac{1}{n} \, (\lambda_i^n - 1) \, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_i \,, \\ \mathbf{E}^{\mathrm{E}}_{(n)} &= \frac{1}{n} \, (\mathbf{I} - \mathbf{V}^{-n}) = \sum_{i=1,3} \frac{1}{n} \, (1 - \lambda_i^{-n}) \, \mathbf{e}_i \otimes \mathbf{e}_i \,. \end{aligned} \tag{2.5.8}$$

[2.2] A more general spectral analysis is provided in Section 2.2.

The logarithmic strain is associated with the limit case $n = 0$ (deduced from the above by L'Hospital rule),

$$\begin{aligned} \mathbf{E}^{\mathrm{L}}_{(0)} &= \mathrm{Ln}\,\mathbf{U} = \sum_{i=1,3} \mathrm{Ln}\,\lambda_i\ \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_i\,, \\ \mathbf{E}^{\mathrm{E}}_{(0)} &= \mathrm{Ln}\,\mathbf{V} = \sum_{i=1,3} \mathrm{Ln}\,\lambda_i\ \mathbf{e}_i \otimes \mathbf{e}_i\,. \end{aligned} \tag{2.5.9}$$

Note the relations, resulting from the spectral decomposition,

$$\mathbf{V} = \mathbf{Q}\cdot\mathbf{U}\cdot\mathbf{Q}^{\mathrm{T}}, \quad \mathbf{V}^2 = \mathbf{Q}\cdot\mathbf{U}^2\cdot\mathbf{Q}^{\mathrm{T}}, \quad \mathrm{Ln}\,\mathbf{V} = \mathbf{Q}\cdot\mathrm{Ln}\,\mathbf{U}\cdot\mathbf{Q}^{\mathrm{T}}\,. \tag{2.5.10}$$

To $n = 2$ correspond a Lagrangian measure $\mathbf{E}_{\mathrm{G}} = \frac{1}{2}(\mathbf{C}-\mathbf{I})$ called Green strain and a Eulerian measure $\mathbf{E}^{\mathrm{co}}_{\mathrm{A}} = \frac{1}{2}(\mathbf{I}-\mathbf{B}^{-1})$ called covariant Almansi strain. Similarly to $n = -2$ correspond the contravariant Almansi strain $\mathbf{E}^{\mathrm{ct}}_{\mathrm{A}} = \frac{1}{2}(\mathbf{I}-\mathbf{C}^{-1})$, a Lagrangian measure, and the Finger strain $\frac{1}{2}(\mathbf{B}-\mathbf{I})$, a Eulerian measure. The deformation gradient itself does not in general belong to that family while Biot strain $\mathbf{E}_{\mathrm{B}} = \mathbf{U}-\mathbf{I}$ corresponds to $n = 1$.

More general Lagrangian strain measures suggested and analyzed by Hill [1968],

$$\mathbf{E} = \sum_{i=1,3} f(\lambda_i)\,\underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_i\,, \tag{2.5.11}$$

may be defined through the smooth monotone function $f(\lambda)$ satisfying $f(0) = 1$, $(df/d\lambda)(1) = 1$, but otherwise arbitrary.

2.5.4 Rate of deformation and rates of strain measures

The infinitesimal strain and rotation tensors are associated with the (gradient of) displacement. Similarly with the velocity gradient,

$$\mathbf{L} = \frac{d\mathbf{F}}{dt}\cdot\mathbf{F}^{-1} = \mathbf{v}\overleftarrow{\boldsymbol{\nabla}}, \quad L_{ij} = \frac{\partial v_i}{\partial x_j}\,, \tag{2.5.12}$$

are associated the rate of deformation $\mathbf{D}$ and the spin $\mathbf{W}$,

$$\begin{aligned} \mathbf{D} &= \tfrac{1}{2}\big(\mathbf{L}+\mathbf{L}^{\mathrm{T}}\big) = \frac{1}{2}\big(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}} + \overrightarrow{\boldsymbol{\nabla}}\mathbf{v}\big)\,, \quad D_{ij} = \tfrac{1}{2}\big(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}\big)\,, \\ \mathbf{W} &= \tfrac{1}{2}\big(\mathbf{L}-\mathbf{L}^{\mathrm{T}}\big) = \frac{1}{2}\big(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}} - \overrightarrow{\boldsymbol{\nabla}}\mathbf{v}\big)\,, \quad W_{ij} = \tfrac{1}{2}\big(\frac{\partial v_i}{\partial x_j} - \frac{\partial v_j}{\partial x_i}\big)\,. \end{aligned} \tag{2.5.13}$$

Note the relations,

$$\frac{d\mathbf{E}_{\mathrm{G}}}{dt} = \mathbf{F}^{\mathrm{T}}\cdot\mathbf{D}\cdot\mathbf{F}, \quad \frac{d\mathbf{B}}{dt} = \mathbf{L}\cdot\mathbf{B}+\mathbf{B}\cdot\mathbf{L}^{\mathrm{T}}, \quad \frac{1}{2}\big(\frac{d\mathbf{U}}{dt}\cdot\mathbf{U}^{-1} + \mathbf{U}^{-1}\cdot\frac{d\mathbf{U}}{dt}\big) = \mathbf{Q}^{\mathrm{T}}\cdot\mathbf{D}\cdot\mathbf{Q}\,. \tag{2.5.14}$$

The rates of rotation of the right and left eigenvectors, respectively, $\underline{\mathbf{e}}_i$ and $\mathbf{e}_i$, $i \in [1,3]$, also referred to as rates of rotation of the Lagrangian and Eulerian strain ellipsoids[2.3],

$$\begin{aligned} \frac{d\underline{\mathbf{e}}_i}{dt} &= \boldsymbol{\Omega}^{\mathrm{L}}\cdot\underline{\mathbf{e}}_i = \sum_{j=1,3} \Omega^{\mathrm{L}}_{ji}\,\underline{\mathbf{e}}_j\,, \\ \frac{d\mathbf{e}_i}{dt} &= \boldsymbol{\Omega}^{\mathrm{E}}\cdot\mathbf{e}_i = \sum_{j=1,3} \Omega^{\mathrm{E}}_{ji}\,\mathbf{e}_j\,, \end{aligned} \tag{2.5.15}$$

are linked by the relation,

$$\boldsymbol{\Omega}^{\mathrm{E}} = \frac{d\mathbf{Q}}{dt}\cdot\mathbf{Q}^{-1} + \mathbf{Q}\cdot\boldsymbol{\Omega}^{\mathrm{L}}\cdot\mathbf{Q}^{-1}\,. \tag{2.5.16}$$

[2.3] Let the three vectors $\mathbf{e}_i$, $i \in [1,3]$, form a cartesian triad. That the second order tensor $\boldsymbol{\Omega}$ such that $d\mathbf{e}_i/dt = \boldsymbol{\Omega}\cdot\mathbf{e}_i$, $i \in [1,3]$, is skew-symmetric is easily proved. Indeed, differentiating $\mathbf{e}_i\cdot\mathbf{e}_i = 1$ yields $\mathbf{e}_i\cdot d\mathbf{e}_i/dt = \Omega_{ii} = 0$ (no sum over i). Also differentiating $\mathbf{e}_i\cdot\mathbf{e}_j = 0$ for $i \neq j$ yields $\Omega_{ij} + \Omega_{ji} = 0$.

As a consequence of the spectral decomposition of the right stretch $\mathbf{U}$, Eqn (2.5.4),

$$\frac{d\mathbf{U}}{dt} = \sum_{i,j} \Big(\frac{d\lambda_i}{dt} I_{ij} + (\lambda_i - \lambda_j)\, \Omega^{\mathrm{L}}_{ji} \Big)\, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \,. \tag{2.5.17}$$

The rate of the general Lagrangian strain measure (2.5.11) follows by analogy with (2.5.17), namely,

$$\frac{d\mathbf{E}}{dt} = \sum_{i,j} \Big(\frac{df(\lambda_i)}{d\lambda_i} \frac{d\lambda_i}{dt} I_{ij} + \big(f(\lambda_i) - f(\lambda_j)\big)\, \Omega^{\mathrm{L}}_{ji} \Big)\, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \,. \tag{2.5.18}$$

The components D_{ij} of the rate of deformation which is a Eulerian tensor,

$$\mathbf{D} = \sum_{i,j} D_{ij}\ \mathbf{e}_i \otimes \mathbf{e}_j \,, \quad \mathbf{Q}^{\mathrm{T}} \cdot \mathbf{D} \cdot \mathbf{Q} = \sum_{i,j} D_{ij}\ \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \,, \tag{2.5.19}$$

may be expressed, in view of $(2.5.14)_2$ and of (2.5.17), in terms of the rates of the stretches and of the Lagrangian rate of rotation[2.4], namely Eqn (1.50) in Hill [1978],

$$D_{ij} = \frac{1}{2} \big(\frac{1}{\lambda_i} + \frac{1}{\lambda_j}\big) \frac{d\lambda_i}{dt} I_{ij} + \frac{1}{2} \big(\frac{\lambda_i}{\lambda_j} - \frac{\lambda_j}{\lambda_i}\big)\, \Omega^{\mathrm{L}}_{ji} \,. \tag{2.5.20}$$

Indeed,

$$D_{ii} = \frac{1}{\lambda_i} \frac{d\lambda_i}{dt}; \quad \Omega^{\mathrm{L}}_{ji} = \frac{2\,\lambda_i\,\lambda_j}{\lambda_i^2 - \lambda_j^2}\, D_{ij}, \quad i \neq j \,. \tag{2.5.21}$$

The Lagrangian components of the rate of strain may thus be expressed in terms of the Eulerian components of the rate of deformation,

$$\frac{d\mathbf{E}}{dt} = \sum_{i,j} \Big(\frac{df(\lambda_i)}{d\lambda_i}\, \lambda_i\, D_{ii}\, I_{ij} + 2\,\lambda_i\,\lambda_j\, \frac{f(\lambda_i) - f(\lambda_j)}{\lambda_i^2 - \lambda_j^2}\, D_{ij} \Big)\, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \,. \tag{2.5.22}$$

The cases of repeated eigenvalues may be considered as limit cases.

2.5.5 Representation theorems for rotations

A second order tensor $\mathbf{R}$ is called a *rotation* or *proper orthogonal tensor* if

$$\mathbf{R} \cdot \mathbf{R}^{\mathrm{T}} = \mathbf{R}^{\mathrm{T}} \cdot \mathbf{R} = \mathbf{I}, \quad \det \mathbf{R} = +1 \,. \tag{2.5.23}$$

The set of rotations has the structure of a group and it is called the proper orthogonal group and denoted by $\mathcal{SO}(3)$. It is a subgroup of the complete orthogonal group $\mathcal{O}(3)$, Section 5.2.3.1.

As a consequence of (2.5.23), the number of independent scalars necessary to describe a rotation is equal to 3, namely 9 components—6 constraints. Several algebraic structures may be devised to embed these three scalars:

1. the standard representation uses the three Euler angles, e.g., Goldstein [1980], p. 146;
2. alternatively, one may consider a unit vector and an angle;
3. one may also consider a skew-symmetric second order tensor, or equivalently a unit vector and a magnitude.

Emphasis is laid on the Cayley and exponential representations which both use a skew-symmetric tensor. The second point of view above is useful to distinguish finite and infinitesimal rotations.

[2.4] The formulas (2.5.20) and (2.5.21) assume no summation over repeated indices.

2.5.5.1 Cayley representation

There exists a one-to-one correspondence between skew-symmetric second order tensors $\mathbf{\Omega}$ and proper orthogonal tensors $\mathbf{R}$, for which -1 is not an eigenvalue, that is, $\det(\mathbf{I}+\mathbf{R}) \neq 0$, e.g., Gantmacher [1959], p. 288:

$$\text{Cayley formula}: \quad \mathbf{R} = (\mathbf{I}-\mathbf{\Omega})^{-1} \cdot (\mathbf{I}+\mathbf{\Omega}), \quad \mathbf{\Omega} = (\mathbf{R}-\mathbf{I}) \cdot (\mathbf{R}+\mathbf{I})^{-1}. \tag{2.5.24}$$

The condition $\det(\mathbf{I}+\mathbf{R}) \neq 0$ excludes a rotation of angle equal to π. Clearly $\mathbf{R}^{-1}(\mathbf{\Omega}) = \mathbf{R}(-\mathbf{\Omega})$.

Consider the component form in cartesian axes of the skew-symmetric tensor $\mathbf{\Omega}$ and of its square $\mathbf{\Omega}^2$,

$$\mathbf{\Omega} = \begin{bmatrix} 0 & \Omega_{12} & \Omega_{13} \\ -\Omega_{12} & 0 & \Omega_{23} \\ -\Omega_{13} & -\Omega_{23} & 0 \end{bmatrix}, \quad \mathbf{\Omega}^2 = \begin{bmatrix} -\Omega_{12}^2-\Omega_{13}^2 & -\Omega_{13}\,\Omega_{23} & \Omega_{12}\,\Omega_{23} \\ -\Omega_{13}\,\Omega_{23} & -\Omega_{12}^2-\Omega_{23}^2 & -\Omega_{12}\,\Omega_{13} \\ \Omega_{12}\Omega_{23} & -\Omega_{12}\,\Omega_{13} & -\Omega_{13}^2-\Omega_{23}^2 \end{bmatrix} = (\mathbf{\Omega}^2)^{\mathrm{T}}. \tag{2.5.25}$$

Therefore,

$$\det \mathbf{\Omega} = 0, \quad \operatorname{tr} \mathbf{\Omega} = 0, \quad \operatorname{tr} \mathbf{\Omega}^2 = -|\mathbf{\Omega}|^2, \tag{2.5.26}$$

so that the characteristic polynomial (2.2.6) simplifies to

$$\det(\lambda\,\mathbf{I}-\mathbf{\Omega}) = \lambda^3 - \operatorname{tr}\mathbf{\Omega}\,\lambda^2 - (\operatorname{tr}\mathbf{\Omega}^2 - (\operatorname{tr}\mathbf{\Omega})^2)\,\frac{\lambda}{2} - \det\mathbf{\Omega} = \lambda^3 + \frac{|\mathbf{\Omega}|^2}{2}\,\lambda. \tag{2.5.27}$$

Consequently,

$$\det(\mathbf{I}-\mathbf{\Omega}) = 1 + \tfrac{1}{2}\,|\mathbf{\Omega}|^2 = \det(\mathbf{I}+\mathbf{\Omega}) > 0, \tag{2.5.28}$$

i.e., $\mathbf{I} \pm \mathbf{\Omega}$ is never singular.

One easily checks the relation $(\mathbf{I}+\mathbf{\Omega}) \cdot (\mathbf{I}-\mathbf{\Omega}) = (\mathbf{I}-\mathbf{\Omega}) \cdot (\mathbf{I}+\mathbf{\Omega})$. Therefore, $\mathbf{R}$ defined as $(\mathbf{I}-\mathbf{\Omega})^{-1} \cdot (\mathbf{I}+\mathbf{\Omega})$ satisfies the property $\mathbf{R}\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{R} = \mathbf{I}$ and $\det\mathbf{R} = 1$ since $\det(\mathbf{I}-\mathbf{\Omega}) = \det(\mathbf{I}+\mathbf{\Omega})$. Thus, $\mathbf{R}$ is proper orthogonal.

Using (2.5.26) and (2.5.28), one deduces,

$$(\mathbf{I}-\mathbf{\Omega})^{-1} = \mathbf{I} + \frac{1}{1+|\mathbf{\Omega}|^2/2}\,(\mathbf{\Omega}+\mathbf{\Omega}^2). \tag{2.5.29}$$

and the more explicit expression of the Cayley representation,

$$\mathbf{R} = (\mathbf{I}-\mathbf{\Omega})^{-1} \cdot (\mathbf{I}+\mathbf{\Omega}) = \mathbf{I} + \frac{2}{1+|\mathbf{\Omega}|^2/2}\,(\mathbf{\Omega}+\mathbf{\Omega}^2). \tag{2.5.30}$$

We knew already, before calculating the characteristic polynomial, that the determinant of a skew-symmetric matrix was zero. Indeed,

- the property results from the representation (2.1.13), namely $\mathbf{\Omega}\cdot\mathbf{x} = \mathbf{x}\wedge\vec{\mathbf{\Omega}}$ for any vector $\mathbf{x}$. Here $\vec{\mathbf{\Omega}}$ with Euclidean norm $|\vec{\mathbf{\Omega}}| = |\mathbf{\Omega}|/\sqrt{2}$ is the pseudo-vector adjoint to $\mathbf{\Omega}$;
- the property also follows from Jacobi theorem for skew-symmetric matrices of any odd order n: $\det\mathbf{\Omega} = \det\mathbf{\Omega}^{\mathrm{T}} = \det(-\mathbf{\Omega}) = (-1)^n \det\mathbf{\Omega} = -\det\mathbf{\Omega}$.

Thus one eigenvalue of $\mathbf{\Omega}$ is zero and the other two are complex conjugate as indicated by (2.5.27),

$$\lambda = 0; \quad \lambda = \pm\, i\,|\vec{\mathbf{\Omega}}|. \tag{2.5.31}$$

The Cayley-Hamilton theorem (2.3.1) simplifies to

$$\mathbf{\Omega}^3 + |\vec{\mathbf{\Omega}}|^2\,\mathbf{\Omega} = \mathbf{0}, \tag{2.5.32}$$

and therefore,

$$\mathbf{\Omega}^{2k+1} = \big(-|\vec{\mathbf{\Omega}}|^2\big)^k\,\mathbf{\Omega}, \quad \mathbf{\Omega}^{2k+2} = \big(-|\vec{\mathbf{\Omega}}|^2\big)^k\,\mathbf{\Omega}^2, \quad k \geq 0. \tag{2.5.33}$$

The half rotation is easily obtained,

$$\mathbf{R} = (\mathbf{I}-\mathbf{\Omega})^{-1} \cdot (\mathbf{I}+\mathbf{\Omega}) \quad \Leftrightarrow \quad \mathbf{R}^{\frac{1}{2}} = (\mathbf{I}-\alpha\,\mathbf{\Omega})^{-1} \cdot (\mathbf{I}+\alpha\,\mathbf{\Omega}), \tag{2.5.34}$$

either by a direct check, yielding $\alpha = (-1+\sqrt{1+|\vec{\mathbf{\Omega}}|^2})/|\vec{\mathbf{\Omega}}|^2 > 0$ or using the rotation angle (2.5.43), namely $\psi = 2\,\arctan|\vec{\mathbf{\Omega}}| = 2\times 2\,\arctan|\alpha\,\vec{\mathbf{\Omega}}|$.

2.5.5.2 Exponential representation

For any proper orthogonal tensor $\mathbf{R}$, there exists a skew-symmetric second order tensor $\mathbf{\Omega}$ such that, e.g., Gantmacher [1959], p. 287,

$$\mathbf{R} = \exp \mathbf{\Omega} \,. \tag{2.5.35}$$

The exponential of the second order tensor $\mathbf{A}$ is defined through a series expansion like for scalars. Indeed

$$\exp \mathbf{A} = \sum_{k=0}^{\infty} \frac{\mathbf{A}^k}{k!} \,, \tag{2.5.36}$$

is absolutely convergent since $|\exp \mathbf{A}| \leq \exp |\mathbf{A}|$. As an alternative definition, note the limit

$$\exp \mathbf{A} = \lim_{k \to \infty} \big(\mathbf{I} + \frac{\mathbf{A}}{k}\big)^k \,. \tag{2.5.37}$$

The estimation of the exponential of a skew-symmetric tensor $\mathbf{\Omega}$ is greatly simplified through the expression [Schwerdtfeger 1961, p. 238][2.5],

$$\mathbf{R} = \exp \mathbf{\Omega} = \mathbf{I} \; + \; \frac{\sin |\vec{\mathbf{\Omega}}|}{|\vec{\mathbf{\Omega}}|} \, \mathbf{\Omega} \; + \; \frac{1 - \cos |\vec{\mathbf{\Omega}}|}{|\vec{\mathbf{\Omega}}|^2} \, \mathbf{\Omega}^2 \,. \tag{2.5.38}$$

The proof starts with the exponential expansion,

$$\exp \mathbf{\Omega} = \mathbf{I} + \sum_{k=0}^{\infty} \frac{\mathbf{\Omega}^{2k+1}}{(2k+1)!} + \sum_{k=0}^{\infty} \frac{\mathbf{\Omega}^{2k+2}}{(2k+2)!} \,, \tag{2.5.39}$$

and uses the Cayley-Hamilton expressions (2.5.33),

$$\begin{aligned} \mathbf{R} = \exp \mathbf{\Omega} \quad &= \quad \mathbf{I} + \Big(\sum_{k=0}^{\infty} (-1)^k \frac{|\vec{\mathbf{\Omega}}|^{2k+1}}{(2k+1)!} \Big) \frac{\mathbf{\Omega}}{|\vec{\mathbf{\Omega}}|} + \Big(1 - \sum_{k=-1}^{\infty} (-1)^{k+1} \frac{|\vec{\mathbf{\Omega}}|^{2(k+1)}}{(2(k+1))!} \Big) \frac{\mathbf{\Omega}^2}{|\vec{\mathbf{\Omega}}|^2} \\ &= \quad \mathbf{I} + \Big(\sum_{k=0}^{\infty} (-1)^k \frac{|\vec{\mathbf{\Omega}}|^{2k+1}}{(2k+1)!} \Big) \frac{\mathbf{\Omega}}{|\vec{\mathbf{\Omega}}|} + \Big(1 - \sum_{k'=0}^{\infty} (-1)^{k'} \frac{|\vec{\mathbf{\Omega}}|^{2k'}}{(2k')!} \Big) \frac{\mathbf{\Omega}^2}{|\vec{\mathbf{\Omega}}|^2} \,. \end{aligned} \tag{2.5.40}$$

The Cayley and exponential representations of a proper orthogonal tensor feature two skew-symmetric tensors which are parallel but have distinct magnitudes as indicated by (2.5.43).

2.5.5.3 Finite versus infinitesimal rotations

The eigenvalues λ of a proper orthogonal tensor $\mathbf{R}$ have modulus one, namely $\lambda \overline{\lambda} = 1$, $\overline{\lambda}$ denoting the complex conjugate of λ. This property results from the definition (2.5.23).

Let $\mathbf{x}$ be an eigenvector associated with the eigenvalue λ. Then $\mathbf{R} \cdot \mathbf{x} = \lambda \, \mathbf{x}$, and thus $\overline{\mathbf{x}}^{\mathrm{T}} \cdot \mathbf{R}^{\mathrm{T}} \cdot \mathbf{R} \cdot \mathbf{x} = \overline{\lambda} \, \lambda \, \overline{\mathbf{x}}^{\mathrm{T}} \cdot \mathbf{x}$, whence $\overline{\lambda} \, \lambda = 1$ since $\mathbf{R}^{\mathrm{T}} \cdot \mathbf{R} = \mathbf{I}$. Actually, since $\mathbf{R}$ is real, there should be one real and two complex conjugate eigenvalues. In fact, the real eigenvalue is equal to one, and its associated eigenvector $\mathbf{n} = \vec{\mathbf{\Omega}}/|\vec{\mathbf{\Omega}}|$ is the axis of the rotation, while the other two eigenvalues can be expressed as $\exp(\pm \, i \, \psi)$. The angle ψ is the angle of rotation in a plane orthogonal to the axis $\mathbf{n}$, counted positive clockwise. Indeed, the image $\mathbf{R} \cdot \mathbf{x}$ of any vector $\mathbf{x}$ may be cast in the format [Goldstein 1980, p. 164],

$$\mathbf{x} \quad \longrightarrow \quad \mathbf{R} \cdot \mathbf{x} = (\mathbf{x} \cdot \mathbf{n}) \, \mathbf{n} + (\mathbf{x} - (\mathbf{x} \cdot \mathbf{n}) \, \mathbf{n}) \, \cos \psi + \mathbf{x} \wedge \mathbf{n} \, \sin \psi \,. \tag{2.5.41}$$

A geometrical representation is displayed in Fig. 2.5.1. The angle of rotation can be estimated quite simply from the sum of the eigenvalues of $\mathbf{R}$,

$$\mathrm{tr} \, \mathbf{R} \quad = \quad 1 + \exp(i \, \psi) + \exp(-i \, \psi) = 1 + 2 \, \cos \psi \,, \tag{2.5.42}$$

[2.5] The estimation of the exponential of an arbitrary matrix is another task, see Moler C. and Van Loan C. (2003). Nineteen Dubious Ways to Compute the Exponential of a Matrix, Twenty-Five Years later, *SIAM Review*, 45(1), 3-46.

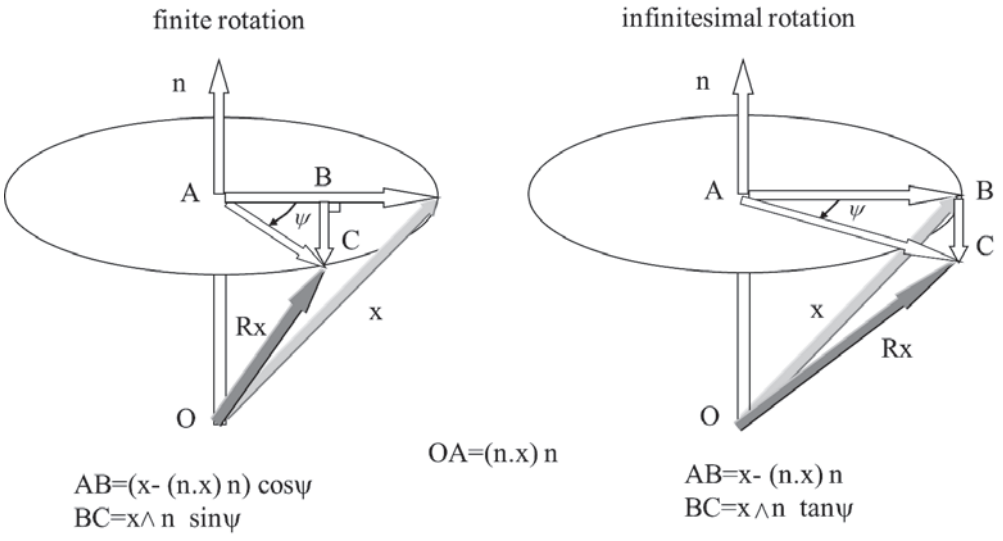

Fig. 2.5.1: Geometrical representations of a finite rotation and of an infinitesimal rotation.

and therefore using (2.5.30) and (2.5.38),

$$\psi = \arccos \tfrac{1}{2}\,(\mathrm{tr}\,\mathbf{R} - 1) = 2\,\arctan\,|\vec{\mathbf{\Omega}}_C| = |\vec{\mathbf{\Omega}}_E|\,, \tag{2.5.43}$$

the subscripts C and E referring to the Cayley and exponential representations, respectively.

A proper orthogonal tensor conserves the norm, i.e., $|\mathbf{R}\cdot\mathbf{a}| = |\mathbf{a}|$ for any vector $\mathbf{a}$[2.6]. Such is not the case for infinitesimal rotations defined via a vector product. Indeed, let $\mathbf{\Omega}$ be a skew-symmetric tensor, $\vec{\mathbf{\Omega}}$ its adjoint pseudo-vector, and $\mathbf{n} = \vec{\mathbf{\Omega}}/|\vec{\mathbf{\Omega}}|$. The transformation

$$\mathbf{x} \quad\longrightarrow\quad (\mathbf{I} + \mathbf{\Omega})\cdot\mathbf{x} = \mathbf{x} + \mathbf{x}\wedge\mathbf{n}\,|\vec{\mathbf{\Omega}}|\,, \tag{2.5.45}$$

both rotates $\mathbf{x}$ in the plane orthogonal to the axis of rotation by a clockwise angle $\psi = \arctan|\vec{\mathbf{\Omega}}|$ and changes its length. Fig. 2.5.1 contrasts the geometrical representations of a finite rotation and of an infinitesimal rotation.

2.5.5.4 Rotations versus projections

Anisotropic properties are often characterized by one or several unit vectors. Let $\mathbf{e} = \mathbf{e}(t)$ be a unit vector with value $\underline{\mathbf{e}} = \mathbf{e}(t=0)$ at time $t = 0$. The deformation gradient, with polar decomposition $\mathbf{F} = \mathbf{R}\cdot\mathbf{U}$, is reckoned from the time $t = 0$. The evolution in time of the unit vector $\mathbf{e}$ is to be traced to its physical interpretation. For example, consider the two evolution rules,

$$\mathbf{e} = \mathbf{R}\cdot\underline{\mathbf{e}}, \quad \mathbf{e} = \frac{\mathbf{F}\cdot\underline{\mathbf{e}}}{|\mathbf{F}\cdot\underline{\mathbf{e}}|}\,. \tag{2.5.46}$$

Since $\mathbf{e}$ is a unit vector, it remains orthogonal to its rate $d\mathbf{e}/dt$. It may be expressed in the form $\boldsymbol{\mathcal{E}}\cdot\mathbf{e}$ but the second order tensor $\boldsymbol{\mathcal{E}}$ is not unique: dyadic terms $\mathbf{e}\otimes\mathbf{e}'$ with $\mathbf{e}'$ orthogonal to $\mathbf{e}$ are elusive. For the first rule, the entity $\boldsymbol{\mathcal{E}}$,

$$\boldsymbol{\mathcal{E}} = \frac{d\mathbf{R}}{dt}\cdot\mathbf{R}^{\mathrm{T}}\,, \tag{2.5.47}$$

is a skew-symmetric tensor. Let $\mathbf{L} = d\mathbf{F}/dt\cdot\mathbf{F}^{-1}$ be the velocity gradient and $\mathbf{D}$ and $\mathbf{W}$ respectively its symmetric and skew-symmetric parts. Then, for the second rule, the rate $\boldsymbol{\mathcal{E}}\cdot\mathbf{e}$, with

$$\boldsymbol{\mathcal{E}} = \big(\mathbf{I} - \mathbf{e}\otimes\mathbf{e}\big)\cdot\mathbf{L}\,, \tag{2.5.48}$$

involves the projection of $\mathbf{L}\cdot\mathbf{e}$ on the plane tangent to the unit sphere at $\mathbf{e} = \mathbf{e}(t)$. Note that the rate $d\mathbf{e}/dt$ may also be expressed in terms of the skew-symmetric tensor,

$$\boldsymbol{\mathcal{E}} = \mathbf{W} + \mathbf{D}\cdot\mathbf{e}\otimes\mathbf{e} - \mathbf{e}\otimes\mathbf{e}\cdot\mathbf{D}\,. \tag{2.5.49}$$

[2.6] As a slightly more general property, if $\mathbf{R}$ is an orthogonal tensor, as defined in Section 5.2.3.1, then

$$|\mathbf{R}\cdot\mathbf{a}| = |\mathbf{a}|, \quad |\mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}}| = |\mathbf{A}|\,, \tag{2.5.44}$$

for any vector $\mathbf{a}$ and any second order tensor $\mathbf{A}$.

2.5.5.5 A differential equation for the rotation tensor

If $\mathbf{R} = \mathbf{R}(t)$ is a proper orthogonal tensor, then $d\mathbf{R}/dt \cdot \mathbf{R}^{\mathrm{T}}$ is skew-symmetric as indicated by (2.5.2). Then if the skew-symmetric tensors $\mathbf{W}(t)$ and $\int_{t_0}^{t} \mathbf{W}(\tau)\, d\tau$ commute, the solution $\mathbf{R}(t)$ of the differential equation,

$$\frac{d\mathbf{R}}{dt}(t) \cdot \mathbf{R}^{\mathrm{T}}(t) = \mathbf{W}(t), \quad t \in [t_0, \infty]\,, \tag{2.5.50}$$

has the analytical expression,

$$\mathbf{R}(t) = \exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau\Big) \cdot \mathbf{R}(t_0), \quad t \in [t_0, \infty]\,. \tag{2.5.51}$$

Indeed, for small Δt,

$$\begin{aligned}
\mathbf{R}(t+\Delta t) - \mathbf{R}(t) &= \Big(\exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau + \int_{t}^{t+\Delta t} \mathbf{W}(\tau) d\tau\Big) \;-\; \exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau\Big)\Big) \cdot \mathbf{R}(t_0) \\
&\simeq \Big(\exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau + \mathbf{W}(t)\Delta t\Big) \qquad - \exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau\Big)\Big) \cdot \mathbf{R}(t_0) \\
&= \Big(\exp\big(\mathbf{W}(t)\Delta t\big) \cdot \exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau\Big) - \exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau\Big)\Big) \cdot \mathbf{R}(t_0) \\
&\simeq \mathbf{W}(t)\Delta t \cdot \exp\Big(\int_{t_0}^{t} \mathbf{W}(\tau) d\tau\Big) \cdot \mathbf{R}(t_0) \\
&= \mathbf{W}(t)\Delta t \cdot \mathbf{R}(t)\,,
\end{aligned} \tag{2.5.52}$$

which shows that (2.5.51) is a solution of (2.5.50). The step from line 2 to line 3 has required $\mathbf{W}(t)$ and $\int_{t_0}^{t} \mathbf{W}(\tau)\, d\tau$ to commute: indeed, the relation $\exp(\mathbf{A}+\mathbf{B}) = \exp\mathbf{A} \cdot \exp\mathbf{B}$ holds only if the two second order tensors $\mathbf{A}$ and $\mathbf{B}$ commute. The step from line 3 to line 4 has used the series expansion of the exponential.

2.5.6 Infinitesimal strains

Assume the deformation gradient $\mathbf{F}$ associated with a displacement field $\mathbf{u}$ to be sufficiently small, so that the norm $|\mathbf{H}|$ of $\mathbf{H} = \mathbf{F} - \mathbf{I} = \mathbf{u}\overleftarrow{\boldsymbol{\nabla}}$ is much smaller than 1. The infinitesimal strain $\boldsymbol{\epsilon}$ and infinitesimal rotation $\boldsymbol{\omega}$ are defined respectively as the symmetric and skew-symmetric parts of $\mathbf{H}$, namely

$$\mathbf{H} = \boldsymbol{\epsilon} + \boldsymbol{\omega}, \quad \boldsymbol{\epsilon} = \frac{1}{2}\big(\mathbf{H} + \mathbf{H}^{\mathrm{T}}\big), \quad \boldsymbol{\omega} = \frac{1}{2}\big(\mathbf{H} - \mathbf{H}^{\mathrm{T}}\big)\,. \tag{2.5.53}$$

The Green strain expresses exactly in terms of $\boldsymbol{\epsilon}$ and $\boldsymbol{\omega}$,

$$\mathbf{E}_{\mathrm{G}} = \frac{1}{2}\,(\mathbf{F}^{\mathrm{T}} \cdot \mathbf{F} - \mathbf{I}) = \boldsymbol{\epsilon} + \frac{1}{2}\,\mathbf{H}^{\mathrm{T}} \cdot \mathbf{H} = \boldsymbol{\epsilon} + \frac{1}{2}\,(\boldsymbol{\epsilon}^2 + \boldsymbol{\epsilon} \cdot \boldsymbol{\omega} - \boldsymbol{\omega} \cdot \boldsymbol{\epsilon} - \boldsymbol{\omega}^2)\,, \tag{2.5.54}$$

and an exact expansion of $\det(\mathbf{I} + \mathbf{H})$ is derived in (2.2.34).

The polar decomposition $\mathbf{F} = \mathbf{R} \cdot \mathbf{U} = \mathbf{V} \cdot \mathbf{R}$ is approximated to first order by the expressions,

$$\mathbf{U} = \mathbf{I} + \boldsymbol{\epsilon} + O(|\mathbf{H}|^2), \quad \mathbf{V} = \mathbf{I} + \boldsymbol{\epsilon} + O(|\mathbf{H}|^2), \quad \mathbf{R} = \mathbf{I} + \boldsymbol{\omega} + O(|\mathbf{H}|^2)\,, \tag{2.5.55}$$

and $\det\mathbf{F} = 1 + \mathrm{tr}\,\boldsymbol{\epsilon} + O(|\mathbf{H}|^2)$.

Second order approximations may be derived as well, e.g., Casey [1985],

$$\begin{aligned}
\mathbf{F}^{-1} &= \mathbf{I} - \mathbf{H} + \mathbf{H}^2 + (O(|\mathbf{H}|^3), \\
\mathbf{U} &= \mathbf{I} + \boldsymbol{\epsilon} + \frac{1}{2}\,(\boldsymbol{\epsilon} \cdot \boldsymbol{\omega} - \boldsymbol{\omega} \cdot \boldsymbol{\epsilon} - \boldsymbol{\omega}^2) + (O(|\mathbf{H}|^3), \\
\mathbf{V} &= \mathbf{I} + \boldsymbol{\epsilon} - \frac{1}{2}\,(\boldsymbol{\epsilon} \cdot \boldsymbol{\omega} - \boldsymbol{\omega} \cdot \boldsymbol{\epsilon} + \boldsymbol{\omega}^2) + O(|\mathbf{H}|^3), \\
\mathbf{R} &= \mathbf{I} + \boldsymbol{\omega} - \frac{1}{2}\,(\boldsymbol{\epsilon} \cdot \boldsymbol{\omega} + \boldsymbol{\omega} \cdot \boldsymbol{\epsilon} - \boldsymbol{\omega}^2) + O(|\mathbf{H}|^3)\,.
\end{aligned} \tag{2.5.56}$$

Exercise 2.2 provides an instance where two motions have identical infinitesimal strains but distinct infinitesimal rotations.

2.5.7 Volume change and incompressibility

The relative volume change under a deformation gradient $\mathbf{F}$ is equal to $\det \mathbf{F}$, or $\sqrt{\det \mathbf{C}}$, with $\mathbf{C} = \mathbf{F}^{\mathrm{T}} \cdot \mathbf{F} = \mathbf{I} + 2\,\mathbf{E}_{\mathrm{G}}$ the right Cauchy-Green tensor. According to (2.2.34),

$$\det \mathbf{C} = \det \mathbf{F}^2 = \det\left(\mathbf{I} + 2\,\mathbf{E}_{\mathrm{G}}\right) = 1 + I_1(2\,\mathbf{E}_{\mathrm{G}}) + I_2(2\,\mathbf{E}_{\mathrm{G}}) + I_3(2\,\mathbf{E}_{\mathrm{G}})\,, \tag{2.5.57}$$

where the I's are the isotropic invariants of $2\,\mathbf{E}_{\mathrm{G}}$ defined in Section 2.2.2. For infinitesimal strains, $\det \mathbf{F}$ is thus equal to $1 + \operatorname{tr} \mathbf{E}_{\mathrm{G}}$ to first order wrt to $|\mathbf{E}_{\mathrm{G}}|$, that is, neglecting terms of the order of $|\mathbf{E}_{\mathrm{G}}|^2$ or higher. Therefore, for infinitesimal strains, the relative volume change is estimated by $\operatorname{tr} \mathbf{E}_{\mathrm{G}}$.

Let us turn now to finite strains, and consider an incompressible solid, namely one for which $\det \mathbf{F} = 1$ at any time. In this case, the above approximation and interpretation of $\operatorname{tr} \mathbf{E}_{\mathrm{G}}$ are no longer valid. Indeed, even the inequality $\operatorname{tr} \mathbf{E}_{\mathrm{G}} \geq 0$ does not imply that the volume change is positive.

But, why does this inequality hold? In fact, it results from the classical theorem of algebra that the arithmetic mean of n real positive numbers a_i is larger than their geometric mean,

$$\frac{1}{n}\left(a_1 + a_2 \cdots + a_n\right) \geq \sqrt[n]{a_1\, a_2 \cdots a_n}\,, \tag{2.5.58}$$

with equality only if all the a's are equal. Applied to the three (positive) eigenvalues of the right Cauchy-Green tensor, this inequality yields,

$$\frac{1}{3}\operatorname{tr} \mathbf{C} = \frac{1}{3}\left(3 + 2\operatorname{tr} \mathbf{E}_{\mathrm{G}}\right) \geq \sqrt[3]{\det \mathbf{C}} = 1 \quad \Rightarrow \quad \operatorname{tr} \mathbf{C} \geq 3, \quad \operatorname{tr} \mathbf{E}_{\mathrm{G}} \geq 0\,. \tag{2.5.59}$$

Actually, we know more: for positive real numbers, the arithmetic mean is larger than the geometric mean, which itself is larger than the harmonic mean,

$$\frac{1}{n}\left(a_1 + a_2 \cdots + a_n\right) \geq \sqrt[n]{a_1\, a_2 \cdots a_n} \geq \frac{n}{\dfrac{1}{a_1} + \dfrac{1}{a_2} \cdots + \dfrac{1}{a_n}}\,. \tag{2.5.60}$$

These inequalities have interesting consequences for the scalar invariants of second order tensors.

2.6 Transports between reference and current configurations

The motion of the points $\mathbf{x}$ of the solid animated with the velocity $\mathbf{v}_s$ is tracked by the deformation gradient $\mathbf{F}$ measured with respect to a reference configuration. Entities and operators reckoned from the reference configuration are underlined. The motion is considered to shift the point $\underline{\mathbf{x}} = (\underline{x}_I)$ in the reference configuration to its current position $\mathbf{x} = (x_i)$. Differential operators are reckoned from either configuration. For example, for a generic entity ψ, the gradient with respect to the current configuration $\boldsymbol{\nabla}\psi = \partial\psi/\partial\mathbf{x}$ becomes with respect to the reference configuration $\underline{\boldsymbol{\nabla}}\psi = \partial\psi/\partial\underline{\mathbf{x}} = \boldsymbol{\nabla}\psi \cdot \mathbf{F}$.

• **Elementary surface and volume**:

The vector product of any two vectors $\mathbf{a}$ and $\mathbf{b}$ represents the oriented area of the underlying parallelepiped. In the cartesian axes $\{\mathbf{e}_i,\, i \in [1,3]\}$, it is defined componentwise via the permutation symbol e_{ijk},

$$\mathbf{a} \wedge \mathbf{b} = e_{ijk}\, a_i\, b_j\, \mathbf{e}_k\,. \tag{2.6.1}$$

Let $(d\underline{\mathbf{x}}_1, d\underline{\mathbf{x}}_2, d\underline{\mathbf{x}}_3)$ be a triad of infinitesimal vectors, and $(d\mathbf{x}_1, d\mathbf{x}_2, d\mathbf{x}_3)$ their image under the transformation of gradient $\mathbf{F}$. Then the elementary volumes defined by these triads transform as follows,

$$d\underline{V} = (d\underline{\mathbf{x}}_1 \wedge d\underline{\mathbf{x}}_2) \cdot d\underline{\mathbf{x}}_3 \quad \overset{\mathbf{F}}{\longmapsto} \quad dV = (d\mathbf{x}_1 \wedge d\mathbf{x}_2) \cdot d\mathbf{x}_3\,. \tag{2.6.2}$$

• **Transformation of a material volume and relations with determinants**:

According to (2.1.15), the determinant of the second order tensor $\mathbf{F}$ with components F_{iI} in cartesian axes satisfies, for any $(I, J, K) \in [1,3]$, (note: $e_{IJK}e_{IJK} = 3!$),

$$e_{IJK} \det \mathbf{F} = e_{ijk}\, F_{iI}\, F_{jJ}\, F_{kK} \Rightarrow \det \mathbf{F} = e_{ijk}\, F_{i1}\, F_{j2}\, F_{k3} \text{ and } \det \mathbf{F} = \frac{1}{3!}\, e_{ijk}\, e_{IJK}\, F_{iI}\, F_{jJ}\, F_{kK}\,. \tag{2.6.3}$$

From the definitions of an area and of a determinant results the rule of transformation of volume,

$$dV = \det \mathbf{F}\, d\underline{V}\,. \tag{2.6.4}$$

Indeed

$$\begin{aligned}(\mathbf{a}\wedge\mathbf{b})\cdot\mathbf{c} &= e_{ijk}\, a_i\, b_j\, c_k \\ &= e_{ijk}\, F_{iI}\, \underline{a}_I\, F_{jJ}\, \underline{b}_J\, F_{kK}\, \underline{c}_K \\ &= e_{IJK} \det \mathbf{F}\, \underline{a}_I\, \underline{b}_J\, \underline{c}_K \\ &= \det \mathbf{F}\ (\underline{\mathbf{a}}\wedge\underline{\mathbf{b}})\cdot\underline{\mathbf{c}} \quad \square\,.\end{aligned} \tag{2.6.5}$$

Therefore,

$$\int_V \psi\ dV = \int_{\underline{V}} \det \mathbf{F}\, \psi\ d\underline{V}\,. \tag{2.6.6}$$

Two additional differential relations are recorded, see, e.g., Bowen [1989], p. 45, for a proof:

$$\underline{\mathrm{div}}\ \Big((\det \mathbf{F})\, \mathbf{F}^{-\mathrm{T}}\Big) = \mathbf{0}, \quad \mathrm{div}\ \Big((\det \mathbf{F}^{-1})\, \mathbf{F}^{\mathrm{T}}\Big) = \mathbf{0}\,. \tag{2.6.7}$$

Here the differential operators are the right divergence, namely componentwise,

$$\frac{\partial}{\partial \underline{x}_I}\Big(\det \mathbf{F}\, \frac{\partial \underline{x}_I}{\partial x_i}\Big) = 0, \quad \frac{\partial}{\partial x_i}\Big(\det \mathbf{F}^{-1}\, \frac{\partial x_i}{\partial \underline{x}_I}\Big) = 0\,. \tag{2.6.8}$$

• **Transformation of a material surface, Nanson's rule**:

Let $d\underline{\mathbf{S}}$ be the elementary material area and $d\mathbf{S}$ the transformed area under the transformation of gradient $\mathbf{F}$. Then

$$d\mathbf{S} = \det \mathbf{F}\, \mathbf{F}^{-\mathrm{T}}\cdot d\underline{\mathbf{S}} = \det \mathbf{F}\, d\underline{\mathbf{S}}\cdot \mathbf{F}^{-1}\,. \tag{2.6.9}$$

Proof: Let $d\underline{\mathbf{S}} = d\underline{\mathbf{a}}\wedge d\underline{\mathbf{b}}$ and $d\mathbf{S} = d\mathbf{a}\wedge d\mathbf{b}$ with $d\mathbf{a} = \mathbf{F}\cdot d\underline{\mathbf{a}}$ and $d\mathbf{b} = \mathbf{F}\cdot d\underline{\mathbf{b}}$. Then

$$\begin{aligned}d\mathbf{S}\cdot\mathbf{F} &= (e_{ijk}\, da_i\, db_j\, \mathbf{e}_k)\cdot(F_{lL}\mathbf{e}_l\otimes\mathbf{e}_L) \\ &= e_{ijk}\, F_{iI} F_{jJ} F_{kK}\, d\underline{a}_I\, d\underline{b}_J\, \mathbf{e}_K \\ &= e_{IJK} \det \mathbf{F}\, d\underline{a}_I\, d\underline{b}_J\, \mathbf{e}_K \\ &= \det \mathbf{F}\, d\underline{\mathbf{a}}\wedge d\underline{\mathbf{b}} \\ &= \det \mathbf{F}\, d\underline{\mathbf{S}} \quad \square\,.\end{aligned} \tag{2.6.10}$$

Alternatively,

$$\begin{aligned}dV &= \det \mathbf{F}\, d\underline{V} \\ d\mathbf{S}\cdot d\mathbf{c} &= \det \mathbf{F}\, d\underline{\mathbf{S}}\cdot d\underline{\mathbf{c}} \\ &= \det \mathbf{F}\, d\underline{\mathbf{S}}\cdot \mathbf{F}^{-1}\cdot d\mathbf{c}\end{aligned} \tag{2.6.11}$$

which holds for any $d\mathbf{c}$ $\square$.

• **Conservation of flux**:

Let $\underline{\mathbf{M}}$ and $\mathbf{M}$ be the fluxes of matter per unit reference area and per unit current area, respectively. The conservation of the flux,

$$\underline{\mathbf{M}}\cdot d\underline{\mathbf{S}} = \mathbf{M}\cdot d\mathbf{S}\,, \tag{2.6.12}$$

together with the transformation rule for areas (2.6.9), implies the relation,

$$\underline{\mathbf{M}} = \det \mathbf{F}\, \mathbf{F}^{-1}\cdot\mathbf{M} = \det \mathbf{F}\, \mathbf{M}\cdot\mathbf{F}^{-\mathrm{T}}, \quad \mathbf{M} = \det \mathbf{F}^{-1}\, \mathbf{F}\cdot\underline{\mathbf{M}}\,. \tag{2.6.13}$$

Note also the conservation relation for the divergence of a flux,

$$\underline{\mathrm{div}}\ \underline{\mathbf{M}} = \det \mathbf{F}\, \mathrm{div}\, \mathbf{M}\,. \tag{2.6.14}$$

Indeed, using (2.6.13),

$$\begin{aligned}
\underline{\mathrm{div}}\ \underline{\mathbf{M}} &= \underline{\mathrm{div}}\left(\mathbf{M}\cdot(\det\mathbf{F}\,\mathbf{F}^{-\mathrm{T}})\right)\\
&= \frac{\partial}{\partial\underline{x}_I}\left(M_i\det\mathbf{F}\,(\mathbf{F}^{-1})_{iI}\right)\\
&= \frac{\partial M_i}{\partial\underline{x}_I}\det\mathbf{F}\,(\mathbf{F}^{-1})_{iI}+M_i\frac{\partial}{\partial\underline{x}_I}\left(\det\mathbf{F}\,(\mathbf{F}^{-1})_{iI}\right)\\
&\overset{(2.6.7)}{=} \frac{\partial M_i}{\partial\underline{x}_I}\det\mathbf{F}\,\frac{\partial\underline{x}_I}{\partial x_i}\\
&= \frac{\partial M_i}{\partial x_i}\det\mathbf{F}\\
&= \det\mathbf{F}\,\mathrm{div}\,\mathbf{M}\quad\square\,.
\end{aligned}\tag{2.6.15}$$

• **Conservation of traction**:
The balance of momentum in the reference configuration is phrased in terms of the first Piola-Kirchhoff stress $\underline{\boldsymbol{\tau}}$ which is such that traction is conserved,

$$\boldsymbol{\sigma}\cdot d\mathbf{S}=\underline{\boldsymbol{\tau}}\cdot d\underline{\mathbf{S}},\tag{2.6.16}$$

and therefore with the rule of transformation of areas,

$$\underline{\boldsymbol{\tau}}=\det\mathbf{F}\,\boldsymbol{\sigma}\cdot\mathbf{F}^{-\mathrm{T}},\quad \boldsymbol{\sigma}=\det\mathbf{F}^{-1}\,\underline{\boldsymbol{\tau}}\cdot\mathbf{F}^{\mathrm{T}}\,.\tag{2.6.17}$$

Similarly to (2.6.14), the transformation rule for the divergence operator takes the form,

$$\underline{\mathrm{div}}\ \underline{\boldsymbol{\tau}}=\det\mathbf{F}\,\mathrm{div}\ \boldsymbol{\sigma}\,,\tag{2.6.18}$$

which is a direct consequence of (2.6.7).

• **Conservation of mass and energy**:
Let us envisage a pure change of configuration, at constant mass,

$$dM=\rho\,dV=d\underline{M}=\underline{\rho}\,d\underline{V}\,,\tag{2.6.19}$$

so that the current and reference mass densities vary as indicated by the volume change,

$$\rho\mapsto\underline{\rho}=\rho\det\mathbf{F}\,.\tag{2.6.20}$$

Material properties, like the energies, can be defined per unit current volume V, unit reference (or initial) volume $\underline{V}$, unit current mass M or unit reference mass $\underline{M}$. They are denoted respectively by Ψ, $\underline{\Psi}$ and ψ and $\underline{\psi}$. Conservation of energy under a change of configuration implies

$$\Psi\,V=\underline{\Psi}\,\underline{V}=\psi\,M=\underline{\psi}\,\underline{M}\,.\tag{2.6.21}$$

Under a change of volume only, the entities measured per unit volume change like the mass density while the entities measured per unit mass are not modified, e.g.,

$$\Psi\mapsto\underline{\Psi}=\Psi\det\mathbf{F},\quad \psi\mapsto\underline{\psi}=\psi\,.\tag{2.6.22}$$

In a mixture, both internal mass and energy exchanges between species and mass and energy exchanges with the surroundings may take place. These phenomena are considered in Chapter 4. While certain properties Ψ^k attached to the species k are measured per unit (current or reference) volume of the mixture, the corresponding properties ψ_k are measured per unit (current or reference) mass of the species. Instances are internal energy, free energy, enthalpy, entropy, etc. The notation (2.6.21) is extended so as to involve the total volume of the mixture and not the volume of the species[2.7],

$$\Psi^k\,V=\underline{\Psi}^k\,\underline{V}=\psi_k\,M_k=\underline{\psi}_k\,\underline{M}_k\,.\tag{2.6.23}$$

[2.7] The convention of summation over repeated indices does not apply in Eqns (2.6.23), (2.6.24) and (2.6.25).

• **Mass and volume contents**:

In order to avoid confusion of notation, for any species k, Biot's approach to mixtures introduces besides the intrinsic and partial densities, ρ_k and ρ^k respectively, and *volume fractions* n^k,

$$\rho_k \equiv \frac{M_k}{V_k}, \quad \rho^k \equiv \frac{M_k}{V}, \quad n^k \equiv \frac{V_k}{V}, \quad \rho^k = n^k \, \rho_k \,, \tag{2.6.24}$$

the *mass contents* m^k and *volume contents* v^k which are defined per unit *reference* volume,

$$m^k \equiv \frac{M_k}{\underline{V}} = \rho^k \det \mathbf{F}, \quad v^k \equiv \frac{V_k}{\underline{V}} = n^k \det \mathbf{F}, \quad m^k = v^k \, \rho_k \,. \tag{2.6.25}$$

The mass content of the mixture as a whole differs from its mass density,

$$m \equiv \frac{M}{\underline{V}} = \rho \det \mathbf{F} \neq \rho \equiv \frac{M}{V} \,. \tag{2.6.26}$$

Leaving aside diffusion, the density $\underline{\rho}^k$ of the species k in the reference configuration, say at time $t = 0$, will be different from the mass content m^k, i.e., the current mass per unit reference volume, if internal mass transfer and/or growth take place. Similarly, the density of the mixture in the reference configuration $\underline{\rho}$ is different from the mass content m if growth takes place.

2.7 Time derivatives and Reynolds theorems

Let $\Psi = \Psi(\mathbf{x}, t)$ be a sufficiently smooth field in a volume V so that there is no *discontinuity surface* of the gradient $\partial\Psi/\partial\mathbf{x}$ crossing the volume.

• **Material time derivatives**:

In a mixture context, besides the partial time derivative $\partial\,/\partial t$, two types of material time derivatives will be used, namely $D\,/Dt$ and $d^k\,/dt$ following respectively the mass center of the mixture with velocity $\mathbf{v}$ and the particles of species k with velocity $\mathbf{v}_k$,

$$\frac{D\Psi}{Dt} = \frac{\partial\Psi}{\partial t} + \boldsymbol{\nabla}\Psi \cdot \mathbf{v}; \quad \frac{d^k\Psi}{dt} = \frac{\partial\Psi}{\partial t} + \boldsymbol{\nabla}\Psi \cdot \mathbf{v}_k, \quad k \in \mathcal{K} \,. \tag{2.7.1}$$

To simplify the notation, $d^{\mathrm{s}}\,/dt$ is noted $d\,/dt$.

Repeated use will be made of the rate formula,

$$\frac{d}{dt}\det \mathbf{F} = \det \mathbf{F} \, \mathrm{tr} \, \frac{d\mathbf{F}}{dt} \cdot \mathbf{F}^{-1} = \det \mathbf{F} \, \mathrm{div} \, \mathbf{v}_{\mathrm{s}} \,. \tag{2.7.2}$$

To prove this relation, let us consider the spectral decomposition of $\mathbf{F}$. Then $\det \mathbf{F} = F_1 \, F_2 \, F_3$. Since $\mathbf{F}$ is assumed invertible, it makes sense to consider the time derivative of $\mathrm{Ln} \det \mathbf{F}$. The result (2.7.2) follows directly. As a direct consequence of (2.7.2),

$$\frac{\partial \det \mathbf{F}}{\partial \mathbf{F}} = \det \mathbf{F} \; \mathbf{F}^{-\mathrm{T}}, \quad \frac{\partial \det \mathbf{F}}{\partial \mathbf{E}_{\mathrm{G}}} = \det \mathbf{F} \; \mathbf{F}^{-1} \cdot \mathbf{F}^{-\mathrm{T}}, \quad \frac{\partial \det \mathbf{C}}{\partial \mathbf{C}} = \det \mathbf{C} \; \mathbf{C}^{-1} \,. \tag{2.7.3}$$

As an immediate consequence for any scalar X,

$$\frac{\partial X}{\partial \mathbf{E}_{\mathrm{G}}} = \frac{1}{\det \mathbf{F}} \frac{\partial (\det \mathbf{F} \, X)}{\partial \mathbf{E}_{\mathrm{G}}} - X \, \mathbf{F}^{-1} \cdot \mathbf{F}^{-\mathrm{T}} \,, \tag{2.7.4}$$

which is instrumental when expressing energies in distinct configurations.

• **Generalized Reynolds theorem**:

Let

- $V = V(t)$ be a mobile volume; the points of its surface $\partial V(t)$ have the velocity $\mathbf{v}_k$;
- $\mathbf{v}_{\mathrm{s}}$ be the velocity of the material point $\mathbf{x}$.

Then

$$\begin{aligned}
\frac{d}{dt}\int_V \Psi\, dV &= \frac{d}{dt}\int_{\underline{V}} \Psi \det \mathbf{F}\, d\underline{V} \\
&= \int_{\underline{V}} \frac{d}{dt}(\Psi \det \mathbf{F})\, d\underline{V} + \int_{\partial \underline{V}} \Psi \det \mathbf{F}\, \big(\mathbf{F}^{-1}\cdot(\mathbf{v}_k - \mathbf{v}_s)\big)\cdot d\underline{\mathbf{S}} \\
&= \int_V \frac{d\Psi}{dt} + \Psi \operatorname{div} \mathbf{v}_s\, dV + \int_{\partial V} \Psi\,(\mathbf{v}_k - \mathbf{v}_s)\cdot d\mathbf{S} \\
&= \int_V \frac{\partial \Psi}{\partial t} + \operatorname{div}\,(\Psi\, \mathbf{v}_s)\, dV + \int_{\partial V} \Psi\,(\mathbf{v}_k - \mathbf{v}_s)\cdot d\mathbf{S} \\
&= \int_V \frac{\partial \Psi}{\partial t}\, dV + \int_{\partial V} \Psi\, \mathbf{v}_k \cdot d\mathbf{S} \\
&= \int_V \frac{\partial \Psi}{\partial t} + \operatorname{div}\,(\Psi\, \mathbf{v}_k)\, dV
\end{aligned} \tag{2.7.5}$$

Indeed, the second line and the line before last can be interpreted as follows: the rate of change of the integral is equal to the integral of the rate of change of the integrand plus the variation due to the incoming and outgoing fluxes. Green's theorem has been used repeatedly.

• **Reynolds theorem**:

If V is a *material volume*, then $\mathbf{v}_k = \mathbf{v}_s$, and the above relation simplifies to Reynolds theorem:

$$\frac{d}{dt}\int_V \Psi\, dV = \int_V \frac{\partial \Psi}{\partial t}\, dV + \int_{\partial V} \Psi\, \mathbf{v}_s \cdot d\mathbf{S}\,. \tag{2.7.6}$$

• **Time derivatives of a material line/surface**:

Along a closed *material* curve $\mathcal{C}$ and along a *material* surface S where points $\mathbf{x}$ have velocity $\mathbf{v}$ and velocity gradient $\mathbf{L} = \partial \mathbf{v}/\partial \mathbf{x} = \boldsymbol{\nabla}\mathbf{v}$, the material time derivatives of the differential increment $d\mathbf{x} = \mathbf{v}\, dt$ and of the differential area $d\mathbf{S}$ write

$$\frac{d}{dt}\big(d\mathbf{x}\big) = d\mathbf{v}, \quad \frac{d}{dt}\big(d\mathbf{S}\big) = \big(\operatorname{div}\mathbf{v}\ \mathbf{I} - \mathbf{L}^{\mathrm{T}}\big)\cdot d\mathbf{S}\,, \tag{2.7.7}$$

due to (2.6.9) and (2.7.2). Whence the material time derivatives of a material curve and material surface,

$$\begin{aligned}
\frac{d}{dt}\oint_{\mathcal{C}} \Phi\, d\mathbf{x} &= \oint_{\mathcal{C}} \big(\frac{d\Phi}{dt}\,\mathbf{I} + \Phi\,\mathbf{L}\big)\cdot d\mathbf{x} = \oint_{\mathcal{C}} \frac{d\Phi}{dt}\, d\mathbf{x} + \Phi\, d\mathbf{v}, \\
\frac{d}{dt}\int_S \Phi\, d\mathbf{S} &= \int_S \Big(\big(\frac{d\Phi}{dt} + \Phi \operatorname{div}\mathbf{v}\big)\,\mathbf{I} - \Phi\,\mathbf{L}^{\mathrm{T}}\Big)\cdot d\mathbf{S}\,,
\end{aligned} \tag{2.7.8}$$

for Φ sufficiently regular scalar, or arbitrary tensor with appropriate notations.

• **Circulation, theorems of Kelvin and Helmholtz**:

As an application of (2.7.8), we may consider the concept of *circulation*,

$$C(t) \equiv \oint_{\mathcal{C}} \mathbf{v}\cdot d\mathbf{x}\,, \tag{2.7.9}$$

along the closed material curve $\mathcal{C}$. For an inviscid fluid, subjected to conservative body forces as defined by (2.4.19), the *theorem of Kelvin* provides an estimate of this line integral in terms of the pressure p and mass density ρ,

$$\frac{dC(t)}{dt} = -\oint_{\mathcal{C}} \frac{dp}{\rho}\,, \tag{2.7.10}$$

while the *theorem of Helmholtz* indicates that the integral vanishes,

$$\frac{dC(t)}{dt} = 0\,, \tag{2.7.11}$$

if the fluid is inviscid barotropic (its mass density depends only on the pressure $\rho = \rho(p)$). Therefore the circulation is constant in time, $C(t) = C(t_0)$. If this constant is zero, the velocity $\mathbf{v}$ derives from a potential, and therefore the vorticity vector $\boldsymbol{\nabla}\wedge\mathbf{v}$ vanishes due to Stokes theorem $(2.4.13)_2$ and therefore the flow is irrotational. These theorems are addressed in Section 15.7.1.

2.8 Work-conjugate stress-strain pairs

The first Piola-Kirchhoff stress $\underline{\boldsymbol{\tau}} = (\underline{\tau}_{iJ})$ defined by (2.6.17) is not symmetric (the first Piola-Kirchhoff stress is sometimes defined as the transpose of the entity used here), but the symmetry of the Cauchy stress implies relations between its components and those of the deformation gradient. The Kirchhoff stress $\boldsymbol{\tau}$,

$$\boldsymbol{\tau} = \det \mathbf{F}\, \boldsymbol{\sigma} = \underline{\boldsymbol{\tau}} \cdot \mathbf{F}^{\mathrm{T}} = \mathbf{F} \cdot \underline{\boldsymbol{\tau}}^{\mathrm{T}} \,, \tag{2.8.1}$$

is indeed symmetric.

Various stress measures are obtained by considering the purely mechanical incremental work $\underline{\mathcal{W}}$ measured per unit *reference volume* which can be expressed in terms of the generic work-conjugate stress-strain pair ($\mathbf{T}$, $\mathbf{E}$) as

$$\delta \underline{\mathcal{W}} = \mathbf{T} : \delta \mathbf{E}, \quad \text{or} \quad \frac{d\underline{\mathcal{W}}}{dt} = \mathbf{T} : \frac{d\mathbf{E}}{dt} \,. \tag{2.8.2}$$

The most common work-conjugate pairs are the following:

- the 1st Piola-Kirchhoff stress $\underline{\boldsymbol{\tau}}$ and the deformation gradient $\mathbf{F}$;
- the 2nd Piola-Kirchhoff stress

$$\underline{\underline{\boldsymbol{\tau}}} = \mathbf{F}^{-1} \cdot \underline{\boldsymbol{\tau}} = \mathbf{F}^{-1} \cdot \boldsymbol{\tau} \cdot \mathbf{F}^{-\mathrm{T}} \,, \tag{2.8.3}$$

  and the Green strain

$$\mathbf{E}_{\mathrm{G}} = \frac{1}{2} \left(\mathbf{F}^{\mathrm{T}} \cdot \mathbf{F} - \mathbf{I} \right) , \tag{2.8.4}$$

- the covariant Piola-Kirchhoff stress

$$\underline{\underline{\boldsymbol{\tau}}}_{c} = \mathbf{F}^{\mathrm{T}} \cdot \boldsymbol{\tau} \cdot \mathbf{F} \,, \tag{2.8.5}$$

  and the contravariant Almansi strain

$$\mathbf{E}^{\mathrm{ct}}_{\mathrm{A}} = \frac{1}{2} \left(\mathbf{I} - (\mathbf{F}^{\mathrm{T}} \cdot \mathbf{F})^{-1} \right) . \tag{2.8.6}$$

Indeed

$$\frac{d\underline{\mathcal{W}}}{dt} = \underline{\boldsymbol{\tau}} : \frac{d\mathbf{F}}{dt} = \underline{\underline{\boldsymbol{\tau}}} : \frac{d\mathbf{E}_{\mathrm{G}}}{dt} = \underline{\underline{\boldsymbol{\tau}}}_{c} : \frac{d\mathbf{E}^{\mathrm{ct}}_{\mathrm{A}}}{dt} = \boldsymbol{\tau} : \mathbf{D} \,. \tag{2.8.7}$$

2.8.1 Stress conjugate to a given Lagrangian strain measure

Hill [1970] has provided a method to define the stress $\mathbf{T}$ conjugate to a given Lagrangian strain $\mathbf{E}$ of the class defined by the function f as in (2.5.11). Indeed, consider the symmetric stress with components $\underline{\underline{T}}_{ij}$ on the Lagrangian strain ellipsoid,

$$\mathbf{T} = \sum_{i,j} \underline{\underline{T}}_{ij}\, \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \,. \tag{2.8.8}$$

The components of the strain rate $d\mathbf{E}/dt$ being given in explicit form by (2.5.22), work-conjugacy $\mathbf{T} : d\mathbf{E}/dt = \boldsymbol{\tau} : \mathbf{D}$ implies,

$$\sum_{i,j} \underline{\underline{T}}_{ij} \Big(\frac{df(\lambda_i)}{d\lambda_i}\, \lambda_i\, D_{ii}\, I_{ij} + 2\, \lambda_i\, \lambda_j\, \frac{f(\lambda_i) - f(\lambda_j)}{\lambda_i^2 - \lambda_j^2}\, D_{ij} \Big) = \sum_{i,j} \tau_{ij}\, D_{ij} \,, \tag{2.8.9}$$

from which follow the relations, Eqn (24) in Hill [1970],

$$\underline{\underline{T}}_{\underline{ii}} = \frac{\tau_{ii}}{\lambda_i\, df(\lambda_i)/d\lambda_i}, \quad i \in [1,3]; \quad \underline{\underline{T}}_{ij} = \begin{cases} \dfrac{\lambda_i^2 - \lambda_j^2}{f(\lambda_i) - f(\lambda_j)} \dfrac{\tau_{ij}}{2\,\lambda_i\,\lambda_j}, & \lambda_i \neq \lambda_j, \\ \dfrac{\tau_{ij}}{\lambda_i\, df(\lambda_i)/d\lambda}, & \lambda_i = \lambda_j \,, \end{cases} \quad i \neq j \in [1,3]. \tag{2.8.10}$$

The convention of summation over repeated indices does not apply in (2.8.10). The proof rests on the assumption that the principal axes of the strain ellipsoid are well defined, that is, that the principal stretches are distinct.

The general explicit expression of the stress conjugate to $\mathrm{Ln}\,\mathbf{U}$ has been derived by Hoger [1987]: it is unfortunately hardly tractable.

2.8.2 Issues related to the logarithmic strain

There is no measure of strain whose material derivative $d\mathbf{E}/dt$ is equal to an arbitrary rate of deformation $\mathbf{D}$. Therefore there is no measure of strain directly conjugated to Kirchhoff stress $\boldsymbol{\tau}$. Still, the logarithm of the left stretch of the deformation gradient $\operatorname{Ln}\mathbf{V}$ is a serious candidate. The conditions under which it is indeed a strain measure conjugate to Kirchhoff stress have been considered along several lines.

Perhaps the simplest condition is that of coaxiality between the Kirchhoff stress and the logarithmic strain. This property holds in particular for isotropic elasticity where the Kirchhoff stress depends linearly on $\mathbf{I}$, $\operatorname{Ln}\mathbf{V}$ and $(\operatorname{Ln}\mathbf{V})^2$, namely

$$\boldsymbol{\tau} = a_1\,\mathbf{I} + a_2\operatorname{Ln}\mathbf{V} + a_3\,(\operatorname{Ln}\mathbf{V})^2\,, \tag{2.8.11}$$

with coefficients a_1, a_2, and a_3 that are functions of the three scalar isotropic invariants of $\operatorname{Ln}\mathbf{V}$.

The logarithm of the left stretch $\operatorname{Ln}\mathbf{V}$ is a member of the Eulerian measures defined in Section 2.5.3. Some useful relations follow from its spectral decomposition over the principal axes of the Eulerian strain ellipsoid, whose rate of rotation is denoted by $\boldsymbol{\Omega}^{\mathrm{E}}$,

$$\begin{aligned}
&\operatorname{Ln}\mathbf{V} = \sum_{i=1,3} \operatorname{Ln}\lambda_i\ \mathbf{e}_i\otimes\mathbf{e}_i\,,\\
&\frac{d}{dt}\operatorname{Ln}\mathbf{V} = \sum_{i=1,3} \frac{1}{\lambda_i}\frac{d\lambda_i}{dt}\ \mathbf{e}_i\otimes\mathbf{e}_i + \operatorname{Ln}\lambda_i\ \boldsymbol{\Omega}^{\mathrm{E}}\cdot\mathbf{e}_i\otimes\mathbf{e}_i + \operatorname{Ln}\lambda_i\ \mathbf{e}_i\otimes\boldsymbol{\Omega}^{\mathrm{E}}\cdot\mathbf{e}_i\,,\\
&\mathbf{e}_i\cdot\frac{d}{dt}\operatorname{Ln}\mathbf{V}\cdot\mathbf{e}_i = \frac{1}{\lambda_i}\frac{d\lambda_i}{dt},\quad i\in[1,3]\,.
\end{aligned} \tag{2.8.12}$$

Now assume the Kirchhoff stress $\boldsymbol{\tau} = \sum_i \tau_{ii}\,\mathbf{e}_i\otimes\mathbf{e}_i$ to be coaxial with the Eulerian strain ellipsoid. Consequently $\boldsymbol{\tau}:\mathbf{D} = \sum_i \tau_{ii}\,D_{ii}$ and $\boldsymbol{\tau}:d\operatorname{Ln}\mathbf{V}/dt = \sum_i \tau_{ii}\,\mathbf{e}_i\cdot d\operatorname{Ln}\mathbf{V}/dt\cdot\mathbf{e}_i$. In view of (2.5.21), $d\operatorname{Ln}\lambda_i/dt$ is equal to the Eulerian component D_{ii} of the rate of deformation, and, according to (2.8.12), $\mathbf{e}_i\cdot d\operatorname{Ln}\mathbf{V}dt\cdot\mathbf{e}_i = d\operatorname{Ln}\lambda_i/dt$. Therefore,

$$\boldsymbol{\tau}:\mathbf{D} = \boldsymbol{\tau}:\frac{d\operatorname{Ln}\mathbf{V}}{dt}\,, \tag{2.8.13}$$

that is, the logarithmic strain is work-conjugate to the Kirchhoff stress, Xiao and Chen [2003].

Here is another proof of (2.8.13) that does not use the relation (2.5.21). Gurtin and Spear [1983] have tried to link the rate of deformation to a corotational derivative. In fact, they obtain the following relation,

$$\mathbf{D} = \frac{d\operatorname{Ln}\mathbf{V}}{dt} + \operatorname{Ln}\mathbf{V}\cdot\boldsymbol{\Omega} - \boldsymbol{\Omega}\cdot\operatorname{Ln}\mathbf{V} - \frac{1}{2}\big(\mathbf{F}\cdot\boldsymbol{\Omega}^{\mathrm{L}}\cdot\mathbf{F}^{-1} + (\mathbf{F}\cdot\boldsymbol{\Omega}^{\mathrm{L}}\cdot\mathbf{F}^{-1})^{\mathrm{T}}\big)\,. \tag{2.8.14}$$

Consequently,

$$\begin{aligned}
\boldsymbol{\tau}:\mathbf{D} \;&=\; \boldsymbol{\tau}:\frac{d\operatorname{Ln}\mathbf{V}}{dt}\\
&+\; (\boldsymbol{\tau}\cdot\operatorname{Ln}\mathbf{V} - \operatorname{Ln}\mathbf{V}\cdot\boldsymbol{\tau}):\boldsymbol{\Omega} + \frac{1}{2}\big(\mathbf{F}^{-1}\cdot\boldsymbol{\tau}\cdot\mathbf{F} - (\mathbf{F}^{-1}\cdot\boldsymbol{\tau}\cdot\mathbf{F})^{\mathrm{T}}\big):\boldsymbol{\Omega}^{\mathrm{L}}\,.
\end{aligned} \tag{2.8.15}$$

As we have seen just above, the second scalar product on the rhs cancels if the coaxiality property holds. The third does as well because $\mathbf{F}^{-1}\cdot\boldsymbol{\tau}\cdot\mathbf{F} = \sum_i \tau_{ii}\,\mathbf{e}_i\otimes\mathbf{e}_i$ is symmetric.

Finally, here is another consequence of coaxiality. Taking the time derivative of (2.5.10), the rotated Kirchhoff stress is seen to be work-conjugate to the Lagrangian logarithmic strain. Indeed,

$$\begin{aligned}
\boldsymbol{\tau}:\frac{d\operatorname{Ln}\mathbf{V}}{dt} \;&=\; (\mathbf{Q}^{\mathrm{T}}\cdot\boldsymbol{\tau}\cdot\mathbf{Q}):\frac{d\operatorname{Ln}\mathbf{U}}{dt} + \boldsymbol{\tau}:\big(\boldsymbol{\Omega}\cdot\operatorname{Ln}\mathbf{V} - \operatorname{Ln}\mathbf{V}\cdot\boldsymbol{\Omega}\big)\\
&=\; (\mathbf{Q}^{\mathrm{T}}\cdot\boldsymbol{\tau}\cdot\mathbf{Q}):\frac{d\operatorname{Ln}\mathbf{U}}{dt} + (\boldsymbol{\tau}\cdot\operatorname{Ln}\mathbf{V} - \operatorname{Ln}\mathbf{V}\cdot\boldsymbol{\tau}):\boldsymbol{\Omega}\\
&=\; (\mathbf{Q}^{\mathrm{T}}\cdot\boldsymbol{\tau}\cdot\mathbf{Q}):\frac{d\operatorname{Ln}\mathbf{U}}{dt}\,,
\end{aligned} \tag{2.8.16}$$

where $\boldsymbol{\Omega} = d\mathbf{Q}/dt\cdot\mathbf{Q}^{-1}$. The last line is due to the fact, since $\boldsymbol{\tau}$ and $\operatorname{Ln}\mathbf{V}$ are coaxial, they commute.

The above discussion was concerned with conjugate stress-strain measures. Interesting properties related to rates of the logarithmic strain may be recorded. Gurtin and Spear [1983] have shown that, when the axes of the Lagrangian strain ellipsoid are fixed, namely $\boldsymbol{\Omega}^{\mathrm{L}} = \mathbf{0}$, there exist at least two corotational derivatives which are equal

to the rate of deformation. The corresponding spins are the rate of rotation of the Eulerian strain ellipsoid $\mathbf{\Omega}^{\mathrm{E}}$ and $\mathbf{W} = (\mathbf{L} - \mathbf{L}^{\mathrm{T}})/2$ associated with the Jaumann rate. As a more general result, Xiao et al. [1997] have established that there always exist a single corotational derivative and a single strain measure, namely the logarithmic strain $\mathrm{Ln}\,\mathbf{V}$, such that the corotational derivative of this strain is equal to the rate of deformation $\mathbf{D}$. However the spin defining the derivative is complex, their Eqn (38). By contrast, Bruhns et al. [2004] show that there exist infinitely many non corotational derivatives of all strain measures of the class (2.5.11) which are equal to the rate of deformation $\mathbf{D}$. The Oldroyd rates of the Finger strain and of the covariant Almansi strain are noticeable examples.

2.9 Small upon large

Small perturbations upon a finitely deformed solid may be used to gain information on the dependence of its mechanical properties with respect to its deformation. Indeed, assume a thermoelastic material to be governed by linear isotropic constitutive equations phrased in terms of the 2nd Piola-Kirchhoff stress and Green strain,

$$\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\tau}}}(\mathbf{E}_{\mathrm{G}}, T) = \underline{\underline{\boldsymbol{\tau}}}_i + \mathbb{E} : (\mathbf{E}_{\mathrm{G}} - c_{\mathrm{T}}\,\Delta T\,\mathbf{I}) = \underline{\underline{\boldsymbol{\tau}}}_i + \lambda\,\mathrm{tr}\,\mathbf{E}_{\mathrm{G}}\,\mathbf{I} + 2\,\mu\,\mathbf{E}_{\mathrm{G}} - 3\,K\,c_{\mathrm{T}}\,\Delta T\,\mathbf{I}\,, \tag{2.9.1}$$

with $\mathbb{E} = \lambda\,\mathbf{I}\otimes\mathbf{I} + 2\,\mu\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}$ the tensor of isotropic elasticity defined by the Lamé moduli λ and μ, $K = \lambda + 2\,\mu/3$ the bulk modulus, and c_{T} the coefficient of thermal expansion.

The temperature changes from T_0 to $T = T_0 + \delta T$ and the deformation gradient $\mathbf{F}$ undergoes a slight perturbation $\delta\mathbf{F}$ from $\mathbf{F}_0$ to $\mathbf{F}$,

$$\mathbf{F} = (\mathbf{I} + \delta\mathbf{F}) \cdot \mathbf{F}_0\,. \tag{2.9.2}$$

Then the Green strain and the 2nd Piola-Kirchhoff stress become to first order in $\delta\mathbf{F}$,

$$\mathbf{E}_{\mathrm{G}} = \mathbf{E}_{\mathrm{G}0} + \mathbf{F}_0^{\mathrm{T}} \cdot \boldsymbol{\epsilon} \cdot \mathbf{F}_0\,, \tag{2.9.3}$$

and

$$\underline{\underline{\boldsymbol{\tau}}}(\mathbf{E}_{\mathrm{G}}, T) = \underline{\underline{\boldsymbol{\tau}}}(\mathbf{E}_{\mathrm{G}0}, T_0) + \lambda\,\mathrm{tr}\,(\mathbf{F}_0^{\mathrm{T}} \cdot \boldsymbol{\epsilon} \cdot \mathbf{F}_0)\,\mathbf{I} + 2\,\mu\,\mathbf{F}_0^{\mathrm{T}} \cdot \boldsymbol{\epsilon} \cdot \mathbf{F}_0 - 3\,K\,c_{\mathrm{T}}\,\delta T\,\mathbf{I}\,, \tag{2.9.4}$$

where $\mathbf{E}_{\mathrm{G}0} = \mathbf{E}_{\mathrm{G}}(\mathbf{F}_0)$ is the Green strain associated with $\mathbf{F}_0$, $\boldsymbol{\epsilon} = \frac{1}{2}\,(\delta\mathbf{F} + \delta\mathbf{F}^{\mathrm{T}})$ is the infinitesimal strain associated with the change in the deformation gradient $\delta\mathbf{F}$, and

$$\underline{\underline{\boldsymbol{\tau}}}(\mathbf{E}_{\mathrm{G}0}, T_0) = \underline{\underline{\boldsymbol{\tau}}}_i + \underline{\underline{\mathbb{E}}} : (\mathbf{E}_{\mathrm{G}0} - c_{\mathrm{T}}\,\Delta T_0\,\mathbf{I})\,. \tag{2.9.5}$$

The change of the Kirchhoff stress $\boldsymbol{\tau} = \mathbf{F} \cdot \underline{\underline{\boldsymbol{\tau}}} \cdot \mathbf{F}^{\mathrm{T}}$ and Cauchy stress from their values at $(\mathbf{F}_0, T_0)$,

$$\boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) = \mathbf{F}_0 \cdot \underline{\underline{\boldsymbol{\tau}}}(\mathbf{E}_{\mathrm{G}0}, T_0) \cdot \mathbf{F}_0^{\mathrm{T}} = \det\mathbf{F}_0\,\boldsymbol{\sigma}(\mathbf{E}_{\mathrm{G}0}, T_0)\,, \tag{2.9.6}$$

may be estimated to first order in $\delta\mathbf{F}$ and δT as,

$$\begin{aligned}
\boldsymbol{\tau} &= \boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) + \boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) \cdot \delta\mathbf{F}^{\mathrm{T}} + \delta\mathbf{F} \cdot \boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) + \mathbb{E}(\mathbf{B}_0) : \boldsymbol{\epsilon} - 3\,K\,c_{\mathrm{T}}\,\delta T\,\mathbf{B}_0\,, \\
\boldsymbol{\sigma} &= (1 - \mathrm{tr}\,\boldsymbol{\epsilon})\,\boldsymbol{\sigma}(\mathbf{E}_{\mathrm{G}0}) + \boldsymbol{\sigma}(\mathbf{E}_{\mathrm{G}0}) \cdot \delta\mathbf{F}^{\mathrm{T}} + \delta\mathbf{F} \cdot \boldsymbol{\sigma}(\mathbf{E}_{\mathrm{G}0}) \\
&\quad + (\det\mathbf{F}_0)^{-1}\left(\mathbb{E}(\mathbf{B}_0) : \boldsymbol{\epsilon} - 3\,K\,c_{\mathrm{T}}\,\delta T\,\mathbf{B}_0\right).
\end{aligned} \tag{2.9.7}$$

The tensor of linear elasticity $\mathbb{E}(\mathbf{B}_0)$ is modified by the left Cauchy-Green tensor $\mathbf{B}_0 = \mathbf{F}_0 \cdot \mathbf{F}_0^{\mathrm{T}}$,

$$\mathbb{E}(\mathbf{B}_0) = \lambda\,\mathbf{B}_0 \otimes \mathbf{B}_0 + 2\,\mu\,\mathbf{B}_0\,\underline{\overline{\otimes}}\,\mathbf{B}_0\,, \tag{2.9.8}$$

and, with the notation of Section 2.1.2,

$$\mathbb{E}(\mathbf{B}_0) : \boldsymbol{\epsilon} = \lambda\,(\mathbf{B}_0 : \boldsymbol{\epsilon})\,\mathbf{B}_0 + 2\,\mu\,\mathbf{B}_0 \cdot \boldsymbol{\epsilon} \cdot \mathbf{B}_0\,. \tag{2.9.9}$$

Clearly, large pre-deformations $\mathbf{F}_0$ induce an anisotropic thermoelastic response in the current configuration, even if the material response is isotropic in the reference configuration. However, in the special case where

$$\underline{\underline{\boldsymbol{\tau}}}_i = X_i\,\mathbf{I}, \quad \mathbf{F}_0 = F_0\,\mathbf{I}\,, \tag{2.9.10}$$

the response remains isotropic but the Lamé moduli and the coefficient of thermal expansion are modified,

$$\boldsymbol{\tau} = X\,\mathbf{I} + F_0^4\,\lambda\,\mathrm{tr}\,\boldsymbol{\epsilon}\,\mathbf{I} + 2\,(F_0^4\,\mu + X)\,\boldsymbol{\epsilon} - 3\,K\,c_{\mathrm{T}}\;F_0^2\,\delta T\,\mathbf{I}\,, \tag{2.9.11}$$

where

$$\boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) = X\,\mathbf{I}, \quad X = F_0^2\,X_i + \frac{3}{2}\,K\,(F_0^2\,-1)\,F_0^2 - 3\,K\,c_{\mathrm{T}}\;F_0^2\,\Delta T_0\,. \tag{2.9.12}$$

The linearized response in terms of Cauchy stress $\boldsymbol{\sigma} \sim \boldsymbol{\tau}\,(1-\mathrm{tr}\,\boldsymbol{\epsilon})/F_0^3$ has the isotropic format,

$$\boldsymbol{\sigma} = \frac{X}{F_0^3}\,\mathbf{I} + \Big(F_0\,\lambda - \frac{X}{F_0^3}\Big)\,\mathrm{tr}\,\boldsymbol{\epsilon}\,\mathbf{I} + 2\,\Big(F_0\,\mu + \frac{X}{F_0^3}\Big)\,\boldsymbol{\epsilon} - 3\,K\,\frac{c_{\mathrm{T}}}{F_0}\,\delta T\,\mathbf{I}\,. \tag{2.9.13}$$

For arbitrary anisotropic thermoelasticity, namely $\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\tau}}}_i + \mathbb{E} : (\mathbf{E}_{\mathrm{G}} - \mathbf{c}_{\mathrm{T}}\,\Delta T)$, the linearized expression of the Kirchhoff stress becomes,

$$\boldsymbol{\tau} = \boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) + \boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0)\cdot\delta\mathbf{F}^{\mathrm{T}} + \delta\mathbf{F}\cdot\boldsymbol{\tau}(\mathbf{E}_{\mathrm{G}0}, T_0) + \mathbb{E}(\mathbf{F}_0) : \boldsymbol{\epsilon} - \mathbb{E}_T(\mathbf{F}_0) : \mathbf{c}_{\mathrm{T}}\,\delta T\,, \tag{2.9.14}$$

with the modified thermoelastic moduli,

$$\big(\mathbb{E}(\mathbf{F}_0)\big)_{ijkl} = F_{0im}\,F_{0jn}\,F_{0kp}\,F_{0lq}\,\mathbb{E}_{mnpq}, \quad \big(\mathbb{E}_T(\mathbf{F}_0)\big)_{ijpq} = F_{0im}\,F_{0jn}\,\mathbb{E}_{mnpq}\,. \tag{2.9.15}$$

2.10 Kinematical constraints and reaction stresses

Some materials may not undergo arbitrary strains and some equality constraints $f(\mathbf{E}_{\mathrm{G}}) = 0$ or some inequality constraints $f(\mathbf{E}_{\mathrm{G}}) \geq 0$ may have to be to satisfied. These restrictions influence the format of the constitutive equations. Only equality constraints are addressed below.

The kinematical constraints are assumed to hold for any thermomechanical processes. For example we accept that a body which does not change volume under arbitrary mechanical loads does not undergo thermal expansion. And similarly for the inextensibility condition.

Let $\mathbf{L} = (d\mathbf{F}/dt)\cdot\mathbf{F}^{-1}$ be the velocity gradient and $\mathbf{D} = (\mathbf{L}+\mathbf{L}^{\mathrm{T}})/2$ the rate of deformation. Let the free energy be independent of $\mathbf{D}$ as for an elastic material. Typically, the stress is obtained through the dissipation inequality,

$$\boldsymbol{\sigma} : \mathbf{D} - \frac{dE}{dt} + \cdots \geq 0\,, \tag{2.10.1}$$

by collecting the coefficients of the components of rate of deformation $\mathbf{D}$. If the six components of $\mathbf{D}$ are independent, six relations will be obtained for the six components of the symmetric stress tensor, by giving arbitrary values to the components of $\mathbf{D}$ and still requiring the inequality to be satisfied (so-called Coleman-Noll device). Therefore the stress is completely determined by the free energy.

Such is not the case if some components of $\mathbf{D}$ are subjected to one or several constraints. In that case, the standard procedure is to split the stress in two components, the reaction stress $\mathbf{r}$ and the effective stress $\boldsymbol{\sigma}'$ [Spencer 1972],

$$\boldsymbol{\sigma} = \mathbf{r} + \boldsymbol{\sigma}'\,. \tag{2.10.2}$$

The reaction stress does not work in a deformation that satisfies the constraint. As a first example, let us consider incompressibility, namely $\mathbf{I} : \mathbf{D} = 0$. The candidate reaction stress is $-p\,\mathbf{I}$, where p is to be determined, not by constitutive equations, but by satisfaction of field and boundary conditions in a boundary value problem[2.8]. The total stress may be further recast by requiring, without loss of generality[2.9] the effective stress to be orthogonal to the reaction stress [Spencer 1972],

$$\boldsymbol{\sigma} = \mathbf{r} + \boldsymbol{\sigma}', \quad \mathbf{r} = -p\,\mathbf{I}, \quad \mathbf{I} : \boldsymbol{\sigma}' = 0\,. \tag{2.10.3}$$

[2.8] Several examples are worked out, e.g., in Sections 7.5, 21.7.1.2 and 24.8.1.

[2.9] In practice, however, this orthogonality condition might not be applied to ease the interpretation of the Lagrange multiplier. For example, for an elastic porous solid saturated by a fluid, a constraint arises when both the solid and fluid constituents are incompressible. The reaction stress is interpreted as the fluid pressure, say $\mathbf{r} = -p\,\mathbf{I}$, while the effective stress derives from the skeleton strain through the drained properties of the solid skeleton which includes both a shear component and an isotropic component, see Section 7.3.6. For an elementary volume at equilibrium in a bath at pressure p_{B}, the total stress $\boldsymbol{\sigma}$ is equal to $-p_{\mathrm{B}}\,\mathbf{I}$, the fluid pressure p inside the porous solid is equal to the external bath pressure since there is no meniscus wrapping the porous solid, and the effective stress vanishes.

Therefore only five components of the effective stress should be provided by constitutive equations.

A material which is inextensible in the current direction $\mathbf{a}$, namely $\mathbf{a}\cdot\mathbf{D}\cdot\mathbf{a}=0$, is a second example. The associated reaction stress is $\mathbf{r}=T\,\mathbf{a}\otimes\mathbf{a}$, where T is to be defined in a boundary value problem. Again the effective stress and reaction stress may be redefined so as to be orthogonal,

$$\boldsymbol{\sigma}=\mathbf{r}+\boldsymbol{\sigma}',\quad \mathbf{r}=T\,\mathbf{a}\otimes\mathbf{a},\quad (\mathbf{a}\otimes\mathbf{a}):\boldsymbol{\sigma}'=0\,. \tag{2.10.4}$$

If the material is *both* incompressible and inextensible along the direction $\mathbf{a}$, then,

$$\boldsymbol{\sigma}=\mathbf{r}+\boldsymbol{\sigma}',\quad \mathbf{r}=-p\,\mathbf{I}+T\,\mathbf{a}\otimes\mathbf{a},\quad \mathbf{I}:\boldsymbol{\sigma}'=0,\quad (\mathbf{a}\otimes\mathbf{a}):\boldsymbol{\sigma}'=0\,. \tag{2.10.5}$$

As expected four components of the effective stress are independent and are to be defined by constitutive equations.

Let $\mathbf{E}_{\rm G}=(\mathbf{F}^{\rm T}\cdot\mathbf{F}-\mathbf{I})/2$ be the Green strain. In view of the relation linking the Kirchhoff stress $\boldsymbol{\tau}=\det\mathbf{F}\,\boldsymbol{\sigma}$ and the 2nd Piola-Kirchhoff stress $\underline{\underline{\boldsymbol{\tau}}}=\mathbf{F}^{-1}\cdot(\det\mathbf{F}\,\boldsymbol{\sigma})\cdot\mathbf{F}^{-\rm T}$, one may explore the stress split in the reference configurations implied by the stress split in the current configuration. For example, the incompressibility condition $\det\mathbf{F}=1$ expresses in rate form in terms of the Green strain via (2.7.3) and in terms of the rate of deformation via (2.5.14),

$$\frac{d}{dt}\det\mathbf{F}=(\det\mathbf{F}\,\mathbf{F}^{-1}\cdot\mathbf{F}^{-\rm T}):\frac{d\mathbf{E}_{\rm G}}{dt}=\det\mathbf{F}\,\mathbf{I}:\mathbf{D}\,, \tag{2.10.6}$$

and similarly for the inextensibility condition $\mathbf{a}_0\cdot\mathbf{E}_{\rm G}\cdot\mathbf{a}_0$ constant, with help of (2.5.14),

$$\frac{d}{dt}(\mathbf{a}_0\cdot\mathbf{E}_{\rm G}\cdot\mathbf{a}_0)=\mathbf{a}_0\cdot(\mathbf{F}^{\rm T}\cdot\mathbf{D}\cdot\mathbf{F})\cdot\mathbf{a}_0=\mathbf{a}\cdot\mathbf{D}\cdot\mathbf{a}\,. \tag{2.10.7}$$

Note that the constraint has to be objective and it does not include temperature: mechanical incompressibility being understood to imply zero thermal expansion as discussed in the case of fluids in Section 3.3.2.

For the incompressibility condition, the 2nd Piola-Kirchhoff stress split writes,

$$\underline{\underline{\boldsymbol{\tau}}}=-p\det\mathbf{F}\,\mathbf{F}^{-1}\cdot\mathbf{F}^{-\rm T}+\underline{\underline{\boldsymbol{\tau}}}',\quad (\mathbf{F}^{\rm T}\cdot\mathbf{F}):\underline{\underline{\boldsymbol{\tau}}}'=0\,. \tag{2.10.8}$$

If $\mathbf{a}_0\sim\mathbf{F}^{-1}\cdot\mathbf{a}$ is the reference direction of inextensibility, the split of the 2nd Piola-Kirchhoff stress becomes

$$\underline{\underline{\boldsymbol{\tau}}}=T\det\mathbf{F}\,\mathbf{a}_0\otimes\mathbf{a}_0+\underline{\underline{\boldsymbol{\tau}}}',\quad (\mathbf{F}^{\rm T}\cdot\mathbf{F}\cdot\mathbf{a}_0\otimes\mathbf{F}^{\rm T}\cdot\mathbf{F}\cdot\mathbf{a}_0):\underline{\underline{\boldsymbol{\tau}}}'=0\,. \tag{2.10.9}$$

Quite generally, with help of (2.5.14), the constraint $f(\mathbf{E}_{\rm G})=0$ may be expressed in terms of Lagrangian and Eulerian forms,

$$\frac{df}{dt}=\frac{\partial f}{\partial\mathbf{E}_{\rm G}}:\frac{d\mathbf{E}_{\rm G}}{dt}=\Big(\mathbf{F}\cdot\frac{\partial f}{\partial\mathbf{E}_{\rm G}}\cdot\mathbf{F}^{\rm T}\Big):\mathbf{D}=0\,, \tag{2.10.10}$$

with the stress splits,

$$\begin{aligned}\boldsymbol{\sigma}&=-p\,\mathbf{F}\cdot\frac{\partial f}{\partial\mathbf{E}_{\rm G}}\cdot\mathbf{F}^{\rm T}+\boldsymbol{\sigma}',\quad \Big(\mathbf{F}\cdot\frac{\partial f}{\partial\mathbf{E}_{\rm G}}\cdot\mathbf{F}^{\rm T}\Big):\boldsymbol{\sigma}'=0,\\ \underline{\underline{\boldsymbol{\tau}}}&=-p\det\mathbf{F}\,\frac{\partial f}{\partial\mathbf{E}_{\rm G}}+\underline{\underline{\boldsymbol{\tau}}}',\quad \Big(\mathbf{F}^{\rm T}\cdot\mathbf{F}\cdot\frac{\partial f}{\partial\mathbf{E}_{\rm G}}\cdot\mathbf{F}^{\rm T}\cdot\mathbf{F}\Big):\underline{\underline{\boldsymbol{\tau}}}'=0\,.\end{aligned} \tag{2.10.11}$$

The power relation,

$$\boldsymbol{\tau}:\mathbf{D}=\underline{\underline{\boldsymbol{\tau}}}:\frac{d\mathbf{E}_{\rm G}}{dt}\Big(=\underline{\underline{\boldsymbol{\tau}}}:\frac{d\mathbf{F}}{dt}\Big)\,, \tag{2.10.12}$$

shows that neither the Lagrangian nor the Eulerian reaction stress does work if the kinematical constraint is satisfied. Here the orthogonality between the reaction stress and the effective stress has been postulated in the current configuration. Alternatively, the orthogonality condition may be required in the reference configuration: it does not hold simultaneously in the two configurations.

2.11 Invariance, objectivity, isotropy

The implications on the form of the thermomechanical constitutive equations of a change of reference configuration or of current coordinate axes are explored successively. Additional issues arise when the thermomechanical constitutive equations are formulated in terms of rates.

2.11.1 Tensor invariance

Constitutive equations should be invariant under changes of coordinate axes which are independent of time. This requirement is addressed by using tensors and tensor rules. Equivalently, all tensor quantities may be subjected to an orthogonal transformation.

Moreover, Lagrangian constitutive equations should be form invariant under changes of the *reference* configuration. This invariance does not preclude the fact that certain symmetries may be displayed in particular reference configurations. The consequences for elastic-growing material with directors are addressed in Section 23.4.2.

As an example, let us consider the thermoelastic solid $\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{E}_{\rm G}, T)$ for which the 2nd Piola-Kirchhoff stress $\underline{\underline{\boldsymbol{\tau}}}$ is a one to one function of the Green strain $\mathbf{E}_{\rm G}$, at given temperature T. The stress and strain are assumed to refer to the same configuration noted 1. A new configuration 2 is defined by the deformation $\mathbf{F}_2 \cdot \mathbf{R} = \mathbf{F}_1$ with $\mathbf{R}$ a rotation. For any $\mathbf{R}$, the constitutive function should satisfy the relation,

$$\underline{\underline{\boldsymbol{\tau}}}_2 = \mathbf{R} \cdot \underline{\underline{\boldsymbol{\tau}}}_1 \cdot \mathbf{R}^{\rm T} = \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{R} \cdot \mathbf{E}_{\rm G1} \cdot \mathbf{R}^{\rm T}, T) = \mathbf{R} \cdot \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{E}_{\rm G1}, T) \cdot \mathbf{R}^{\rm T} . \tag{2.11.1}$$

Thus the constitutive responses in the two configurations deduce as,

$$\underline{\underline{\boldsymbol{\mathcal{F}}}}_2(\mathbf{E}_{\rm G2}, T) = \mathbf{R} \cdot \underline{\underline{\boldsymbol{\mathcal{F}}}}_1(\underbrace{\mathbf{R}^{\rm T} \cdot \mathbf{E}_{\rm G2} \cdot \mathbf{R}}_{\mathbf{E}_{\rm G1}}, T) \cdot \mathbf{R}^{\rm T} . \tag{2.11.2}$$

The ensuing relations for the Cauchy stress response $\det \mathbf{F}\, \boldsymbol{\sigma} = \mathbf{F} \cdot \underline{\underline{\boldsymbol{\tau}}} \cdot \mathbf{F}^{\rm T}$

$$\begin{aligned} \det \mathbf{F}_2\ \boldsymbol{\sigma}_2 \quad &= \quad \mathbf{F}_2 \cdot \underline{\underline{\boldsymbol{\mathcal{F}}}}_2(\mathbf{E}_{\rm G2}, T) \cdot \mathbf{F}_2^{\rm T} \quad \overset{(2.11.2)}{=} \quad \mathbf{F}_2 \cdot \mathbf{R} \cdot \underline{\underline{\boldsymbol{\mathcal{F}}}}_1(\mathbf{E}_{\rm G1}, T) \cdot \mathbf{R}^{\rm T} \cdot \mathbf{F}_2^{\rm T} \\ &= \quad \mathbf{F}_1 \cdot \underline{\underline{\boldsymbol{\mathcal{F}}}}_1(\mathbf{E}_{\rm G1}, T) \cdot \mathbf{F}_1^{\rm T} \\ &= \quad \det \mathbf{F}_2\, \boldsymbol{\mathcal{F}}_2(\mathbf{F}_2, T) \quad = \quad \det \mathbf{F}_1\, \boldsymbol{\mathcal{F}}_1(\mathbf{F}_1, T) . \end{aligned} \tag{2.11.3}$$

imply, with $\det \mathbf{R} = 1$, the invariance of the constitutive response in the *current* configuration,

$$\boldsymbol{\mathcal{F}}_2(\mathbf{F}_2, T) = \boldsymbol{\mathcal{F}}_1(\mathbf{F}_1, T) . \tag{2.11.4}$$

Usually the reference configuration is a position that the body can actually possess, and the working axes in the reference and current configurations are both right handed. Then the current configuration deduces from the reference configuration by a deformation gradient $\mathbf{F}$ with $\det \mathbf{F} > 0$ and the transformation is said *proper*. If either the current configuration is deduced from the one mentioned above by a symmetry, or if the working axes in the reference and current configurations are, respectively, right-handed and left-handed, or conversely, then $\det \mathbf{F} < 0$, and the transformation is said *improper*.

2.11.2 Material frame indifference or material objectivity

The reference configuration being held fixed, we now question the effects of a time changing frame in the current configurations.

2.11.2.1 Objective constitutive equations

Consider a body undergoing some loading process. In one case, the body is at rest with respect to the fixed laboratory axes. In another case, it undergoes some time dependent rotation. The underlying idea is that the nature of the *contact forces* does not change. Constitutive equations should reflect this property. In other words, even if they are moving with respect to one another, two observers should record the same material response, e.g., the same stress, in a body. On the other hand, Newton's second law does not satisfy this frame indifference principle without recourse to inertia forces.

While the frame in the initial configuration is assumed to be common to the two observers, the rates of change of the current frames may be different. As a particular case, the current frames may be assumed to coincide at any time t, but not their rates. The question of frame indifference does not arise if the constitutive equations are phrased in terms of Lagrange variables, e.g., for a thermoelastic solid $\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{E}_{\rm G}, T)$ for which the 2nd Piola-Kirchhoff stress $\underline{\underline{\boldsymbol{\tau}}}$ is a function of the Green strain $\mathbf{E}_{\rm G}$ and temperature T. A Lagrangian tensor is identical to the two observers unlike

an Eulerian tensor. Consequently, a constitutive equation involving a Lagrangian entity and an Eulerian entity will not be objective.

Consider two observers moving with the frames $\mathbf{x}(t)$ and $\mathbf{x}_*(t)$,

$$\mathbf{x}_*(t) = \mathbf{R}(t)\cdot\mathbf{x}(t) + \mathbf{t}(t)\,, \tag{2.11.5}$$

related by a rotation $\mathbf{R}(t)$ and a translation $\mathbf{t}(t)$. Think of two runners, possibly starting from the same point, and heading along different directions.

The representations of tensor quantities in the two frames express following tensor rules, e.g., $\boldsymbol{\sigma}_* = \mathbf{R}\cdot\boldsymbol{\sigma}\cdot\mathbf{R}^{\mathrm{T}}$ for the stress matrix, $\mathbf{Q}_* = \mathbf{R}\cdot\mathbf{Q}$ for the heat flux vector, see Exercise 2.1 for details. Gradients wrt the two frames require some derivations (the right gradient of a vector $\mathbf{v}\overleftarrow{\boldsymbol{\nabla}}$ is defined componentwise as $\partial v_i/\partial x_j$, $\overleftarrow{\boldsymbol{\nabla}}_*$ denotes the gradient wrt the coordinate $\mathbf{x}_*$, and $\underline{\overleftarrow{\boldsymbol{\nabla}}}$ the gradient wrt the coordinate $\underline{\mathbf{x}}$), namely

$$\begin{aligned}
&\mathbf{x}_*(t) = \mathbf{R}(t)\cdot\mathbf{x}(t) + \mathbf{t}(t), \quad \mathbf{v}_*(t) = \mathbf{R}(t)\cdot\mathbf{v}(t) + \frac{d\mathbf{R}}{dt}(t)\cdot\mathbf{x}(t) + \frac{d\mathbf{t}(t)}{dt}\,;\\
&\mathbf{v}_*\overleftarrow{\boldsymbol{\nabla}} = \mathbf{R}\cdot(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}}) + \frac{d\mathbf{R}}{dt}, \quad \mathbf{v}_*\overleftarrow{\boldsymbol{\nabla}}_* = \mathbf{v}_*\overleftarrow{\boldsymbol{\nabla}}\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{R}\cdot(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}})\cdot\mathbf{R}^{\mathrm{T}} + \frac{d\mathbf{R}}{dt}\cdot\mathbf{R}^{\mathrm{T}}\,.
\end{aligned} \tag{2.11.6}$$

Consider a fluid for which the stress $\boldsymbol{\sigma} = \boldsymbol{\mathcal{F}}(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}}, \rho, T)$ is a function of the velocity gradient $\mathbf{v}\overleftarrow{\boldsymbol{\nabla}}$, mass density ρ and temperature T. Thus the matrix of the stress of the second observer $\boldsymbol{\sigma}_* = \mathbf{R}\cdot\boldsymbol{\sigma}\cdot\mathbf{R}^{\mathrm{T}}$ expresses as,

$$\boldsymbol{\sigma}_* = \mathbf{R}\cdot\boldsymbol{\mathcal{F}}(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}}, \rho, T)\cdot\mathbf{R}^{\mathrm{T}} = \boldsymbol{\mathcal{F}}(\mathbf{R}\cdot(\mathbf{v}\overleftarrow{\boldsymbol{\nabla}})\cdot\mathbf{R}^{\mathrm{T}} + \frac{d\mathbf{R}}{dt}\cdot\mathbf{R}^{\mathrm{T}}, \rho, T)\,. \tag{2.11.7}$$

Since the rate of the rotation is arbitrary, it can be chosen so as to eliminate the skew-symmetric part $\mathbf{W}$ of the velocity gradient $\mathbf{L} \equiv \mathbf{v}\overleftarrow{\boldsymbol{\nabla}} = \mathbf{D} + \mathbf{W}$, namely such that $\mathbf{R}\cdot\mathbf{W}\cdot\mathbf{R}^{\mathrm{T}} + (d\mathbf{R}/dt)\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{0}$. Therefore, the constitutive equation should have the format $\boldsymbol{\sigma} = \boldsymbol{\mathcal{F}}(\mathbf{D}, \rho, T)$ and the constitutive function $\boldsymbol{\mathcal{F}}$ should satisfy the constraint,

$$\mathbf{R}\cdot\boldsymbol{\mathcal{F}}(\mathbf{D}, \rho, T)\cdot\mathbf{R}^{\mathrm{T}} = \boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{D}\cdot\mathbf{R}^{\mathrm{T}}, \rho, T)\,, \tag{2.11.8}$$

for any rotation $\mathbf{R}$. Actually, if the property holds for $\mathbf{R}$, it does for $-\mathbf{R}$. Then the condition is to be satisfied for any orthogonal transformation $\mathbf{R} \in \mathcal{O}(3)$: the function $\boldsymbol{\mathcal{F}}$ is said to be isotropic with respect to its first argument.

Perhaps, assuming the current frames at any time t to be identical for the two observers, i.e., $\mathbf{R}(t) = \mathbf{I}$ while $d\mathbf{R}/dt \neq \mathbf{0}$, provides some further hint why the constitutive relation should be phrased in terms of the rate of deformation and not in terms of the velocity gradient. Indeed then the stress matrices $\boldsymbol{\sigma}$ and $\boldsymbol{\sigma}_*$ are identical for the two observers and, according to (2.11.7), $\boldsymbol{\mathcal{F}}(\mathbf{D}+\mathbf{W}, \rho, T) = \boldsymbol{\mathcal{F}}(\mathbf{D}+\mathbf{W}+d\mathbf{R}/dt, \rho, T)$. The equality is satisfied by symmetrizing the first argument of $\boldsymbol{\mathcal{F}}$.

For a Newtonian fluid, the stress depends linearly on the rate of deformation $\mathbf{D}$. If the constitutive function $\boldsymbol{\mathcal{F}}$ has no other tensor argument than $\mathbf{D}$, this dependence expresses via two viscosity coefficients λ_v and μ_v, Section 2.11.3.2. Actually, the stress is contributed by a static pressure $p = p(\rho, T)$ and the viscous response, namely $\boldsymbol{\sigma} = -p(\rho, T)\,\mathbf{I} + \lambda_v\,\mathrm{tr}\,\mathbf{D}\,\mathbf{I} + 2\,\mu_v\,\mathbf{D}$. Dissipation and invertibility require $3\,\lambda_v + 2\,\mu_v > 0$, $\mu_v > 0$. Invertibility does not hold for a Stokes fluid for which $3\,\lambda_v + 2\,\mu_v = 0$.

As another example of Eulerian constitutive equation, consider Fourier's heat law expressing the heat flux $\mathbf{Q} = -\mathbf{k}_{\mathrm{T}}(\mathbf{F})\cdot(T\overleftarrow{\boldsymbol{\nabla}})$ in terms of temperature gradient $T\overleftarrow{\boldsymbol{\nabla}}$ and tensor of thermal conductivity $\mathbf{k}_{\mathrm{T}}(\mathbf{F})$ assumed to depend on the deformation gradient $\mathbf{F}$. With help of the relations,

$$\mathbf{F}_* = \mathbf{x}_*\,\underline{\overleftarrow{\boldsymbol{\nabla}}} = \mathbf{R}\cdot(\mathbf{x}\,\underline{\overleftarrow{\boldsymbol{\nabla}}}) = \mathbf{R}\cdot\mathbf{F}, \quad T\overleftarrow{\boldsymbol{\nabla}}_* = \mathbf{R}\cdot(T\overleftarrow{\boldsymbol{\nabla}})\,, \tag{2.11.9}$$

the equation expresses in the second frame in the format $\mathbf{R}\cdot\mathbf{Q} = -\mathbf{k}_{\mathrm{T}}(\mathbf{R}\cdot\mathbf{F})\cdot(\mathbf{R}\cdot(T\overleftarrow{\boldsymbol{\nabla}}))$. Therefore, $\mathbf{k}_{\mathrm{T}}(\mathbf{F}) = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{k}_{\mathrm{T}}(\mathbf{R}\cdot\mathbf{F})\cdot\mathbf{R}$. If further the rotation $\mathbf{R}$ is taken equal to the transpose of the rotation involved in the polar decomposition of the deformation gradient, namely $\mathbf{F} = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{U}$, then the tensor of thermal conductivity should depend on the deformation gradient through the format,

$$\mathbf{k}_{\mathrm{T}}(\mathbf{F}) = \mathbf{R}\cdot\mathbf{k}_{\mathrm{T}}(\mathbf{U})\cdot\mathbf{R}^{\mathrm{T}}\,. \tag{2.11.10}$$

Hence, even if the conductivity does not depend on the pure deformation, its dependence wrt the deformation gradient should be accounted for because the orientation of the body is observer dependent.

For an elastic solid, the Cauchy stress is a priori a function of the deformation gradient, and temperature, and (2.11.7) becomes,

$$\boldsymbol{\sigma}_* = \mathbf{R}\cdot\boldsymbol{\mathcal{F}}(\mathbf{F},T)\cdot\mathbf{R}^{\mathrm{T}} = \boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{F},T)\,, \tag{2.11.11}$$

or $\boldsymbol{\sigma} = \boldsymbol{\mathcal{F}}(\mathbf{F},T) = \mathbf{R}^{\mathrm{T}}\cdot\boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{F},T)\cdot\mathbf{R}$. Again, with the rotation $\mathbf{R}$ taken equal to the transpose of the rotation involved in the polar decomposition of the deformation gradient, namely $\mathbf{F} = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{U}$, the objectivity requirement implies the constitutive relation to adopt the following reduced formats, namely

$$\begin{aligned}
\boldsymbol{\sigma} &= \mathbf{R}^{\mathrm{T}}\cdot\boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{F},T)\cdot\mathbf{R}\\
&= \mathbf{R}^{\mathrm{T}}\cdot\boldsymbol{\mathcal{F}}(\mathbf{U},T)\cdot\mathbf{R}\\
&= \mathbf{F}\cdot\big(\mathbf{U}^{-1}\cdot\boldsymbol{\mathcal{F}}(\mathbf{U},T)\cdot\mathbf{U}^{-1}\big)\cdot\mathbf{F}^{\mathrm{T}}\\
&= \mathbf{F}\cdot\big(\mathbf{U}^{-1}\cdot\boldsymbol{\mathcal{F}}(\mathbf{U},T)\cdot\mathbf{U}\big)\cdot\mathbf{F}^{-1}\\
&= \mathbf{F}^{-\mathrm{T}}\cdot\big(\mathbf{U}\cdot\boldsymbol{\mathcal{F}}(\mathbf{U},T)\cdot\mathbf{U}\big)\cdot\mathbf{F}^{-1}\\
&= \mathbf{F}^{-\mathrm{T}}\cdot\big(\mathbf{U}\cdot\boldsymbol{\mathcal{F}}(\mathbf{U},T)\cdot\mathbf{U}^{-1}\big)\cdot\mathbf{F}^{\mathrm{T}}\,.
\end{aligned} \tag{2.11.12}$$

Alternatively, starting from a constitutive relation in terms of the 2nd Piola-Kirchhoff stress, the latter should be independent of the change of current frame, i.e. $\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{F},T) = \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{R}\cdot\mathbf{F},T)$, and therefore $\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\mathcal{F}}}}(\mathbf{U},T)$, which is consistent with the expression of $\det\mathbf{F}\,\mathbf{F}^{-1}\cdot\boldsymbol{\sigma}\cdot\mathbf{F}^{-\mathrm{T}}$ associated with the 3rd line of (2.11.12), namely $\det\mathbf{U}\,\mathbf{U}^{-1}\cdot\boldsymbol{\mathcal{F}}(\mathbf{U},T)\cdot\mathbf{U}^{-1}$ since $\det\mathbf{F} = \det\mathbf{U}$. The associated requirement for the free energy relative to the reference configuration $\underline{E}(\mathbf{F},T)$ implies the dependence in $\mathbf{F}$ to be realized via the pure deformation $\mathbf{U}$ or by the right Cauchy-Green tensor $\mathbf{C} = \mathbf{U}^2 = \mathbf{F}^{\mathrm{T}}\cdot\mathbf{F}$ or by the Green strain $\mathbf{E}_{\mathrm{G}}$. Then one can prove the following relation between partial derivatives (with an abuse of notation),

$$\frac{\partial\underline{E}}{\partial\mathbf{F}}(\mathbf{C},T) = 2\,\mathbf{F}\cdot\frac{\partial\underline{E}}{\partial\mathbf{C}}(\mathbf{C},T);\quad \frac{\partial\underline{E}}{\partial\mathbf{F}}(\mathbf{E}_{\mathrm{G}},T) = \mathbf{F}\cdot\frac{\partial\underline{E}}{\partial\mathbf{E}_{\mathrm{G}}}(\mathbf{E}_{\mathrm{G}},T)\,. \tag{2.11.13}$$

The proof is simple, namely $d\underline{E} = \partial\underline{E}/\partial\mathbf{E}_{\mathrm{G}} : d\mathbf{E}_{\mathrm{G}} = \partial\underline{E}/\partial\mathbf{E}_{\mathrm{G}} : (d\mathbf{F}^{\mathrm{T}}\cdot\mathbf{F}) = \mathbf{F}\cdot\partial\underline{E}/\partial\mathbf{E}_{\mathrm{G}} : d\mathbf{F}$.

2.11.2.2 Objective entities and time derivatives

Consider a body submitted to the constant stress $\boldsymbol{\sigma}$. The stress associated with the moving frame expresses as $\boldsymbol{\sigma}_* = \mathbf{R}\cdot\boldsymbol{\sigma}\cdot\mathbf{R}^{\mathrm{T}}$. The time derivative of $\boldsymbol{\sigma}_*$ does not vanish: it should not be introduced as such in constitutive equations. Therefore we have to define *objective* time derivatives.

Taking a step backward, let us first observe that the matrix representations of the velocity gradient, its symmetric and skew-symmetric parts in the frame 1, namely $\mathbf{L}$, $\mathbf{D}$ and $\mathbf{W}$, and in the frame 2, namely $\mathbf{L}_*$, $\mathbf{D}_*$ and $\mathbf{W}_*$, relate according to (2.11.6),

$$\mathbf{L}_* = \mathbf{R}\cdot\mathbf{L}\cdot\mathbf{R}^{\mathrm{T}} + \boldsymbol{\Omega},\quad \mathbf{D}_* = \mathbf{R}\cdot\mathbf{D}\cdot\mathbf{R}^{\mathrm{T}},\quad \mathbf{W}_* = \mathbf{R}\cdot\mathbf{W}\cdot\mathbf{R}^{\mathrm{T}} + \boldsymbol{\Omega}\,, \tag{2.11.14}$$

where $\boldsymbol{\Omega} = (d\mathbf{R}/dt)\cdot\mathbf{R}^{\mathrm{T}}$.

Scalars, vectors and tensors are said to be *frame indifferent* or *objective* if they follow tensor rules under changes of frames. Thus the velocity $\mathbf{v}$ and the acceleration are not objective according to (2.11.6), neither are the velocity gradient $\mathbf{L}$ and the spin $\mathbf{W}$ according to (2.11.14), but the rate of deformation $\mathbf{D}$ is. Moreover, the relations (2.11.15) below show implicitly that the time derivatives $d\mathbf{a}/dt$ and $d\mathbf{A}/dt$ of a vector $\mathbf{a}$ or a second order tensor $\mathbf{A}$ are not objective either.

There are several ways to build objective derivatives. A first method introduces *corotational derivatives*. Consider a vector $\mathbf{a}$ and a second order tensor $\mathbf{A}$ which express respectively as $\mathbf{a}_* = \mathbf{R}\cdot\mathbf{a}$ and $\mathbf{A}_* = \mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}}$ in the moving frame. Then, upon differentiation of these expressions and re-arrangement of the results, one may display so-called corotational derivatives denoted by the symbol $D\,/Dt$ to make a distinction with the material time derivative $d\,/dt$, namely with $\boldsymbol{\Omega} = (d\mathbf{R}/dt)\cdot\mathbf{R}^{\mathrm{T}}$,

$$\begin{aligned}
&\mathbf{a}_* = \mathbf{R}\cdot\mathbf{a}; && \frac{D\mathbf{a}_*}{Dt} = \frac{d\mathbf{a}_*}{dt} - \boldsymbol{\Omega}\cdot\mathbf{a}_* = \mathbf{R}\cdot\frac{d\mathbf{a}}{dt}\,;\\
&\mathbf{A}_* = \mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}}; && \frac{D\mathbf{A}_*}{Dt} = \frac{d\mathbf{A}_*}{dt} - \boldsymbol{\Omega}\cdot\mathbf{A}_* + \mathbf{A}_*\cdot\boldsymbol{\Omega} = \mathbf{R}\cdot\frac{d\mathbf{A}}{dt}\cdot\mathbf{R}^{\mathrm{T}}\,.
\end{aligned} \tag{2.11.15}$$

Note the relations based on the property (2.5.44) for $\mathbf{R}$ an orthogonal tensor,

$$\begin{aligned} \mathbf{A}_* &= \mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}} \quad\Rightarrow\quad |\mathbf{A}_*| = |\mathbf{A}|, \\ \frac{D\mathbf{A}_*}{Dt} &= \mathbf{R}\cdot\frac{d\mathbf{A}}{dt}\cdot\mathbf{R}^{\mathrm{T}} \quad\Rightarrow\quad |\frac{D\mathbf{A}_*}{Dt}| = |\frac{d\mathbf{A}}{dt}|\,. \end{aligned} \tag{2.11.16}$$

When $\mathbf{R}$ is the rotation involved in the polar decomposition of the deformation gradient, the derivative is called Green-Naghdi rate. Now using $(2.11.14)_3$, one may transform $(2.11.15)_2$ to build another corotational derivative, called Jaumann derivative, namely

$$\begin{aligned} &\mathbf{A}_* = \mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}}; \\ &\frac{D\mathbf{A}_*}{Dt} = \frac{d\mathbf{A}_*}{dt} - \mathbf{W}_*\cdot\mathbf{A}_* + \mathbf{A}_*\cdot\mathbf{W}_* = \mathbf{R}\cdot\big(\frac{d\mathbf{A}}{dt} - \mathbf{W}\cdot\mathbf{A} + \mathbf{A}\cdot\mathbf{W}\big)\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{R}\cdot\frac{D\mathbf{A}}{Dt}\cdot\mathbf{R}^{\mathrm{T}}\,. \end{aligned} \tag{2.11.17}$$

The notion of convective derivative provides another means to construct objective derivatives. Indeed, with any second order tensor $\mathbf{A}_*(t)$ may be associated a second order tensor $\mathbf{A}(t)$ relative to the reference configuration through various transfer rules based on the deformation gradient $\mathbf{F}$. For example,

$$\begin{aligned} \mathbf{A}_* = \mathbf{F}^{-\mathrm{T}}\cdot\mathbf{A}\cdot\mathbf{F}^{-1}, \quad \frac{D\mathbf{A}_*}{Dt} = \frac{d\mathbf{A}_*}{dt} + \mathbf{A}_*\cdot\mathbf{L} + \mathbf{L}^{\mathrm{T}}\cdot\mathbf{A}_* &= \mathbf{F}^{-\mathrm{T}}\cdot\frac{d\mathbf{A}}{dt}\cdot\mathbf{F}^{-1}, \\ \mathbf{A}_* = \mathbf{F}\cdot\mathbf{A}\cdot\mathbf{F}^{\mathrm{T}}, \quad \frac{D\mathbf{A}_*}{Dt} = \frac{d\mathbf{A}_*}{dt} - \mathbf{A}_*\cdot\mathbf{L}^{\mathrm{T}} - \mathbf{L}\cdot\mathbf{A}_* &= \mathbf{F}\cdot\frac{d\mathbf{A}}{dt}\cdot\mathbf{F}^{\mathrm{T}}, \end{aligned} \tag{2.11.18}$$

where $\mathbf{L} = d\mathbf{F}/dt\cdot\mathbf{F}^{-1}$ is the velocity gradient. These derivatives are referred to as Oldroyd rates. The convective derivative is seen to be the image in the current configuration of the time derivative in the reference configuration.

The procedure applies to vectors as well, e.g.,

$$\mathbf{a}_* = \mathbf{F}\cdot\mathbf{a}, \quad \frac{D\mathbf{a}_*}{Dt} = \frac{d\mathbf{a}_*}{dt} - \mathbf{L}\cdot\mathbf{a}_* = \mathbf{F}\cdot\frac{d\mathbf{a}}{dt}\,. \tag{2.11.19}$$

The right and left Cauchy-Green tensors or Green strain are not objective: this statement follows from (2.5.14) and the fact that the rate of deformation $\mathbf{D}$ is not the derivative of a strain measure. However, the Rivlin-Ericksen tensors are objective tensors related to the derivative of the right Cauchy-Green tensor. They are defined through the scheme, e.g., Malvern [1969],

$$\begin{aligned} d\mathbf{x}\cdot\mathbf{A}^{(0)}\cdot d\mathbf{x} &= d\underline{\mathbf{x}}\cdot\mathbf{C}\cdot d\underline{\mathbf{x}} \\ d\mathbf{x}\cdot\mathbf{A}^{(n)}\cdot d\mathbf{x} &= d\underline{\mathbf{x}}\cdot\frac{d^n\mathbf{C}}{dt^n}\cdot d\underline{\mathbf{x}}\,, \end{aligned} \tag{2.11.20}$$

so that $d^n\mathbf{C}/dt^n = \mathbf{F}^{\mathrm{T}}\cdot\mathbf{A}^{(n)}\cdot\mathbf{F}$, $n = 0, 1, 2\cdots$ with the convention $\mathbf{A}^{(0)} = \mathbf{I}$ and the recursion formula $\mathbf{A}^{(n+1)} = d\mathbf{A}^{(n)}/dt + \mathbf{L}^{\mathrm{T}}\cdot\mathbf{A}^{(n)} + \mathbf{A}^{(n)}\cdot\mathbf{L}$ deduced by derivation of $(2.11.20)_2$.

2.11.3 Material symmetries

Constitutive equations should embody the properties and in particular the symmetry properties of the body. Indeed, some constitutive functions remain invariant under certain changes of axes $\mathbf{R}$ of the reference configuration κ_1. While the matrix of the deformation gradient changes from $\mathbf{F}_1 = \mathbf{F}\cdot\mathbf{R}$ to $\mathbf{F}$, the constitutive response relative to the configuration κ_1, say $\boldsymbol{\mathcal{F}}_1$, remains unchanged, namely

$$\boldsymbol{\mathcal{F}}_1(\mathbf{F}\cdot\mathbf{R},\, T) = \boldsymbol{\mathcal{F}}_1(\mathbf{F},\, T)\,. \tag{2.11.21}$$

The set of these changes of axes has the structure of a group, an algebraic structure defined in Section 5.2.3.1, and it is termed the symmetry group of the material relative to the reference configuration κ_1. Indeed, first the dot product can be viewed as an internal composition which is associative: if $\mathbf{R}_1$ and $\mathbf{R}_2$ are two such changes of axes, then $\mathbf{R}_1\cdot\mathbf{R}_2$ belongs to the set,

$$\boldsymbol{\mathcal{F}}_1(\mathbf{F}\cdot\mathbf{R}_1\cdot\mathbf{R}_2,\, T) = \boldsymbol{\mathcal{F}}_1(\mathbf{F}\cdot\mathbf{R}_1,\, T) = \boldsymbol{\mathcal{F}}_1(\mathbf{F},\, T)\,. \tag{2.11.22}$$

Second the identity $\mathbf{I}$ belongs to the set and plays the role of the neutral element. Third and finally, each element $\mathbf{R}$ has an inverse that leaves invariant the constitutive response, i.e., it belongs to the set. Indeed,

$$\boldsymbol{\mathcal{F}}_1(\mathbf{F}\cdot\mathbf{R}\cdot\mathbf{R}^{-1},\,T)=\boldsymbol{\mathcal{F}}_1(\mathbf{F},\,T)=\boldsymbol{\mathcal{F}}_1(\mathbf{F}\cdot\mathbf{R},\,T)\quad\overset{\mathbf{F}'\equiv\mathbf{F}\cdot\mathbf{R}}{\Rightarrow}\quad\boldsymbol{\mathcal{F}}_1(\mathbf{F}'\cdot\mathbf{R}^{-1},\,T)=\boldsymbol{\mathcal{F}}_1(\mathbf{F}',\,T)\,. \tag{2.11.23}$$

Consider now the change of reference configuration $\kappa_1\to\kappa_2$, with $\mathbf{F}_1=\mathbf{F}_2\cdot\mathbf{R}$. Then if $\mathbf{R}_1$ belongs to the isotropy group of the material relative to the reference configuration κ_1, the isotropy group relative to the configuration κ_2 is of the form $\mathbf{R}_2=\mathbf{R}\cdot\mathbf{R}_1\cdot\mathbf{R}^{-1}$. Indeed,

$$\boldsymbol{\mathcal{F}}_2(\mathbf{F}_2,\,T)\overset{(2.11.4)}{=}\boldsymbol{\mathcal{F}}_1(\mathbf{F}_1,\,T)\overset{(2.11.21)}{=}\boldsymbol{\mathcal{F}}_1(\mathbf{F}_1\cdot\mathbf{R}_1,\,T)\overset{(2.11.4)}{=}\boldsymbol{\mathcal{F}}_2(\mathbf{F}_1\cdot\mathbf{R}_1\cdot\mathbf{R}^{-1},\,T)\overset{\mathbf{F}_1=\mathbf{F}_2\cdot\mathbf{R}}{=}\boldsymbol{\mathcal{F}}_2(\mathbf{F}_2\cdot\mathbf{R}_2,\,T)\,. \tag{2.11.24}$$

The proper orthogonal group $\mathcal{SO}(3)$ which includes only rotations and the complete orthogonal group $\mathcal{O}(3)$ which includes in addition symmetries play a prominent role in this context and are defined in Section 5.2.3.1. They are both subgroups of the unimodular group whose elements have a determinant equal to ±1. A function which is left invariant under the complete orthogonal group $\mathcal{O}(3)$ is termed *isotropic*. It is termed *hemitropic* if it is left invariant under the proper orthogonal group $\mathcal{SO}(3)$ only.

Under the change of axes (2.11.5), the deformation gradient changes from $\mathbf{F}$ to $\mathbf{R}\cdot\mathbf{F}$, and the stress from $\boldsymbol{\sigma}=\boldsymbol{\sigma}(\mathbf{F},\,T)$ to $\boldsymbol{\sigma}(\mathbf{R}\cdot\mathbf{F},\,T)=\mathbf{R}\cdot\boldsymbol{\sigma}(\mathbf{F},\,T)\cdot\mathbf{R}^{\mathrm{T}}$ along tensor rules. Moreover, if $\mathbf{R}$ belongs to the group, so does $\mathbf{R}^{\mathrm{T}}$. Then,

$$\mathbf{R}\cdot\boldsymbol{\mathcal{F}}(\mathbf{F},T)\cdot\mathbf{R}^{\mathrm{T}}=\boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{F},T)\overset{(2.11.21)}{=}\boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{F}\cdot\mathbf{R}^{\mathrm{T}},T)\,. \tag{2.11.25}$$

This relation can be extended regarding the nature of both the constitutive function and its arguments. Consider a scalar-valued function f, a vector-valued function $\mathbf{f}$ and a tensor-valued function $\boldsymbol{\mathcal{F}}$ of the set $(\mathbf{A},\,\mathbf{a},\,a)$ which involves a second order tensor $\mathbf{A}$, a vector $\mathbf{a}$ and a scalar a. These functions are invariant relative to the symmetry group $\mathcal{S}$ if, for any element $\mathbf{R}$ of $\mathcal{S}$,

$$\begin{aligned}\mathbf{R}\cdot\boldsymbol{\mathcal{F}}(\mathbf{A},\,\mathbf{a},\,a)\cdot\mathbf{R}^{\mathrm{T}}&=\boldsymbol{\mathcal{F}}(\mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}},\,\mathbf{R}\cdot\mathbf{a},\,a);\\ \mathbf{R}\cdot\mathbf{f}(\mathbf{A},\,\mathbf{a},\,a)&=\mathbf{f}(\mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}},\,\mathbf{R}\cdot\mathbf{a},\,a);\\ f(\mathbf{A},\,\mathbf{a},\,a)&=f(\mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}},\,\mathbf{R}\cdot\mathbf{a},\,a)\,.\end{aligned} \tag{2.11.26}$$

Isotropy requires the above relations to hold for any orthogonal tensor $\mathbf{R}$, that is, for $\mathcal{S}=\mathcal{O}(3)$. The symmetry group associated with material isotropy with a center of symmetry is the full orthogonal group $\mathcal{O}(3)$ while the symmetry group associated with material isotropy with no center of symmetry (hemitropy) is the proper orthogonal group $\mathcal{SO}(3)$.

2.11.3.1 Scalar-valued isotropic functions

The coefficients of the characteristic equation $\det(\lambda\mathbf{I}-\mathbf{A})=0$ are termed principal invariants because they are isotropic functions of $\mathbf{A}$. Indeed, for $\mathbf{R}$ an orthogonal transformation, $\det(\lambda\mathbf{I}-\mathbf{R}^{\mathrm{T}}\cdot\mathbf{A}\cdot\mathbf{R})=\det\left(\mathbf{R}^{\mathrm{T}}\cdot(\lambda\mathbf{I}-\mathbf{A})\cdot\mathbf{R}\right)=\det(\lambda\mathbf{I}-\mathbf{A})=0$. Due to isotropy, the scalar invariants are symmetric functions of the eigenvalues, Eqn (2.2.13). Any symmetric function of the eigenvalues of $\mathbf{A}$ is also a function of its scalar invariants.

Let $\mathbf{A}$ be a second order tensor. A scalar-valued function $f(\mathbf{A})$ is isotropic if, for any orthogonal transformation $\mathbf{R}\in\mathcal{O}(3)$ [2.10],

$$f(\mathbf{A})=f(\underline{\mathbf{A}}=\mathbf{R}\cdot\mathbf{A}\cdot\mathbf{R}^{\mathrm{T}})\,. \tag{2.11.27}$$

If the function f is smooth, then differentiation for arbitrary $\mathbf{A}$ and $\mathbf{R}$ yields,

$$\begin{aligned}\frac{\partial f(\mathbf{A})}{\partial\mathbf{A}}&=\mathbf{R}^{\mathrm{T}}\cdot\frac{\partial f(\underline{\mathbf{A}})}{\partial\underline{\mathbf{A}}}\cdot\mathbf{R},\\ \mathbf{A}\cdot\frac{\partial f}{\partial\mathbf{A}^{\mathrm{T}}}+\mathbf{A}^{\mathrm{T}}\cdot\frac{\partial f}{\partial\mathbf{A}}&=\left(\mathbf{A}\cdot\frac{\partial f}{\partial\mathbf{A}^{\mathrm{T}}}+\mathbf{A}^{\mathrm{T}}\cdot\frac{\partial f}{\partial\mathbf{A}}\right)^{\mathrm{T}}.\end{aligned} \tag{2.11.28}$$

[2.10] When it comes to constitutive relations, the fact that the function f depends on the point and on the configuration spills on the definition of isotropy. Linear elastic constitutive equations, which are isotropic when phrased in terms of Lagrangian variables, become anisotropic when expressed in the current configuration, as shown in Section 2.9. This dependence wrt the reference configuration is not conflicting with the fact that Lagrangian constitutive equations keep their structure upon a change of reference configuration.

The last result simplifies if the second order tensor $\mathbf{A}$ is symmetric,

$$\mathbf{A} \cdot \frac{\partial f}{\partial \mathbf{A}} = \frac{\partial f}{\partial \mathbf{A}} \cdot \mathbf{A} \,. \tag{2.11.29}$$

Then, the further following implication results using standard algebra,

$$\begin{aligned} \frac{df(\mathbf{A})}{dt} &= \frac{\partial f}{\partial \mathbf{A}} : \frac{d\mathbf{A}}{dt} \\ &= \frac{\partial f}{\partial \mathbf{A}} : \big(\frac{D\mathbf{A}}{Dt} + \boldsymbol{\Omega} \cdot \mathbf{A} - \mathbf{A} \cdot \boldsymbol{\Omega}\big) \\ &= \frac{\partial f}{\partial \mathbf{A}} : \frac{D\mathbf{A}}{Dt} + \boldsymbol{\Omega} : \big(\frac{\partial f}{\partial \mathbf{A}} \cdot \mathbf{A}^{\mathrm{T}} - \mathbf{A}^{\mathrm{T}} \cdot \frac{\partial f}{\partial \mathbf{A}}\big) \\ &= \frac{\partial f}{\partial \mathbf{A}} : \frac{D\mathbf{A}}{Dt} \,, \end{aligned} \tag{2.11.30}$$

where $D\mathbf{A}/Dt$ denotes the corotational derivative (2.11.15),

$$\frac{D\mathbf{A}}{Dt} = \frac{d\mathbf{A}}{dt} - \boldsymbol{\Omega} \cdot \mathbf{A} + \mathbf{A} \cdot \boldsymbol{\Omega} \,. \tag{2.11.31}$$

The properties extend to a scalar function with two or more arguments, e.g., for two symmetric second order tensors,

$$f(\mathbf{A}_1, \mathbf{A}_2) = f(\underline{\mathbf{A}}_1 = \mathbf{R} \cdot \mathbf{A}_1 \cdot \mathbf{R}^{\mathrm{T}}, \underline{\mathbf{A}}_2 = \mathbf{R} \cdot \mathbf{A}_2 \cdot \mathbf{R}^{\mathrm{T}}) \,. \tag{2.11.32}$$

Then,

$$\begin{aligned} \frac{\partial f}{\partial \mathbf{A}_i} &= \mathbf{R}^{\mathrm{T}} \cdot \frac{\partial f}{\partial \underline{\mathbf{A}}_i} \cdot \mathbf{R}, \quad i = 1, 2, \\ \sum_{i=1,2} \mathbf{A}_i \cdot \frac{\partial f}{\partial \mathbf{A}_i} &= \sum_{i=1,2} \frac{\partial f}{\partial \mathbf{A}_i} \cdot \mathbf{A}_i \,. \end{aligned} \tag{2.11.33}$$

Relation (2.11.30) again with the corotational derivative (2.11.31) extends in the form,

$$\begin{aligned} \frac{df}{dt}(\mathbf{A}_1, \mathbf{A}_2) &= \frac{\partial f}{\partial \mathbf{A}_1} : \frac{d\mathbf{A}_1}{dt} + \frac{\partial f}{\partial \mathbf{A}_2} : \frac{d\mathbf{A}_2}{dt} \\ &= \frac{\partial f}{\partial \mathbf{A}_1} : \frac{D\mathbf{A}_1}{Dt} + \frac{\partial f}{\partial \mathbf{A}_2} : \frac{D\mathbf{A}_2}{Dt} \,. \end{aligned} \tag{2.11.34}$$

2.11.3.2 Tensor-valued isotropic functions

Let $\mathbf{A}$ be a second order tensor. A tensor-valued function $\boldsymbol{\mathcal{F}}(\mathbf{A})$ is isotropic if, for any orthogonal transformation $\mathbf{R} \in \mathcal{O}(3)$,

$$\mathbf{R} \cdot \boldsymbol{\mathcal{F}}(\mathbf{A}) \cdot \mathbf{R}^{\mathrm{T}} = \boldsymbol{\mathcal{F}}(\mathbf{R} \cdot \mathbf{A} \cdot \mathbf{R}^{\mathrm{T}}) \,. \tag{2.11.35}$$

As an example, Exercise 2.9 shows that the square root of a positive (semi-)definite second order tensor is isotropic.

The important following result should be recorded, Mandel [1974], Gurtin [1981]: a second order isotropic function $\boldsymbol{\mathcal{F}}(\mathbf{A}, a)$ of a symmetric second order tensor $\mathbf{A}$ and scalar a expresses in the format,

$$\boldsymbol{\mathcal{F}}(\mathbf{A}, a) = \sum_{i=0}^{m-1} b_i \, \mathbf{A}^i \,, \tag{2.11.36}$$

where m is the number of distinct eigenvalues of $\mathbf{A}$ and the coefficients b depend on the scalar invariants of $\mathbf{A}$ and on a.

A proof in $\mathbb{R}^3$ is detailed in Exercise 2.8 but the result holds for any space dimension n. The sum in (2.11.36) can be extended to $i = n$ but the coefficients are not unique if $m < n$.

As a consequence of (2.11.36), an isotropic function of a scalar a is of the form $\boldsymbol{\mathcal{F}}(a) = b_0 \, \mathbf{I}$. An affine function of a symmetric second order tensor reads $\boldsymbol{\mathcal{F}}(\mathbf{A}) = b_0 \, \mathbf{I} + b_1 \, \mathbf{A}$ with $b_0 = b_{00} + b_{01} \operatorname{tr} \mathbf{A}$ depending on the linear invariant $\operatorname{tr} \mathbf{A}$, and b_{00}, b_{01} and b_1 being constants. Finally it is worth recording the explicit expression (2.11.36) in $\mathbb{R}^3$, namely $\boldsymbol{\mathcal{F}}(\mathbf{A}, a) = b_0 \, \mathbf{I} + b_1 \, \mathbf{A} + b_2 \, \mathbf{A}^2$ with the coefficients b depending on the three scalar invariants of $\mathbf{A}$ and on a.

2.11.3.3 From anisotropy to isotropy via a change of arguments

Available tables of representation concern a priori isotropic functions. A theorem of Liu [1982] shows how to transform anisotropic functions into isotropic functions by augmenting the set of variables and therefore allows to capitalize upon available representation tables.

Let f be a scalar-valued, vector-valued or tensor-valued function of a tensor $\mathbf{A}$ and vector $\mathbf{a}$ which is invariant under the group $\mathcal{S}$ as detailed by (2.11.26). Consider a material that is characterized by preferred directions represented by the unit vector $\mathbf{m}$ and the tensor $\mathbf{M}$ and let $s = \{\mathbf{R} \in \mathcal{S},\ \mathbf{R}\cdot\mathbf{m} = \mathbf{m};\ \mathbf{R}\cdot\mathbf{M}\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{M}\}$.

Liu's theorem asserts that the function $f(\mathbf{A}, \mathbf{a})$ is invariant relative to s iff it can be represented by the function $F(\mathbf{A}, \mathbf{a}, \mathbf{M}, \mathbf{m})$ invariant relative to $\mathcal{S}$.

The theorem will be applied to two particularly useful symmetries, namely transverse isotropy and orthotropy [2.11].

First, consider the *transversely isotropic groups*

$$s_{\mathrm{trans}'} = \{\mathbf{R} \in \mathcal{O}_3,\ \mathbf{R}\cdot\mathbf{m} = \mathbf{m}\}\,, \tag{2.11.37}$$

and

$$s_{\mathrm{trans}''} = \{\mathbf{R} \in \mathcal{O}_3,\ \mathbf{R}\cdot\mathbf{m} = \mathbf{m} \text{ or } \mathbf{R}\cdot\mathbf{m} = -\mathbf{m}\}\,. \tag{2.11.38}$$

Then the function $f(\mathbf{A}, \mathbf{a})$ which is invariant under $s_{\mathrm{trans}'}$ can be represented by the isotropic function $F(\mathbf{A}, \mathbf{a}, \mathbf{m})$, and the function $f(\mathbf{A}, \mathbf{a})$ which is invariant under $s_{\mathrm{trans}''}$ can be represented by the isotropic function $F(\mathbf{A}, \mathbf{a}, \mathbf{M} = \mathbf{m}\otimes\mathbf{m})$.

Next, consider the orthotropic symmetry group

$$s_{\mathrm{ortho}} = \{\mathbf{R} \in \mathcal{O}_3,\ \mathbf{R}\cdot\mathbf{m}_i = \mathbf{m}_i \text{ or } \mathbf{R}\cdot\mathbf{m}_i = -\mathbf{m}_i,\ i \in [1,3]\}\,, \tag{2.11.39}$$

where the $\mathbf{m}$'s constitute a cartesian triad. Then the function $f(\mathbf{A}, \mathbf{a})$ which is invariant under s_{ortho} can be represented by the isotropic function $F(\mathbf{A}, \mathbf{a}, \mathbf{M}_1 = \mathbf{m}_1\otimes\mathbf{m}_1, \mathbf{M}_2 = \mathbf{m}_2\otimes\mathbf{m}_2)$.

It is worth to come back to transverse isotropy which is characterized by a preferred direction $\mathbf{m}$. In fact, transverse isotropy covers five groups of symmetry which can be defined either in extenso [Spencer 1971, p. 251], or by their properties [Liu 1982]. They are listed in Table 2.11.1 from the smallest s_1 to the largest s_5 in terms of the rotation $\mathbf{R}_\theta$ of angle θ about $\mathbf{m}$ and *reflections* $\mathbf{R}_i = \mathbf{I} - 2\,\mathbf{m}_i\otimes\mathbf{m}_i$ about planes of normal $\mathbf{m}_i$, $i \in [1,3]$, which can the expressed componentwise in the cartesian triad $(\mathbf{m}_1, \mathbf{m}_2, \mathbf{m}_3 = \mathbf{m})$,

$$\mathbf{R}_\theta = \begin{bmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix},\quad \mathbf{R}_1 = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix},\quad \mathbf{R}_2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix},\quad \mathbf{R}_3 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}. \tag{2.11.40}$$

Table 2.11.1: The five subgroups of transverse isotropy about the vector $\mathbf{m}$ [Spencer 1971, Liu 1982]. In the definition of the group s_3, the tensor $\mathbf{M}^- = \mathbf{m}_1\otimes\mathbf{m}_2 - \mathbf{m}_2\otimes\mathbf{m}_1$ is the skew-symmetric tensor associated with the vector $\mathbf{m}$, Eqn (2.1.11).

Definition of the symmetry group	Elements of the symmetry group
$s_1 = \{\mathbf{R} \in \mathcal{SO}(3),\ \mathbf{R}\cdot\mathbf{m} = \mathbf{m}\}$	$\mathbf{I}$, $\mathbf{R}_\theta$
$s_2 = \{\mathbf{R} \in \mathcal{O}(3),\ \mathbf{R}\cdot\mathbf{m} = \mathbf{m}\}$	$\mathbf{I}$, $\mathbf{R}_\theta$, $\mathbf{R}_1$
$s_3 = \{\mathbf{R} \in \mathcal{O}(3),\ \mathbf{R}\cdot\mathbf{M}^-\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{M}^-\}$	$\mathbf{I}$, $\mathbf{R}_\theta$, $\mathbf{R}_3$
$s_4 = \{\mathbf{R} \in \mathcal{SO}(3),\ \mathbf{R}\cdot(\mathbf{m}\otimes\mathbf{m})\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{m}\otimes\mathbf{m}\}$	$\mathbf{I}$, $\mathbf{R}_\theta$, $-\mathbf{R}_2 = \mathbf{R}_1\cdot\mathbf{R}_3$
$s_5 = \{\mathbf{R} \in \mathcal{O}(3),\ \mathbf{R}\cdot(\mathbf{m}\otimes\mathbf{m})\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{m}\otimes\mathbf{m}\}$	$\mathbf{I}$, $\mathbf{R}_\theta$, $\mathbf{R}_1$, $\mathbf{R}_3$, $-\mathbf{R}_2 = \mathbf{R}_1\cdot\mathbf{R}_3$

Both laminates and materials with woven fabrics are reinforced by fibers. In laminates, the sense of the fibers is elusive while it matters for woven fabrics. In other words, laminates exhibit material symmetry with respect to planes orthogonal to the fiber directions. The property does not hold for certain woven fabrics. The mechanical implications of the presence of arrows on fibers are touched upon for lamellar tissues in Sections 19.19.2.1 and 19.19.2.5.

[2.11] In the following text, we assume $\mathcal{S} = \mathcal{O}_3$ and invoke isotropic functions. For $\mathcal{S} = \mathcal{SO}_3$, we would invoke hemitropic functions.

2.11.3.4 Representation theorems for scalar-valued isotropic functions

Scalar and tensor invariant generators of sets of vectors and second order symmetric and skew-symmetric tensors have been elaborated in the 1960s and 1970s, [Truesdell and Noll 1965; Smith 1970; Wang 1970; Smith 1971; Spencer 1971; Boehler 1978, 1987]. The sets of generators were also required to be irreducible so as to constitute bases. A distinction should be made between *functional* bases and *integrity* bases. Integrity bases assume the constitutive functions to be polynomial invariants of the set of variables. At variance, the lists displayed here are functional bases.

A list of irreducible isotropic scalar invariants of a few vectors and tensors is displayed in Table 2.11.2. To compact the representation, only the elements specific to each line have been listed. For example, the complete list of scalar invariants of the set ($\mathbf{A}$, $\mathbf{a}$) consists of the invariants pertaining to $\mathbf{A}$, in the invariants pertaining to $\mathbf{a}$ and in the mixed invariants.

Table 2.11.2: Irreducible and complete list of isotropic scalar invariants of symmetric second order tensors $\mathbf{A}$, of a skew-symmetric second order tensor $\mathbf{W}$, vectors $\mathbf{a}$, and of some combinations of these elements [Wang 1970].

Variables	Invariants
$\mathbf{A}$	$\operatorname{tr}\mathbf{A}$, $\operatorname{tr}\mathbf{A}^2$, $\operatorname{tr}\mathbf{A}^3$
$\mathbf{W}$	$\operatorname{tr}\mathbf{W}^2$
$\mathbf{a}$	$\operatorname{tr}\mathbf{a}\otimes\mathbf{a}=\mathbf{a}\cdot\mathbf{a}$
$\mathbf{a}_1$, $\mathbf{a}_2$	$\mathbf{a}_1\cdot\mathbf{a}_2$
$\mathbf{A}$, $\mathbf{a}$	$\mathbf{a}\cdot\mathbf{A}\cdot\mathbf{a}$, $\mathbf{a}\cdot\mathbf{A}^2\cdot\mathbf{a}$
$\mathbf{A}_1$, $\mathbf{A}_2$	$\operatorname{tr}\mathbf{A}_1\cdot\mathbf{A}_2$, $\operatorname{tr}\mathbf{A}_1^2\cdot\mathbf{A}_2$, $\operatorname{tr}\mathbf{A}_1\cdot\mathbf{A}_2^2$, $\operatorname{tr}\mathbf{A}_1^2\cdot\mathbf{A}_2^2$
$\mathbf{A}_1$, $\mathbf{A}_2$, $\mathbf{A}_3$	$\operatorname{tr}\mathbf{A}_1\cdot\mathbf{A}_2\cdot\mathbf{A}_3$

Table 2.11.3 displays two equivalent irreducible representations of orthotropic scalar invariants of the symmetric second order tensor $\mathbf{A}$. The preferred directions of the material form a cartesian triad ($\mathbf{m}_1$, $\mathbf{m}_2$, $\mathbf{m}_3$). The symmetry group

$$\mathcal{S}_{\text{ortho}}=\{\pm\mathbf{I},\,\mathbf{R}_1,\,\mathbf{R}_2,\,\mathbf{R}_3\}\,, \tag{2.11.41}$$

consists, besides of the identity $\mathbf{I}$ (neutral element) and its opposite $-\mathbf{I}$ (centrosymmetry), of the reflections $\mathbf{R}_1$, $\mathbf{R}_2$ and $\mathbf{R}_3$ about the respective planes ($\mathbf{m}_2$, $\mathbf{m}_3$), ($\mathbf{m}_3$, $\mathbf{m}_1$) and ($\mathbf{m}_1$, $\mathbf{m}_2$), namely $\mathbf{R}_i=\mathbf{I}-2\,\mathbf{m}_i\otimes\mathbf{m}_i$ for $i\in[1,3]$. Since the sense of the preferred directions is elusive, the second order tensors $\mathbf{M}_i=\mathbf{m}_i\otimes\mathbf{m}_i$, $i\in[1,3]$, are involved in the representations rather than the vectors $\mathbf{m}_i$ themselves. Ad hoc equivalent representations are trivially obtained by playing with the identity,

$$\mathbf{M}_1+\mathbf{M}_2+\mathbf{M}_3=\mathbf{I}\,. \tag{2.11.42}$$

Table 2.11.3: Two equivalent irreducible and complete lists of orthotropic scalar invariants of a symmetric second order tensor $\mathbf{A}$ [Boehler 1987]. $\mathbf{M}_i=\mathbf{m}_i\otimes\mathbf{m}_i$ with $\cup_{i\in[1,3]}\,\mathbf{m}_i$ cartesian triad of preferred directions.

Variable	Invariants
$\mathbf{A}$	$\operatorname{tr}\mathbf{M}_1\cdot\mathbf{A}$, $\operatorname{tr}\mathbf{M}_1\cdot\mathbf{A}^2$, $\operatorname{tr}\mathbf{A}^3$,
	$\operatorname{tr}\mathbf{M}_2\cdot\mathbf{A}$, $\operatorname{tr}\mathbf{M}_2\cdot\mathbf{A}^2$
	$\operatorname{tr}\mathbf{M}_3\cdot\mathbf{A}$, $\operatorname{tr}\mathbf{M}_3\cdot\mathbf{A}^2$

Variable	Invariants
$\mathbf{A}$	$\operatorname{tr}\mathbf{A}$, $\operatorname{tr}\mathbf{A}^2$, $\operatorname{tr}\mathbf{A}^3$,
	$\operatorname{tr}\mathbf{M}_1\cdot\mathbf{A}$, $\operatorname{tr}\mathbf{M}_1\cdot\mathbf{A}^2$
	$\operatorname{tr}\mathbf{M}_2\cdot\mathbf{A}$, $\operatorname{tr}\mathbf{M}_2\cdot\mathbf{A}^2$

Table 2.11.4 displays an irreducible representation of transversely isotropic scalar invariants of the symmetric second order tensor $\mathbf{A}$. A cartesian triad $\{\mathbf{e}_1,\,\mathbf{e}_2,\,\mathbf{e}_3=\mathbf{m}\}$ is defined from the preferred direction $\mathbf{m}$. The symmetry group

$$\mathcal{S}_{\text{trans}}=\{\pm\mathbf{I},\,\mathbf{R}_1,\,\mathbf{R}_2,\,\mathbf{R}_3,\,\mathbf{R}_\theta\}\,, \tag{2.11.43}$$

consists of the same elements as the orthotropy group plus arbitrary rotations $\mathbf{R}_\theta$, $\theta\in[0,2\,\pi[$, about the preferred axis. Again, since the sense of the preferred direction is elusive, the second order tensor $\mathbf{M}=\mathbf{m}\otimes\mathbf{m}$ is involved in the representations rather than the vector $\mathbf{m}$ itself.

Table 2.11.4: Irreducible and complete list of transversely isotropic scalar invariants of a symmetric second order tensor $\mathbf{A}$ [Boehler 1987]. $\mathbf{M} = \mathbf{m} \otimes \mathbf{m}$ with $\mathbf{m}$ unit vector along the preferred direction.

Variable	Invariants
$\mathbf{A}$	$\operatorname{tr}\mathbf{A}$, $\operatorname{tr}\mathbf{A}^2$, $\operatorname{tr}\mathbf{A}^3$,
	$\operatorname{tr}\mathbf{M}\cdot\mathbf{A}$, $\operatorname{tr}\mathbf{M}\cdot\mathbf{A}^2$

2.11.3.5 Representation tables for symmetric and skew-symmetric isotropic second order tensors

Given a list of vectors and symmetric and skew-symmetric tensors, tools to build isotropic second order tensors are listed in the tables below. Table 2.11.5 displays generators of symmetric second order tensors built from various vector and tensor variables. Table 2.11.6 displays generators of symmetric and skew-symmetric second order tensors built from two symmetric second order tensors. These tables can be applied to obtain Table 2.11.8 pertaining to transverse isotropy, accounting for simplifications due to $\mathbf{M}^2 = \mathbf{M}$. They need to be extended to include the set of variables $(\mathbf{A}, \mathbf{M}_1, \mathbf{M}_2)$ to obtain, with help of Liu's theorem, Table 2.11.7 pertaining to orthotropic symmetry. Simplifications arise due to the identities $\mathbf{M}_i \cdot \mathbf{M}_j = \mathbf{M}_i\, I_{ij}$ (no sum on i), $i, j \in [1, 3]$, and (2.11.42).

Table 2.11.5: Irreducible list of isotropic symmetric second order generators of a symmetric second order tensor $\mathbf{A}$, a skew-symmetric second order tensor $\mathbf{W}$, vectors $\mathbf{a}$, and some combinations of these elements [Wang 1970].

Variables	Generators
	$\mathbf{I}$
$\mathbf{A}$	$\mathbf{A}$, $\mathbf{A}^2$
$\mathbf{W}$	$\mathbf{W}^2$
$\mathbf{a}$	$\mathbf{a}\otimes\mathbf{a}$
$\mathbf{a}_1$, $\mathbf{a}_2$	$\mathbf{a}_1\otimes\mathbf{a}_2 + \mathbf{a}_2\otimes\mathbf{a}_1$
$\mathbf{A}$, $\mathbf{a}$	$\mathbf{a}\otimes\mathbf{A}\cdot\mathbf{a} + \mathbf{A}\cdot\mathbf{a}\otimes\mathbf{a}$, $\mathbf{a}\otimes\mathbf{A}^2\cdot\mathbf{a} + \mathbf{A}^2\cdot\mathbf{a}\otimes\mathbf{a}$

Table 2.11.6: Irreducible list of isotropic symmetric and skew-symmetric second order generators of two symmetric second order tensors $\mathbf{A}_1$ and $\mathbf{A}_2$ [Wang 1970]. The symmetric generator $\mathbf{A}_1^2\cdot\mathbf{A}_2^2 + \mathbf{A}_2^2\cdot\mathbf{A}_1^2$ listed by Wang [1970]-II, p. 215, is redundant [Boehler 1987].

Variables	Symmetric Generators
$\mathbf{A}_1$, $\mathbf{A}_2$	$\mathbf{A}_1\cdot\mathbf{A}_2 + \mathbf{A}_2\cdot\mathbf{A}_1$, $\mathbf{A}_1\cdot\mathbf{A}_2^2 + \mathbf{A}_2^2\cdot\mathbf{A}_1$, $\mathbf{A}_1^2\cdot\mathbf{A}_2 + \mathbf{A}_2\cdot\mathbf{A}_1^2$
Variables	Skew-Symmetric Generators
$\mathbf{A}_1$, $\mathbf{A}_2$	$\mathbf{A}_1\cdot\mathbf{A}_2 - \mathbf{A}_2\cdot\mathbf{A}_1$, $\mathbf{A}_1\cdot\mathbf{A}_2^2 - \mathbf{A}_2^2\cdot\mathbf{A}_1$, $\mathbf{A}_1^2\cdot\mathbf{A}_2 - \mathbf{A}_2\cdot\mathbf{A}_1^2$,
	$\mathbf{A}_1\cdot\mathbf{A}_2\cdot\mathbf{A}_1^2 - \mathbf{A}_1^2\cdot\mathbf{A}_2\cdot\mathbf{A}_1$, $\mathbf{A}_2\cdot\mathbf{A}_1\cdot\mathbf{A}_2^2 - \mathbf{A}_2^2\cdot\mathbf{A}_1\cdot\mathbf{A}_2$

Table 2.11.7: List of orthotropic symmetric and skew-symmetric second order generators of a symmetric second order tensor $\mathbf{A}$. $\mathbf{M}_i = \mathbf{m}_i \otimes \mathbf{m}_i$ with $\cup_{i\in[1,3]}\, \mathbf{m}_i$ cartesian triad of preferred directions.

Variable	Irreducible Symmetric Generators [Boehler 1987]
	$\mathbf{M}_1,\ \mathbf{M}_2,\ \mathbf{M}_3$
$\mathbf{A}$	$\mathbf{M}_1 \cdot \mathbf{A} + \mathbf{A} \cdot \mathbf{M}_1,\ \mathbf{A}^2$
	$\mathbf{M}_2 \cdot \mathbf{A} + \mathbf{A} \cdot \mathbf{M}_2,$
	$\mathbf{M}_3 \cdot \mathbf{A} + \mathbf{A} \cdot \mathbf{M}_3$
Variable	(nonirreducible) Skew-Symmetric Generators [Wang 1970]
$\mathbf{A}$	$\mathbf{M}_1 \cdot \mathbf{A} - \mathbf{A} \cdot \mathbf{M}_1,\ \mathbf{M}_2 \cdot \mathbf{A} - \mathbf{A} \cdot \mathbf{M}_2,$
	$\mathbf{M}_1 \cdot \mathbf{A}^2 - \mathbf{A}^2 \cdot \mathbf{M}_1,\ \mathbf{M}_2 \cdot \mathbf{A}^2 - \mathbf{A}^2 \cdot \mathbf{M}_2,$
	$\mathbf{A} \cdot \mathbf{M}_1 \cdot \mathbf{A}^2 - \mathbf{A}^2 \cdot \mathbf{M}_1 \cdot \mathbf{A},\ \mathbf{A} \cdot \mathbf{M}_2 \cdot \mathbf{A}^2 - \mathbf{A}^2 \cdot \mathbf{M}_2 \cdot \mathbf{A},$
	$\mathbf{M}_1 \cdot \mathbf{A} \cdot \mathbf{M}_2 - \mathbf{M}_2 \cdot \mathbf{A} \cdot \mathbf{M}_1$

Table 2.11.8: Irreducible list of transversely isotropic symmetric and skew-symmetric second order generators of a symmetric second order tensor $\mathbf{A}$. $\mathbf{M} = \mathbf{m} \otimes \mathbf{m}$ with $\mathbf{m}$ unit vector along the preferred direction.

Variable	Symmetric Generators [Boehler 1987]
	$\mathbf{I},\ \mathbf{M}$
$\mathbf{A}$	$\mathbf{A},\ \mathbf{M} \cdot \mathbf{A} + \mathbf{A} \cdot \mathbf{M},$
	$\mathbf{A}^2,\ \mathbf{M} \cdot \mathbf{A}^2 + \mathbf{A}^2 \cdot \mathbf{M}$
Variable	Skew-Symmetric Generators [Wang 1970]
$\mathbf{A}$	$\mathbf{M} \cdot \mathbf{A} - \mathbf{A} \cdot \mathbf{M},$
	$\mathbf{M} \cdot \mathbf{A}^2 - \mathbf{A}^2 \cdot \mathbf{M},$
	$\mathbf{A} \cdot \mathbf{M} \cdot \mathbf{A}^2 - \mathbf{A}^2 \cdot \mathbf{M} \cdot \mathbf{A}$

Exercises on Chapter 2

Exercise 2.1 Change of coordinate axes

Obtain the components of the stress tensor $\boldsymbol{\sigma}$ under a rotation of the coordinate axes.

Answer: The right handed set of coordinate vectors ($\mathbf{e}_j$, $j \in [1,3]$) is changed to the right handed set ($\mathbf{e}^*_i$, $i \in [1,3]$),

$$\mathbf{e}^*_i = R_{ij}\,\mathbf{e}_j, \quad \mathbf{e}_i = R_{ji}\,\mathbf{e}^*_j\,, \tag{2.E.1}$$

where $R_{ij} = \cos(\mathbf{e}^*_i, \mathbf{e}_j)$. Then the stress $\boldsymbol{\sigma} = \sigma_{ij}\,\mathbf{e}_i \otimes \mathbf{e}_j$ may also be expressed as $\boldsymbol{\sigma} = R_{ki}\,\sigma_{ij}\,R_{lj}\,\mathbf{e}^*_k \otimes \mathbf{e}^*_l$, i.e. $\sigma^*_{kl} = R_{ki}\,\sigma_{ij}\,R_{lj}$, or $\boldsymbol{\sigma}^* = \mathbf{R}\cdot\boldsymbol{\sigma}\cdot\mathbf{R}^{\mathrm{T}}$.

Note that the coordinates x_i change to x^*_i,

$$x^*_i = R_{ij}\,x_j, \quad x_i = R_{ji}\,x^*_j\,. \tag{2.E.2}$$

The components of a tensor $\mathbf{A}$ of arbitrary order transform similarly,

$$A^*_{ijk\ldots} = R_{ip}\,R_{jq}\,R_{kr}\,A^*_{pqr\ldots}, \quad A_{pqr\ldots} = R_{ip}\,R_{jq}\,R_{kr}\,A^*_{ijk\ldots}\,. \tag{2.E.3}$$

Note also the tensor forms of the transformations of the coordinate and basis vectors,

$$\mathbf{x}^* = \mathbf{R}\cdot\mathbf{x}, \quad \mathbf{e}^* = \mathbf{R}\cdot\mathbf{e}, \quad \mathbf{x} = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{x}^*, \quad \mathbf{e} = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{e}^*\,. \tag{2.E.4}$$

Exercise 2.2 Kinematics that differ by a rotation

Compare the kinematics,

$$u^{(1)}_1 = k\,x_2, \quad u^{(1)}_2 = u^{(1)}_3 = 0\,, \tag{2.E.5}$$

and

$$u^{(2)}_1 = \frac{k}{2}\,x_2, \quad u^{(2)}_2 = \frac{k}{2}\,x_1, \quad u^{(2)}_3 = 0\,. \tag{2.E.6}$$

Answer: The infinitesimal strains are identical,

$$\boldsymbol{\epsilon}^{(i)} = \frac{1}{2}\big(\mathbf{u}^{(i)}\overleftarrow{\boldsymbol{\nabla}} + \vec{\boldsymbol{\nabla}}\mathbf{u}^{(i)}\big) = \begin{bmatrix} 0 & \frac{k}{2} & 0 \\ \frac{k}{2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad i = 1,2, \tag{2.E.7}$$

but the two kinematics differ by a rotation around the x_3-axis,

$$\mathbf{u}^{(1)}\overleftarrow{\boldsymbol{\nabla}} = \begin{bmatrix} 0 & k & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} = \overbrace{\begin{bmatrix} 0 & \frac{k}{2} & 0 \\ \frac{k}{2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}}^{\boldsymbol{\epsilon}^{(1)}} + \overbrace{\begin{bmatrix} 0 & \frac{k}{2} & 0 \\ -\frac{k}{2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}}^{\boldsymbol{\omega}^{(1)}}; \quad \mathbf{u}^{(2)}\overleftarrow{\boldsymbol{\nabla}} = \boldsymbol{\epsilon}^{(2)}; \quad \boldsymbol{\omega}^{(2)} = \mathbf{0}\,. \tag{2.E.8}$$

Exercise 2.3 Polar decomposition of a simple shear

Obtain the polar decomposition associated with the simple shear kinematics $\mathbf{x} = \underline{\mathbf{x}} + \mathbf{u}$ [Malvern 1969, p. 182] et seq.,

$$u_1 = k\,\underline{x}_2, \quad u_2 = u_3 = 0\,. \tag{2.E.9}$$

Answer: From the deformation gradient,

$$\mathbf{F} = \begin{bmatrix} 1 & k & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{2.E.10}$$

follows the right Cauchy-Green tensor

$$\mathbf{C} = \begin{bmatrix} 1 & k & 0 \\ k & 1+k^2 & 0 \\ 0 & 0 & 1 \end{bmatrix}_{\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3} = \begin{bmatrix} \lambda_1^2 & 0 & 0 \\ 0 & \lambda_2^2 & 0 \\ 0 & 0 & 1 \end{bmatrix}_{\mathbf{e}^*_1,\mathbf{e}^*_2,\mathbf{e}_3}, \tag{2.E.11}$$

which has the eigenvalues,

$$\lambda_{1,2}^2 = \tfrac{1}{2}\,(2 + k^2 \pm k\,\sqrt{4+k^2}), \tag{2.E.12}$$

and the first eigendirection $\mathbf{e}_1^*$ in the plane 1-2 makes an angle ϕ with the 1-axis, with $\tan 2\,\phi = -2/k$. Further

$$\lambda_1 = \tfrac{1}{2}\,(k + \sqrt{4+k^2}), \quad \lambda_2 = \frac{1}{\lambda_1} = \tfrac{1}{2}\,(-k + \sqrt{4+k^2}), \tag{2.E.13}$$

and

$$\cos^2\phi = \tfrac{1}{2}\,(1 - \frac{k}{\sqrt{4+k^2}}), \quad \sin^2\phi = \tfrac{1}{2}\,(1 + \frac{k}{\sqrt{4+k^2}})\,. \tag{2.E.14}$$

The right stretch deduces,

$$\mathbf{U} = \left[\begin{array}{ccc} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & 1 \end{array}\right]_{\mathbf{e}_1^*,\mathbf{e}_2^*,\mathbf{e}_3} = \frac{1}{\sqrt{4+k^2}} \left[\begin{array}{ccc} 2 & k & 0 \\ k & k^2+2 & 0 \\ 0 & 0 & \sqrt{4+k^2} \end{array}\right]_{\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3}, \tag{2.E.15}$$

and the rotation follows as

$$\mathbf{Q} = \mathbf{F}\cdot\mathbf{U}^{-1} = \frac{1}{\sqrt{4+k^2}} \left[\begin{array}{ccc} 2 & k & 0 \\ -k & 2 & 0 \\ 0 & 0 & \sqrt{4+k^2} \end{array}\right]_{\mathbf{e}_1,\mathbf{e}_2,\mathbf{e}_3}. \tag{2.E.16}$$

Exercise 2.4 A simple example of polar decomposition

Consider the polar decomposition $\mathbf{F} = \mathbf{Q}\cdot\mathbf{U}$ of the deformation gradient $\mathbf{F}$,

$$\mathbf{U} = \left[\begin{array}{cc} 1 & 0 \\ 0 & 2 \end{array}\right], \quad \mathbf{Q} = \left[\begin{array}{cc} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{array}\right], \tag{2.E.17}$$

where α is an arbitrary angle. Obtain the left stretch $\mathbf{V}$, perform its spectral decomposition, and check the expressions (2.5.4).

Answer: The associated deformation gradient and left stretch are obtained as,

$$\mathbf{F} = \left[\begin{array}{cc} \cos\alpha & 2\sin\alpha \\ -\sin\alpha & 2\cos\alpha \end{array}\right], \quad \mathbf{V} = \mathbf{Q}\cdot\mathbf{U}\cdot\mathbf{Q}^{\mathrm{T}} = \left[\begin{array}{cc} 1+\sin^2\alpha & \cos\alpha\,\sin\alpha \\ \cos\alpha\,\sin\alpha & 1+\cos^2\alpha \end{array}\right]. \tag{2.E.18}$$

The eigenvalues are 1 and 2 and, with $\underline{\mathbf{e}}_1$ and $\underline{\mathbf{e}}_2$ the eigenvectors of the right stretch $\mathbf{U}$, the eigenvectors of the left stretch $\mathbf{V}$ write $\mathbf{e}_1 = \cos\alpha\,\underline{\mathbf{e}}_1 - \sin\alpha\,\underline{\mathbf{e}}_1$ and $\mathbf{e}_2 = \sin\alpha\,\underline{\mathbf{e}}_1 + \cos\alpha\,\underline{\mathbf{e}}_1$.

The expressions (2.5.4) are then easily checked.

Exercise 2.5 Proof of the generalized Cayley-Hamilton theorem [Rivlin 1955]

- start from the Cayley-Hamilton theorem,

$$\mathbf{CH}(\mathbf{D}) = \mathbf{D}^3 - I_1\,\mathbf{D}^2 + I_2\,\mathbf{D} - I_3\,\mathbf{I} = \mathbf{0}\,, \tag{2.E.19}$$

  with

$$I_1 = \mathrm{tr}\;\mathbf{D}, \quad I_2 = \frac{1}{2}\,((\mathrm{tr}\;\mathbf{D})^2 - \mathrm{tr}\;\mathbf{D}^2), \quad I_3 = \frac{1}{3}\,\mathrm{tr}\;\mathbf{D}^3 - \frac{1}{2}\,\mathrm{tr}\;\mathbf{D}\,\mathrm{tr}\;\mathbf{D}^2 + \frac{1}{6}\,(\mathrm{tr}\;\mathbf{D})^3\,; \tag{2.E.20}$$

- apply the Cayley-Hamilton theorem to $\mathbf{D} = \mathbf{A}+\mathbf{B}$ and to $\mathbf{D} = \mathbf{A}-\mathbf{B}$. Substract the expressions to obtain $\mathbf{RCH}(\mathbf{A},\mathbf{B}) = \mathbf{CH}(\mathbf{A}+\mathbf{B}) - \mathbf{CH}(\mathbf{A}-\mathbf{B})$;
- use the identity $\mathrm{tr}\;\mathbf{A}\cdot\mathbf{B}\cdot\mathbf{A} = \mathrm{tr}\;\mathbf{A}^2\cdot\mathbf{B}$ and the Cayley-Hamilton theorem applied to $\mathbf{B}$, to eliminate $\mathbf{B}^3$ from $\mathbf{RCH}(\mathbf{A},\mathbf{B})$ and to retrieve the relation $\mathbf{SCH}(\mathbf{A},\mathbf{B})$ defined by (2.3.9);
- apply the Cayley-Hamilton theorem to $\mathbf{D} = \mathbf{A}+\mathbf{B}+\mathbf{C}$, and to $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$, and use relations $\mathbf{SCH}(\mathbf{A},\mathbf{B})$, $\mathbf{SCH}(\mathbf{B},\mathbf{C})$ and $\mathbf{SCH}(\mathbf{C},\mathbf{A})$.

Exercise 2.6 Inverse of a rank two modification of the identity

Show by inspection that the inverse of the rank two modification of the identity (2.3.29) is given by (2.3.30).

Hint: A heuristic proof seeks the inverse as the sum $a_0\,\mathbf{I} + \mathbf{a}\otimes\mathbf{b}' + \mathbf{c}\otimes\mathbf{d}'$ with $\mathbf{b}' = a_1\,\mathbf{b} + a_2\,\mathbf{d}$ and $\mathbf{d}' = a_3\,\mathbf{b} + a_4\,\mathbf{d}$ and identify the coefficients a's simply by requiring that the product of the rank two modification by this inverse is indeed equal to the identity.

Exercise 2.7 Derivatives with respect to the stress and the stress deviator

Let $F = F(I_1, J_2, J_3)$ be a scalar function of the isotropic scalar invariants $I_1 = \operatorname{tr} \boldsymbol{\sigma} = \mathbf{I} : \boldsymbol{\sigma}$ of the stress $\boldsymbol{\sigma}$, and $J_2 = \frac{1}{2} \operatorname{tr} \mathbf{s}^2$ and $J_3 = \frac{1}{3} \operatorname{tr} \mathbf{s}^3$ of the stress deviator $\mathbf{s} = \boldsymbol{\sigma} - \frac{1}{3} I_1 \mathbf{I}$. Calculate $\partial F / \partial \boldsymbol{\sigma}$.

Answer: First observe the relations

$$\frac{\partial \sigma_{kl}}{\partial \sigma_{ij}} = I^{(4)}_{ijkl}\,, \quad \frac{\partial s_{kl}}{\partial s_{ij}} = I^{(4)}_{ijkl}\,, \tag{2.E.21}$$

where $\mathbf{I}^{(4)} = \mathbf{I} \,\overline{\otimes}\, \mathbf{I}$ is the fourth order identity over symmetric second order tensors and the operator $\overline{\otimes}$ is defined by (2.1.24). Now

$$\begin{aligned}
I_1 = \boldsymbol{\sigma} : \mathbf{I} \qquad &\Rightarrow \quad \frac{\partial I_1}{\partial \boldsymbol{\sigma}} = \frac{\partial \boldsymbol{\sigma}}{\partial \boldsymbol{\sigma}} : \mathbf{I} = (\mathbf{I} \,\overline{\otimes}\, \mathbf{I}) : \mathbf{I} = \mathbf{I}, \\
J_2 = \tfrac{1}{2}\, s_{kl}\, s_{kl} \qquad &\Rightarrow \quad \frac{\partial J_2}{\partial s_{ij}} = I^{(4)}_{ijkl}\, s_{kl} = s_{ij} \quad \Rightarrow \quad \frac{\partial J_2}{\partial \mathbf{s}} = \mathbf{s}, \\
J_3 = \tfrac{1}{3}\, s_{kl}\, s_{lm}\, s_{mk} \quad &\Rightarrow \quad \frac{\partial J_3}{\partial s_{ij}} = \tfrac{1}{3}\, I^{(4)}_{ijkl}\, s_{lm}\, s_{mk} + \tfrac{1}{3}\, s_{kl}\, I^{(4)}_{ijlm}\, s_{mk} + \tfrac{1}{3}\, s_{kl}\, s_{lm}\, I^{(4)}_{ijmk} \\
&\Rightarrow \quad \frac{\partial J_3}{\partial \mathbf{s}} = (\mathbf{I} \,\overline{\otimes}\, \mathbf{I}) : (\mathbf{s} \cdot \mathbf{s}) = \mathbf{s} \cdot \mathbf{s}\,.
\end{aligned} \tag{2.E.22}$$

Therefore

$$\mathbf{s} = \boldsymbol{\sigma} - \tfrac{1}{3}\, I_1\, \mathbf{I} \quad \Rightarrow \quad \frac{\partial \mathbf{s}}{\partial \boldsymbol{\sigma}} = \mathbf{I} \,\overline{\otimes}\, \mathbf{I} - \tfrac{1}{3}\, \mathbf{I} \otimes \mathbf{I}\,. \tag{2.E.23}$$

Consequently

$$\begin{aligned}
\frac{\partial J_2}{\partial \boldsymbol{\sigma}} &= \frac{\partial J_2}{\partial \mathbf{s}} : \frac{\partial \mathbf{s}}{\partial \boldsymbol{\sigma}} = \mathbf{s}; \\
\frac{\partial J_3}{\partial \boldsymbol{\sigma}} &= \frac{\partial J_3}{\partial \mathbf{s}} : \frac{\partial \mathbf{s}}{\partial \boldsymbol{\sigma}} = \mathbf{s} \cdot \mathbf{s} - \tfrac{2}{3}\, J_2\, \mathbf{I}\,.
\end{aligned} \tag{2.E.24}$$

Finally,

$$\begin{aligned}
\frac{\partial F}{\partial \boldsymbol{\sigma}} &= \frac{\partial F}{\partial I_1} \frac{\partial I_1}{\partial \boldsymbol{\sigma}} + \frac{\partial F}{\partial J_2} \frac{\partial J_2}{\partial \boldsymbol{\sigma}} + \frac{\partial F}{\partial J_3} \frac{\partial J_3}{\partial \boldsymbol{\sigma}} \\
&= \underbrace{\frac{\partial F}{\partial I_1}\, \mathbf{I}}_{\substack{\text{volumetric} \\ \text{part}}} + \underbrace{\frac{\partial F}{\partial J_2}\, \mathbf{s} + \frac{\partial F}{\partial J_3}\, (\mathbf{s} \cdot \mathbf{s} - \tfrac{2}{3}\, J_2\, \mathbf{I})\,.}_{\substack{\text{deviatoric} \\ \text{part}}}
\end{aligned} \tag{2.E.25}$$

Exercise 2.8 A tensor isotropic function $\boldsymbol{\mathcal{F}}(\mathbf{A}, a)$ of a symmetric second order tensor $\mathbf{A}$ and of a scalar a

The proof in $\mathbb{R}^3$ of (2.11.36) proceeds as follows [Mandel 1974]. First, observe that the eigenvectors of $\mathbf{A}$ are eigenvectors of $\boldsymbol{\mathcal{F}}$. Indeed, let $\mathbf{R}_1$ be the symmetry wrt the axis 1. Then, componentwise in the cartesian basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$,

$$\mathbf{R}_1 \cdot \mathbf{A} \cdot \mathbf{R}_1^{\mathrm{T}} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix} \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} A_{11} & -A_{12} & -A_{13} \\ -A_{21} & A_{22} & A_{23} \\ -A_{31} & A_{32} & A_{33} \end{bmatrix}. \tag{2.E.26}$$

If $\mathbf{e}_1$ is an eigenvector of $\mathbf{A}$, then the components $A_{1i} = A_{i1}$, $i \neq 1$, vanish, and the above transformation is of course elusive. The requirement (2.11.35) imposes that $\boldsymbol{\mathcal{F}}$ and $\mathbf{R}_1 \cdot \boldsymbol{\mathcal{F}} \cdot \mathbf{R}_1^{\mathrm{T}}$ are identical, that is, in view of (2.E.26) applied to $\mathcal{F}$, $\mathcal{F}_{1i} = -\mathcal{F}_{1i} = 0$, $i \neq 1$, so that $\mathbf{e}_1$ is an eigenvector of $\boldsymbol{\mathcal{F}}$.

Therefore, in a cartesian basis formed from the eigenvectors of $\mathbf{A}$, $\boldsymbol{\mathcal{F}}$ is principal and its eigenvalues are functions of the eigenvalues of $\mathbf{A}$.

Moreover, if the eigenvalues A_2 and A_3 of $\mathbf{A}$ are equal, so are the eigenvalues $\mathcal{F}_2$ and $\mathcal{F}_3$ of $\boldsymbol{\mathcal{F}}$. Indeed, let $\mathbf{R}_{23}$ be the transformation that rotates the eigenvector $\mathbf{e}_2$ to the eigenvector $\mathbf{e}_3$. Since $\mathbf{R}_{23} \cdot \mathbf{A} \cdot \mathbf{R}_{23}^{\mathrm{T}} = \mathbf{A}$, then according to (2.11.35), a similar relation should hold for $\boldsymbol{\mathcal{F}}$, that is, the axes $\mathbf{e}_2$ and $\mathbf{e}_3$ are undistinguishable, and the eigenvalues $\mathcal{F}_2$ and $\mathcal{F}_3$ are equal.

Assume that $\mathbf{A}$ has m distinct eigenvalues. The associated eigenvectors constitute a basis and the components b_i, $i \in [1, m]$, in (2.11.36) can be obtained by solving the system of m equations, $\mathcal{F}_j = \sum_{i=0}^{m-1} b_i\, A_j^i$, $j \in [1, m]$, obtained by projecting (2.11.36) on these eigenvectors. The system can be solved uniquely since the eigenvectors constitute a basis of $\mathbb{R}^m$.

The tensor expression (2.11.36) results from the above system expressed on the eigenvectors of $\mathbf{A}$ or of $\boldsymbol{\mathcal{F}}$.

Exercise 2.9 The square root of a positive (semi-)definite symmetric second order tensor

Show that the square root of a positive (semi-)definite symmetric second order tensor $\mathbf{B}$ is isotropic.

Proof: Let $\mathbf{R}$ be an orthogonal transformation. Using the spectral representation, the successive relations below follow,

$$\begin{aligned}
&\mathbf{B} = \sum_{i=1}^{3} b_i \, \mathbf{b}_i \otimes \mathbf{b}_i \\
&\mathbf{B}^{\frac{1}{2}} = \sum_{i=1}^{3} b_i^{\frac{1}{2}} \, \mathbf{b}_i \otimes \mathbf{b}_i \\
&\mathbf{R}\cdot\mathbf{B}^{\frac{1}{2}}\cdot\mathbf{R}^{\mathrm{T}} = \sum_{i=1}^{3} b_i^{\frac{1}{2}} \, \mathbf{R}\cdot\mathbf{b}_i \otimes (\mathbf{R}\cdot\mathbf{b}_i)^{\mathrm{T}} = \big(\sum_{i=1}^{3} b_i \, (\mathbf{R}\cdot\mathbf{b}_i) \otimes (\mathbf{R}\cdot\mathbf{b}_i)^{\mathrm{T}}\big)^{\frac{1}{2}} ,
\end{aligned} \tag{2.E.27}$$

because the triad $\{\mathbf{R}\cdot\mathbf{b}_i,\ i\in[1,3]\}$ is a cartesian basis like $\{\mathbf{b}_i,\ i\in[1,3]\}$. Hence

$$\mathbf{R}\cdot\mathbf{B}^{\frac{1}{2}}\cdot\mathbf{R}^{\mathrm{T}} = (\mathbf{R}\cdot\mathbf{B}\cdot\mathbf{R})^{\frac{1}{2}} . \tag{2.E.28}$$

Exercise 2.10 The square root of a positive definite symmetric second order tensor, Morman [1986]

Calculate the coefficients α, $i\in[1,3]$, involved in the isotropic expansion of $\mathbf{B}^{\frac{1}{2}}$, Eqn (2.3.31), where $\mathbf{B}$ is a positive definite symmetric second order tensor.

Answer:

The square-root $\mathbf{B}^{\frac{1}{2}}$ is an isotropic function of $\mathbf{B}$ and can be expressed as a linear combination of $\mathbf{I}$, $\mathbf{B}$ and $\mathbf{B}^2$,

$$\left\{\begin{aligned}
b_1^{\frac{1}{2}} &= \alpha_0 + \alpha_1 \, b_1 + \alpha_2 \, b_1^2 \\
b_2^{\frac{1}{2}} &= \alpha_0 + \alpha_1 \, b_2 + \alpha_2 \, b_2^2 \\
b_3^{\frac{1}{2}} &= \alpha_0 + \alpha_1 \, b_3 + \alpha_2 \, b_3^2 ,
\end{aligned}\right. \tag{2.E.29}$$

whence

$$\alpha_0 = \sum_{k=1}^{3} I_3 \, \frac{b_k^{-\frac{1}{2}}}{\Delta_k}, \quad \alpha_1 = \sum_{k=1}^{3} \frac{b_k^{\frac{1}{2}} \, (b_k - I_1)}{\Delta_k}, \quad \alpha_2 = \sum_{k=1}^{3} \frac{b_k^{\frac{1}{2}}}{\Delta_k}, \tag{2.E.30}$$

with I_1 and I_3 are scalar invariants of $\mathbf{B}$ and

$$\Delta_k = 2\, b_k^2 - I_1 \, b_k + I_3 \, b_k^{-1}, \quad k\in[1,3] . \tag{2.E.31}$$

Chapter 3

Thermodynamic properties of fluids

3.1 Basic thermodynamic definitions

The basic thermodynamic notions below address essentially pure substances and mixtures of fluids, which are in the realm of chemical engineering, e.g., the comprehensive introduction of Smith et al. [1996]. However, steps toward continuum systems are considered in a transport perspective along Bird et al. [1960] and Haase [1990], and in a thermomechanics perspective along Kestin [1966] [1968].

3.1.1 Open and closed systems. Intensive and extensive properties

An *open* system exchanges mass, momentum, energy and/or entropy with the surroundings, while a *closed* system does not. In practice, an open system can be made closed by including the sources with which the exchanges take place. Conversely, it might be of interest for the analysis to exclude some portions of a closed system, thus turning it open. Fig. 3.1.1 illustrates the concept.

As another example, consider a solid skeleton containing two types of cavities, say (a) and (b), which however host the same type of fluid. Assume the two types of cavities to be connected. There are several points of view to address the mechanical and transport properties of such a system. The analysis could concentrate only on the fluid of the cavities (a) which would be viewed as a system open to mass and momentum exchanges. On the other hand, the standard mixture approach considers the ternary system formed by the solid skeleton and the two fluids: while the system as a whole is closed, none of the three species does so.

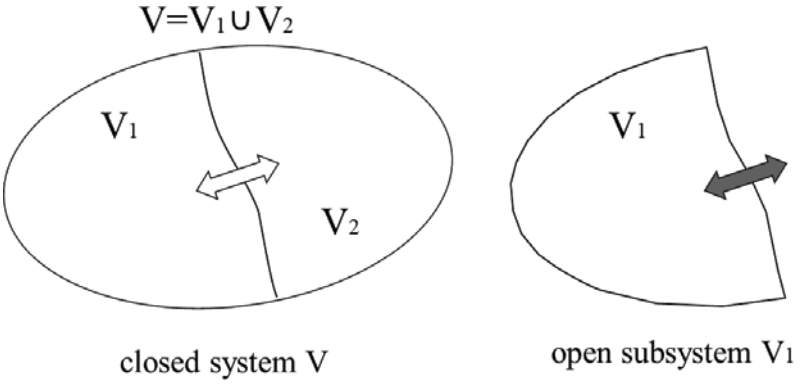

Fig. 3.1.1: A closed system may be turned open by excluding a part with which exchanges of mass, momentum, etc. take place, and conversely.

A property is said *intensive* if it is independent of the quantity of matter. It is *extensive* if it depends on the quantity of matter. Volume, energy, enthalpy, etc. are extensive properties, while pressure p, temperature T, specific energy, specific enthalpy, etc. (measured per unit mass or unit volume) are intensive properties [3.1].

At this point, it is worth mentioning Euler's theorem for homogeneous functions. Let f be a sufficiently smooth function of two vectors, say $\mathbf{x}$ and $\mathbf{y}$. The function f is said to be *homogeneous of degree* m[3.2] with respect to its argument $\mathbf{x}$ if

$$f(\lambda\mathbf{x},\mathbf{y}) = \lambda^m\, f(\mathbf{x},\mathbf{y}), \quad \forall\lambda\,. \tag{3.1.1}$$

Differentiating with respect to λ, namely $\delta f/\delta\lambda = \partial f/\partial(\lambda\mathbf{x})\cdot\mathbf{x} = m\,\lambda^{m-1}\,f(\mathbf{x},\mathbf{y})$, yields

$$\textbf{Euler's theorem for homogeneous functions}: \quad \frac{\partial f}{\partial\mathbf{x}}(\mathbf{x},\mathbf{y})\cdot\mathbf{x} = m\,f(\mathbf{x},\mathbf{y})\,. \tag{3.1.2}$$

This implication, obtained for $\lambda = 1$, is known as Euler's theorem for homogeneous functions. It can be shown that the converse holds as well, namely that a function which satisfies Euler's theorem with a coefficient m is homogeneous of degree m. The homogeneity property may not hold relative to the vector $\mathbf{y}$ or, if it does, it might be of different degree.

Intensive thermodynamic properties are described by homogeneous functions of degree $m = 0$, and extensive properties by homogeneous functions of degree $m = 1$. A typical application will be shown to lead to the Gibbs-Duhem relation[3.3], Section 3.1.4.

3.1.2 Energy, free energy, enthalpy, free enthalpy, Legendre duals

Basic thermodynamic measures of the state of a *closed* fluid system with temperature T, pressure p and volume V are shown in Table 3.1.1. The free enthalpy of a system is also referred to as Gibbs energy. These measures may also be viewed as molar measures, that is, relative to a mole, when the volume V is the molar volume of the system. For a reversible process, $d\mathbb{Q} = T\,d\mathbb{S}$ is the incremental heat exchange.

The expression of the internal energy in Table 3.1.1 is motivated by the balance of energy which, in absence of kinetic energy, states that the increment of internal energy is equal to the sum of the increment of reversible heat and of the work done by the pressure in the volume change.

Table 3.1.1: Thermodynamic measures of the state of a system [unit : J].

Measure	Variables	Arbitrary increment δ
Internal energy	$\mathbb{U} = \mathbb{U}(V,\mathbb{S})$	$\delta\mathbb{U} = -p\,\delta V + T\,\delta\mathbb{S}$
Free energy	$\mathbb{E} = \mathbb{E}(V,T) = \mathbb{U} - T\,\mathbb{S}$	$\delta\mathbb{E} = -p\,\delta V - \mathbb{S}\,\delta T$
Enthalpy	$\mathbb{H} = \mathbb{H}(p,\mathbb{S}) = \mathbb{U} + p\,V$	$\delta\mathbb{H} = V\,\delta p + T\,\delta\mathbb{S}$
Free enthalpy	$\mathbb{G} = \mathbb{G}(p,T) = \mathbb{H} - T\,\mathbb{S}$	$\delta\mathbb{G} = V\,\delta p - \mathbb{S}\,\delta T$

The thermodynamic functions in Table 3.1.1 appear as Legendre transforms[3.4] of one another. Consider a smooth function $\phi = \phi(x)$. The variable x is viewed as a state variable while $y = \partial\phi/\partial x$ is termed the control variable. The Legendre transform (dual) $\phi^*(y)$ of the function $\phi(x)$ is defined through the relation $\phi^*(y) + \phi(x) = x\,y$, and therefore $x = \partial\phi^*/\partial y$. In fact, the construction of the thermodynamic functions makes use of the negative of this definition. For a function of two or more variables, one may consider a partial Legendre transform, eg $\phi^*(y_1,x_2) + \phi(x_1,x_2) = x_1\,y_1$, and then $y_1 = \partial\phi/\partial x_1$, $y_2 = \partial\phi/\partial x_2 = -\partial\phi^*/\partial x_2$, $x_1 = \partial\phi^*/\partial y_1$, or a total Legendre transform, $\phi^*(y_1,y_2) + \phi(x_1,x_2) = x_1\,y_1 + x_2\,y_2$, and then $y_i = \partial\phi/\partial x_i$, $x_i = \partial\phi^*/\partial y_i$, $i = 1,2$.

[3.1] The French engineer and thermodynamicist François Massieu (1832-1896) was the first to have introduced the description of thermodynamic functions in terms of conjugate intensive and extensive variables, at least one extensive variable being required to appear for the size of the system to be accounted for. While nowadays seldom quoted for this fundamental contribution [Massieu 1869, 1876], the negatives of thermodynamic functions divided by absolute temperature bear his name in the current thermodynamics literature: they can be viewed as Legendre transforms in which an extensive variable is replaced by its conjugate intensive counterpart, see e.g., Tschoegl [2000], p. 62, for a presentation.

[3.2] Two slightly distinct properties are sometimes introduced. A function $f(\mathbf{x})$ is said *absolutely* homogeneous of degree m if $f(\lambda\mathbf{x}) = |\lambda|^m\,f(\mathbf{x})$. A function $f(\mathbf{x})$ is said *positively* homogeneous of degree m if $f(\lambda\mathbf{x}) = \lambda^m\,f(\mathbf{x})$ for $\lambda \geq 0$. The latter property is useful on cones, a cone C being a vector space for which, if $\mathbf{x}\in\mathrm{C}$, then $\lambda\,\mathbf{x}\in\mathrm{C}$ for any $\lambda > 0$. Cones may be convex, e.g., a planar fan, or not convex, e.g., two distinct fans emanating from the same origin.

[3.3] Named after the American physicist Josiah Willard Gibbs (1839-1903) and the French physicist and historian of science Pierre Maurice Marie Duhem (1861-1916).

[3.4] Named after the French mathematician Adrien Marie Legendre (1752-1833).

3.1.3 Chemical equilibrium between two multi-species phases

Let us consider a solution with two phases, a and b, separated by some device. For the sake of simplicity the two phases contain the same species which transfer from one phase to the other. The number of moles of the species $k \in [1,\, n]$ in phase α, is denoted by $N_{\alpha k}$.

Chemical equilibrium for all species k between the two phases is defined by the equality of their chemical potentials,

$$g_{ak} = g_{bk}, \quad k \in [1, n]\,. \tag{3.1.3}$$

Indeed altogether the two phase system is assumed to be closed so that its change of Gibbs energy is equal to $d\mathbb{G} = V\,dp - \mathbb{S}\,dT$ (a). Individually on the other hand, each phase is an open system and the increment of its Gibbs energy is defined as $d\mathbb{G}_\alpha = V_\alpha\,dp - \mathbb{S}_\alpha\,dT + \sum_k g_{\alpha k}\,dN_{\alpha k}$, $\alpha = a, b$, where it has been assumed that the equilibrium pressure and temperature are uniform over the system. The Gibbs energy is additive, i.e. the Gibbs energy of the system is obtained by summation of the Gibbs energies of the phases, $\mathbb{G} = \sum_\alpha \mathbb{G}_\alpha$. Therefore, since the volume and the entropy are additive, then $\sum_\alpha V_\alpha\,dp - \mathbb{S}_\alpha\,dT = V\,dp - \mathbb{S}\,dT$. For consistency with the relation (a) above, the constraint $\sum_k g_{ak}\,dN_{ak} + g_{bk}\,dN_{bk} = 0$ should be satisfied. The mass of any species k leaving the phase a enters phase b, and mass conservation implies $dN_{ak} + dN_{bk} = 0$. Thus $\sum_k (g_{ak} - g_{bk})\,dN_{ak} = 0$. Assuming that the dN_{ak}'s are independent and arbitrary finishes the proof □.

Note that the relations (3.1.3) apply only to species that can transfer from one phase to the other. For a species whose transfer is partially or totally hindered, the chemical potentials on each side of the interface are likely to undergo a transient or permanent discontinuity. In some biological systems, e.g., in membrane channels, the transfer is triggered by the build up of the discontinuity once the hindrance has been removed.

The system has been considered closed for simplicity. More generally, it could (1) contain more than two phases, or (2) be open so that the variation of the mole number of a species could be due to phase transfer and exchange with the surroundings, or (3) involve mass exchanges between distinct species. Chemical equilibrium is then defined by appropriate combinations of chemical potentials.

3.1.4 The Gibbs-Duhem relation

Let us consider a fluid phase which is open, namely the number of moles may change. Let $N = \sum_k N_k$ be the total number of moles, and $\mathbb{G}$ be the Gibbs energy for $N = 1$.

The Gibbs energy $N\mathbb{G} = N\mathbb{G}(p, T, \cup_k\{N_k\})$ is an extensive property of a system, while the chemical potentials are intensive properties of the species. Indeed,

$$d(N\mathbb{G}) = \frac{\partial(N\mathbb{G})}{\partial p}_{|T,N} dp + \frac{\partial(N\mathbb{G})}{\partial T}_{|p,N} dT + \sum_k g_k\,dN_k\,, \tag{3.1.4}$$

with the subscript '$_{|N}$' indicating a derivative at fixed chemical content. The chemical potential per unit mole g_k of the species k,

$$g_k = \frac{\partial(N\mathbb{G})}{\partial N_k}_{|p,T}\,, \tag{3.1.5}$$

has unit J, while its counterpart per unit mass μ_k has unit $\mathrm{J/kg} \times \mathrm{m} = \mathrm{m}^2/\mathrm{s}^2$. These two equivalent properties are linked by the molar mass $\widehat{m}_k$ of the species k,

$$g_k = \widehat{m}_k\,\mu_k\,. \tag{3.1.6}$$

Note that $d(N\mathbb{G}) = dN\,\mathbb{G} + N\,d\mathbb{G}$. If $x_k = N_k/N$ is the molar fraction of species k, then $dN_k = x_k\,dN + dx_k\,N$. Inserting this expression in (3.1.4) and using the arbitrariness of N yields,

$$\mathbb{G} = \sum_k g_k\,x_k \quad \Rightarrow \quad N\mathbb{G} = \sum_k g_k\,N_k\,, \tag{3.1.7}$$

and

$$d\mathbb{G} = \frac{\partial\mathbb{G}}{\partial p}_{|T,N} dp + \frac{\partial\mathbb{G}}{\partial T}_{|p,N} dT + \sum_k g_k\,dx_k, \quad d(N\mathbb{G}) = \frac{\partial(N\mathbb{G})}{\partial p}_{|T,N} dp + \frac{\partial(N\mathbb{G})}{\partial T}_{|p,N} dT + \sum_k g_k\,dN_k\,. \tag{3.1.8}$$

Differentiation of $\mathbb{G}$ in the form (3.1.7) yields in turn,

$$d\mathbb{G} = \sum_k dg_k\, x_k + g_k\, dx_k, \quad d(N\mathbb{G}) = \sum_k dg_k\, N_k + g_k\, dN_k\,. \tag{3.1.9}$$

Comparison of (3.1.8) and (3.1.9) provides the Gibbs-Duhem relation for a mixture in two equivalent forms, e.g., Kestin [1966], p. 332, Smith et al. [1996], p. 320,

$$\textbf{Gibbs-Duhem relation}: \quad \begin{array}{rcrcrcl} \dfrac{\partial \mathbb{G}}{\partial p}_{|T,x} dp & + & \dfrac{\partial \mathbb{G}}{\partial T}_{|p,x} dT & - & \displaystyle\sum_k x_k\, dg_k & = & 0\,; \\ \dfrac{\partial (N\,\mathbb{G})}{\partial p}_{|T,N} dp & + & \dfrac{\partial (N\,\mathbb{G})}{\partial T}_{|p,N} dT & - & \displaystyle\sum_k N_k\, dg_k & = & 0\,. \end{array} \tag{3.1.10}$$

In the first line, the partial derivatives at fixed chemical content have been legitimately replaced by partial derivatives at fixed molar fractions.

This relation can be derived, and generalized, as a direct consequence of Euler's theorem. Indeed, assume the function $f(\mathbf{x}, \mathbf{y})$ to be homogeneous of degree one in $\mathbf{x}$ and of degree 0 in $\mathbf{y}$. Then

$$\textbf{Generalized Gibbs-Duhem relation} \quad \frac{\partial f}{\partial \mathbf{y}} \cdot d\mathbf{y} - \mathbf{x} \cdot d\Big(\frac{\partial f}{\partial \mathbf{x}}\Big) = 0\,. \tag{3.1.11}$$

Indeed

$$\begin{array}{lrcll} \text{(a)} & df & = & \dfrac{\partial f}{\partial \mathbf{x}} \cdot d\mathbf{x} + \dfrac{\partial f}{\partial \mathbf{y}} \cdot d\mathbf{y} & \\ \text{(b)} & f & = & \dfrac{\partial f}{\partial \mathbf{x}} \cdot \mathbf{x} & : \text{homogeneity of degree 1 in } \mathbf{x},\ 0 \text{ in } \mathbf{y} \\ \text{(c)} & df & = & d\Big(\dfrac{\partial f}{\partial \mathbf{x}}\Big) \cdot \mathbf{x} + \dfrac{\partial f}{\partial \mathbf{x}} \cdot d\mathbf{x} & : \text{differentiation of (b)}\,, \end{array} \tag{3.1.12}$$

and the result follows by the difference (a)-(c) □. The Gibbs-Duhem relation corresponds to $f \to N\,\mathbb{G}$, $x_k \to N_k$, $\mathbf{y} \to (p,\, T)$.

3.1.5 Chemical affinity associated with a chemical reaction

Let us consider the set of m chemical reactions involving the n chemicals X_j [Kestin 1968, p. 271],

$$\begin{array}{ccc} \nu_1^1\, X_1 + \nu_2^1\, X_2 + \cdots + \nu_n^1\, X_n & \underset{k_1^-}{\overset{k_1^+}{\rightleftharpoons}} & \kappa_1^1\, X_1 + \kappa_2^1\, X_2 + \cdots + \kappa_n^1\, X_n \\ \nu_1^2\, X_1 + \nu_2^2\, X_2 + \cdots + \nu_n^2\, X_n & \underset{k_2^-}{\overset{k_2^+}{\rightleftharpoons}} & \kappa_1^2\, X_1 + \kappa_2^2\, X_2 + \cdots + \kappa_n^2\, X_n \\ \vdots & & \vdots \\ \nu_1^m\, X_1 + \nu_2^m\, X_2 + \cdots + \nu_n^m\, X_n & \underset{k_m^-}{\overset{k_m^+}{\rightleftharpoons}} & \kappa_1^m\, X_1 + \kappa_2^m\, X_2 + \cdots + \kappa_n^m\, X_n \end{array} \tag{3.1.13}$$

The ν's and the κ's are called the stoichiometric coefficients and the k^+'s and k^-'s the forward and backward rate constants.

For the species $j \in [1, n]$, the rate of the concentration $c_j = N_j/V$, defined as the number of moles N_j in the volume of the mixture V, is governed by the kinetic equation,

$$\frac{dc_j}{dt} = \sum_{i=1}^{m} (-\nu_j^i + \kappa_j^i) \left(k_i^+\, c_1^{\nu_1^i}\, c_2^{\nu_2^i} \cdots c_n^{\nu_n^i} - k_i^-\, c_1^{\kappa_1^i}\, c_2^{\kappa_2^i} \cdots c_n^{\kappa_n^i} \right), \quad j \in [1, n]\,. \tag{3.1.14}$$

Mass conservation for the reaction i implies, with $\widehat{m}_j$ the molar mass of species j,

$$\sum_{j=1}^{n} (\nu_j^i - \kappa_j^i)\, \widehat{m}_j = 0, \quad i \in [1, m]\,. \tag{3.1.15}$$

For the reaction i, the *advancement*, or *extent*, of the reaction is defined, in terms of the number of moles of the species, as (the index r denotes a reactant and the index p a product)

$$d\xi_i = \frac{dN_j^{i,r}}{-\nu_j^i} = \frac{dN_j^{i,p}}{\kappa_j^i} = \frac{dN_j^i}{-\nu_j^i + \kappa_j^i}, \quad i \in [1, m]\,. \tag{3.1.16}$$

The sum of the chemical potentials weighted by the (signed) stoichiometric coefficients,

$$\mathcal{G}_i = \sum_{j=1}^{n} -g_j^r\,\nu_j^i + g_j^p\,\kappa_j^i\,, \tag{3.1.17}$$

is termed chemical affinity of the reaction i[3.5]. The chemical work associated with the change of the number of moles dN_j of a species is equal to the product of its chemical potential g_j by this change of mole number, say $g_j\,dN_j$. With help of (3.1.16), the work associated with the chemical reaction i is equal to the work done by the chemical affinity in the variation of the reaction advancement,

$$\sum_{j=1}^{n} g_j^r\,dN_j^{i,r} + g_j^p\,dN_j^{i,p} = \mathcal{G}_i\,d\xi_i\,. \tag{3.1.18}$$

Therefore the change of free enthalpy $G \equiv N\mathbb{G}$, or Gibbs energy, of a phase during the chemical reaction i at constant pressure and temperature which is defined by (3.1.4) can be brought to the format,

$$dG = \sum_{j=1}^{n} g_j^r\,dN_j^{i,r} + g_j^p\,dN_j^{i,p} = \mathcal{G}_i\,d\xi_i\,. \tag{3.1.19}$$

3.1.6 Chemical equilibrium versus steady state

A distinction should made between *chemical* (or *thermodynamic*) equilibrium and steady state (or *kinetic* equilibrium). At steady state, the time derivatives of concentrations vanish. Chemical, or thermodynamic, equilibrium is defined by the equality of the chemical potentials as stated by (3.1.3).

As an example, consider the autocatalytic reaction [Othmer 1981]

$$M_1 + M_2 \quad \underset{k^-}{\overset{k^+}{\rightleftharpoons}} \quad 2\,M_1\,. \tag{3.1.20}$$

The rate of change of the concentration c_1 is described by the kinetic equation,

$$\frac{dc_1}{dt} = k^+\,c_1\,c_2 - k^-\,c_1^2\,, \tag{3.1.21}$$

in such a way that steady state takes place for

$$\frac{c_2}{c_1} = \frac{k^-}{k^+}\,. \tag{3.1.22}$$

For a species in a mixture, the chemical potential includes several contributions, in particular a pressure term, a formation term and an electrical term if the species is electrically charged. For an ideal mixture, it will be sufficient to additively decompose the chemical potential g in a *standard* term g^0 and a chemical term $RT\,\mathrm{Ln}\,x$, with R [unit : J/mole/K] the gas constant, T [unit : K] temperature and x [unit : 1] molar fraction[3.6]. Therefore, the chemical affinity (3.1.17),

$$\mathcal{G} = g_1 - g_2 = \mathcal{G}^0 + RT\,\mathrm{Ln}\frac{c_1}{c_2} = RT\,\mathrm{Ln}\Big(\frac{1}{K^{\mathrm{eq}}}\frac{c_1}{c_2}\Big)\,, \tag{3.1.23}$$

expresses in terms of the concentrations and dimensionless equilibrium constant $K^{\mathrm{eq}} = \exp(-\mathcal{G}^0/RT)$. Chemical equilibrium requires

$$\frac{c_2}{c_1} = \frac{1}{K^{\mathrm{eq}}}\,, \tag{3.1.24}$$

Thus, unless $K^{\mathrm{eq}} = k^+/k^-$, chemical equilibrium and steady states do not coincide.

[3.5] This quantity is sometimes defined with an opposite sign.

[3.6] In a general context, the standard chemical potential is the chemical potential at zero pressure, concentration equal to one, and vanishing electrical potential.

3.1.7 Flux- and energy-driven chemical reactions

It is of interest to delineate chemical reactions that are *flux-driven* and chemical reactions that are *energy-driven*. In Section 19.3, these notions are elaborated in the context of *active transport* across the corneal endothelium where the transfers of chemicals through membranes are seen as physico-chemical reactions.

3.1.7.1 Flux-driven chemical reactions

For a flux-driven chemical reaction in an *open system*, a species A, which is continuously supplied with a flux J_A, undergoes a reversible physico-chemical reaction to the species B, which is continuously extracted with a flux J_B,

$$\xrightarrow{J_A} A \underset{k^-}{\overset{k^+}{\rightleftharpoons}} B \xrightarrow{J_B} \tag{3.1.25}$$

The rate equations governing this reaction result in a matrix-vector format in terms of the forward and backward rate constants, respectively k^+ and k^- [unit : s^{-1}],

$$\frac{d}{dt}\begin{bmatrix} [A] \\ [B] \end{bmatrix} = \begin{bmatrix} -k^+ & k^- \\ k^+ & -k^- \end{bmatrix}\begin{bmatrix} [A] \\ [B] \end{bmatrix} + \begin{bmatrix} J_A \\ -J_B \end{bmatrix}. \tag{3.1.26}$$

Here the steady state, where time derivatives vanish, is not a state of *chemical equilibrium*, as elaborated now. Indeed, along Qian et al. [2003], the analysis is now restricted to *steady states*. Then the total concentration $c_t = [A] + [B]$ is constant, namely $c_t = c_0$. Obviously, a steady state is possible only if the incoming and outgoing fluxes are equal, $J_A = J_B = J$. It is customary to introduce the forward and backward fluxes, $J_+ = k^+ [A]$, $J_- = k^- [B]$, and thus the concentrations of the reactant and product are linked by the relation $J = J_+ - J_-$.

When the system is *closed*, $J = 0$, the steady state is a state of *chemical equilibrium*, and then $[B]/[A] = K^{eq}$, if the equilibrium constant K^{eq} is equal to k^+/k^-. Even so, an open system allows a steady state to be a *non equilibrium* state as elaborated in Section 3.1.6.

Indeed, first note that $J_+/k^+ + J_-/k^-$ is equal to the initial concentration c_0. Thus,

$$J_- = \frac{c_0 - (k^+)^{-1} J}{(k^+)^{-1} + (k^-)^{-1}}, \quad J_+ = \frac{c_0 + (k^-)^{-1} J}{(k^+)^{-1} + (k^-)^{-1}}. \tag{3.1.27}$$

The reaction tends to be irreversible if $k^- \to 0$, and then a steady state is defined by $J = k^+ [A]$. Thus equilibrium can be reached only by exhaustion of the species A.

The chemical affinity may be expressed in terms of concentrations or fluxes,

$$\mathcal{G} = RT \operatorname{Ln} \frac{1}{K^{eq}} \frac{[B]}{[A]} = RT \operatorname{Ln} \frac{J_-}{J_+}. \tag{3.1.28}$$

The total flux J can thus be obtained in terms of the chemical affinity and of the total concentration, as

$$\frac{J}{c_0} = \frac{e^{-X} - 1}{(k^+)^{-1} e^{-X} + (k^-)^{-1}} \quad \text{with} \quad X \equiv \frac{\mathcal{G}}{RT}. \tag{3.1.29}$$

The dissipation inequality, which can be cast in the form, Eqn (4.8.8),

$$-J\mathcal{G} = c_0 RT \frac{X(1 - e^{-X})}{(k^+)^{-1} e^{-X} + (k^-)^{-1}} \geq 0, \tag{3.1.30}$$

is satisfied whatever the sign of the chemical affinity, and the flux is bounded, Fig. 3.1.2. This format has motivated the exponential mass transfer relations of Section 10.2.3.

For small deviations from chemical equilibrium $X = 0$, the flux (3.1.29) can be linearized to

$$\frac{J}{c_0} = \frac{-X}{(k^+)^{-1} + (k^-)^{-1}}, \tag{3.1.31}$$

which is nothing else than an Onsager type of relation between flux and driving force, $J = -K\mathcal{G}$, where the proportionality coefficient $K > 0$ has been linked to the characteristics of the underlying physico-chemical reaction.

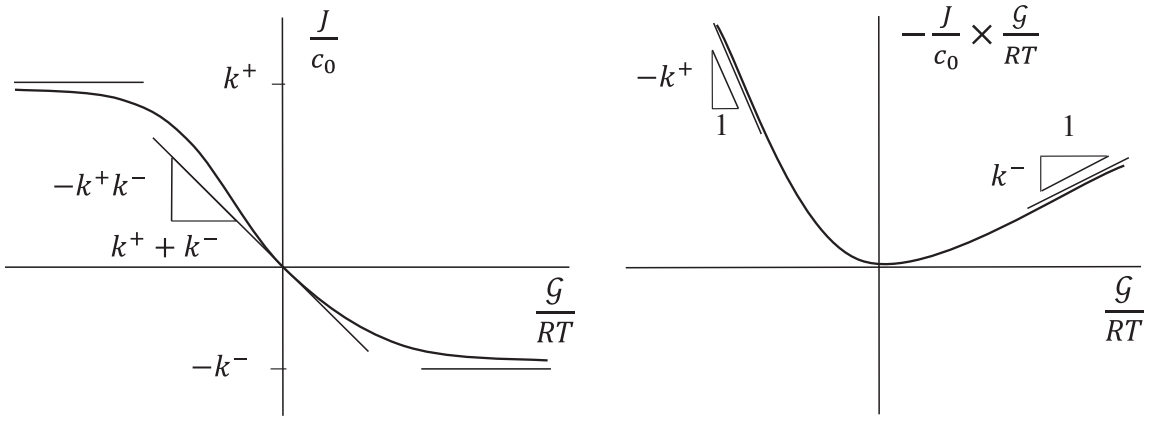

Fig. 3.1.2: Nonlinear and linearized fluxes associated with the chemical reaction (3.1.25), and dissipation associated with the nonlinear transfer law.

3.1.7.2 Energy-driven chemical reactions

An example of an energy-driven chemical reaction may be exhibited via two coupled reactions, say

$$A + X \quad \underset{k^-}{\overset{k^+}{\rightleftharpoons}} \quad B + Y\,. \tag{3.1.32}$$

The concentrations of the species X and Y are *clamped* (fixed) and the reaction $X \to Y$ provides energy to the reaction $A \to B$. Assuming a first order reaction, the kinetic relations write,

$$\frac{d}{dt}\begin{bmatrix} [A] \\ [B] \end{bmatrix} = \begin{bmatrix} -k^+\,[X] & k^-\,[Y] \\ k^+\,[X] & -k^-\,[Y] \end{bmatrix}\begin{bmatrix} [A] \\ [B] \end{bmatrix}. \tag{3.1.33}$$

In contrast to flux-driven reactions, the steady state is now a state of *chemical equilibrium*, endowed with an equilibrium constant $K^{\rm eq}$,

$$K^{\rm eq} = \frac{k^+}{k^-}\frac{[X]}{[Y]} = \frac{[B]^{\rm eq}}{[A]^{\rm eq}}, \tag{3.1.34}$$

In and out of equilibrium, the flux $J = d[B]/dt$ and the variation of free enthalpy in the reaction $\mathcal{G}$, referred to as chemical affinity and defined by (3.1.17), can be expressed in terms of the equilibrium constant,

$$J = k^-\,[Y]\,[B]\left(K^{\rm eq}\frac{[A]}{[B]} - 1\right), \quad \mathcal{G} = RT\,{\rm Ln}\,\frac{1}{K^{\rm eq}}\frac{[B]}{[A]}\,, \tag{3.1.35}$$

so that

$$J = k^-\,[Y]\,[B]\,\left(\,e^{-\mathcal{G}/RT} - 1\right). \tag{3.1.36}$$

Section 20.2.2 displays a typical instance of energy-driven reaction in a biological context where ATP serves as the energy source.

3.2 Phase change

3.2.1 Phase change and the Clapeyron formulas

Consider a two phase system where a liquid is in equilibrium with its vapor at temperature T and saturating pressure $p_{\rm sat}$. Assume some infinitesimal amount of liquid to be added to the system, so that continuing equilibrium can be assumed to hold.

Evaporation at constant pressure and temperature leaves the Gibbs energy of the *system* unchanged, $d\mathbb{G} = V\,dp - \mathbb{S}\,dT = 0$, and the chemical potentials of the liquid and vapor remain equal, $\mu_l = \mu_v$ and $d\mu_l = d\mu_v$. Here we shall make use of enthalpies, entropies and chemical potentials per unit mass, displayed in Table 3.2.1.

Table 3.2.1: Thermodynamic measures of the state per unit mass [unit : J/kg = m^2/s^2] for a fluid endowed with temperature T, specific volume v and pressure p.

Measure	Variables	Arbitrary Increment δ
Internal energy	$u = u(v, s)$	$\delta u = -p\,\delta v + T\,\delta s$
Free energy	$e = e(v, T) = u - T\,s$	$\delta e = -p\,\delta v - s\,\delta T$
Enthalpy	$h = h(p, s) = u + p\,v$	$\delta h = v\,\delta p + T\,\delta s$
Free enthalpy	$\mu = \mu(p, T) = h - T\,s$	$\delta \mu = v\,\delta p - s\,\delta T$

However, while the chemical potentials of the liquid and vapor are equal, their molar volumes are not, and neither are the internal energies, enthalpies and other thermodynamic properties. Their jumps help characterize the phase change. For example, the Clapeyron formula[3.7] provides the jump of enthalpy across the phase transition curve. Indeed, with s_α, $\alpha = l, v$, the entropy of species α, and ρ_α its mass density,

$$\begin{aligned} d\mu_l &= \frac{dp}{\rho_l} - s_l\,dT\,, \\ d\mu_v &= \frac{dp}{\rho_v} - s_v\,dT\,, \end{aligned} \tag{3.2.1}$$

continuing chemical equilibrium $d\mu_l = d\mu_v$ implies the jump of entropy results from the slope of the phase transition curve in the plane (T, p),

$$\textbf{1st Clapeyron formula}: \quad s_v - s_l = \left(\frac{1}{\rho_v} - \frac{1}{\rho_l}\right)\frac{dp_{\rm sat}}{dT}\,. \tag{3.2.2}$$

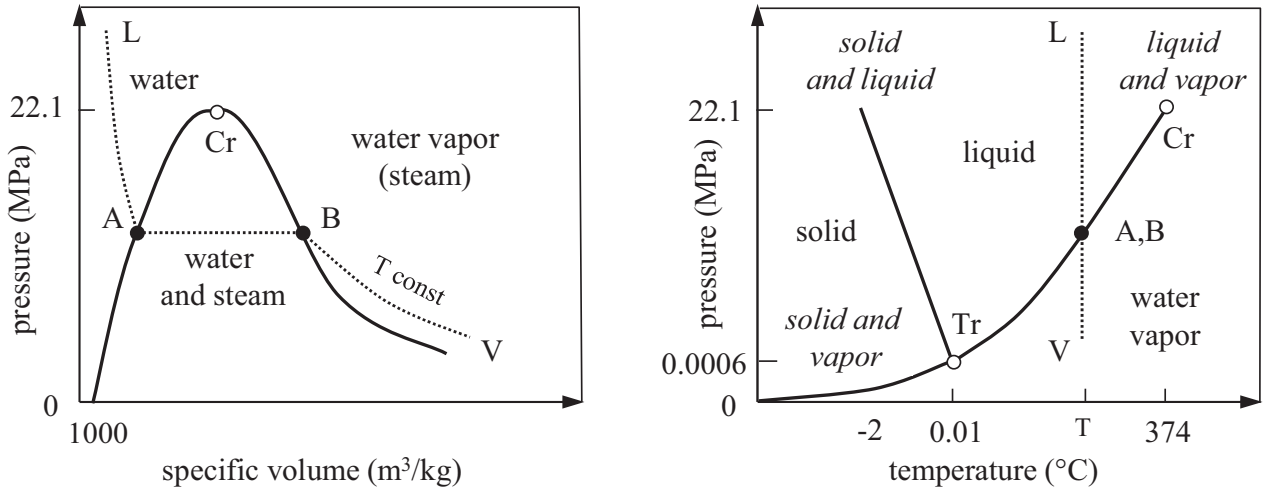

Fig. 3.2.1: Qualitative phase diagrams for water. Typical isotherm LABV obtained by expanding a liquid at constant temperature. The phase transformation A $\rightleftarrows$ B takes place at constant pressure p and temperature T but involves a jump of specific volume v.

Cr critical point; Tr triple point. There exist several analytical approximations of the phase transformation boundaries, e.g., Smith et al. [1996], p. 198. Table 3.2.2 provides accurate values of remarkable points in the phase diagram of the water substance. Under atmospheric pressure, ice melts at 0 °C, a temperature lower than the triple point, water being an anomalous substance.

Phase transformation takes place at constant pressure p and temperature T but with a jump in mass density, Fig. 3.2.1, and therefore the difference of enthalpies is equal to the reversible heat associated with the phase transition,

$$dh_\alpha = \frac{dp}{\rho_\alpha} + T\,ds_\alpha, \quad \alpha = l, v \quad \Rightarrow \quad h_v - h_l = T\,(s_v - s_l)\,. \tag{3.2.3}$$

[3.7] Named after the French physicist Benoît Paul Emile Clapeyron (1799-1864).

Table 3.2.2: Remarkable points along the equilibrium curve of pure water and steam. From IAPWS [2002] and IAPWS [2009].

	Temperature		Density (kg/m^3)		Pressure
	K	°C	Liquid	Vapor	MPa
0°C	273.15	0	999.79184	0.00485123	611.2104×10^{-6}
Triple point	273.16	0.01	999.79252	0.00485458	611.6548×10^{-6}
Boiling point	373.124	99.974	958.367	0.597657	0.101325
Critical point	647.096	373.946	322.00	322.00	22.064000

This relation can also be arrived at by requiring the continuity across the phase line of the chemical potentials $\mu_\alpha = h_\alpha - T\, s_\alpha$, $\alpha = l, v$. The jump of enthalpy,

$$\textbf{2nd Clapeyron formula}: \quad \mathcal{L}_{\rm vap} = h_v - h_l = \Big(\frac{1}{\rho_v} - \frac{1}{\rho_l}\Big)\, T\, \frac{dp_{\rm sat}}{dT}\,, \tag{3.2.4}$$

is called *latent heat of evaporation* (or *vaporization*) per unit mass at constant pressure and temperature. The latent heat of condensation is the negative of the latent heat of evaporation.

If the phase change takes place at temperature much lower than the critical temperature, the specific volume of the liquid may be neglected in front of the specific volume of the vapor. The latter being considered as a perfect gas, its specific volume $1/\rho_v$ is equal to $RT/(\widehat{m}_v\, p)$, with $\widehat{m}_v$ its molar mass. The 2nd Clapeyron formula then provides the saturation pressure of vapor in a differential form,

$$\textbf{Clausius-Clapeyron formula}: \quad \frac{dp}{p} = -\frac{\mathcal{L}_{\rm vap}\, \widehat{m}_v}{R}\, d\Big(\frac{1}{T}\Big)\,, \tag{3.2.5}$$

that can be integrated if the latent heat of vaporization is constant (or a known function of temperature),

$$\mathrm{Ln}\, \frac{p_{\rm sat}(T)}{p_{\rm sat}(T_0)} = -\frac{\mathcal{L}_{\rm vap}\, \widehat{m}_v}{R}\, \Big(\frac{1}{T} - \frac{1}{T_0}\Big)\,. \tag{3.2.6}$$

Several analytical approximations of the saturation pressure of water vapor have been proposed in the literature.

Note that the slope $dp_{\rm sat}/dT$ of the saturating pressure is positive, Fig. 3.2.1. Collecting the two Clapeyron formulas,

$$\frac{\mathcal{L}_{\rm vap}}{T} = \frac{1}{T}\,\big(h_v - h_l\big) = s_v - s_l = \Big(\frac{1}{\rho_v} - \frac{1}{\rho_l}\Big)\, \frac{dp_{\rm sat}}{dT} > 0\,, \tag{3.2.7}$$

we therefore observe that the entropy of water vapor is larger than the entropy of the liquid at identical temperature and pressure. This observation agrees with the general concept that the entropy of gases is larger than the entropy of liquids which in turn is larger than the entropy of solids. Indeed, the entropy is linked to the number of energy microstates and degrees of freedom that molecules/particles can assume: particles have fixed positions in a solid lattice while molecules may vibrate much more freely in a gas. So phase changes are accompanied with entropy jumps.

Relations similar to (3.2.7) exist for the latent heats of melting (or fusion) and sublimation. These energies are positive: the body absorbs energy. The converse latent heats of condensation and freezing are negative: the body releases energy. These results are gathered in a qualitative proposition that substantiates the idea that entropy increases as the spatial organization of the matter becomes looser:

Proposition 3.1 on the entropies per unit mass of the three phases of a substance.

The entropy increases as the substance transforms from solid to liquid to gas.

Fig. 3.2.1 also shows that the slope $dp_{\rm melt}/dT$ along the melting boundary is negative. Moreover a (pressure, specific volume, temperature) diagram shows that the specific volume of ice is larger than that of the liquid at the same temperature and pressure. These two unusual properties, while keeping the latent heat of melting positive, have led water to be coined an 'anomalous substance'.

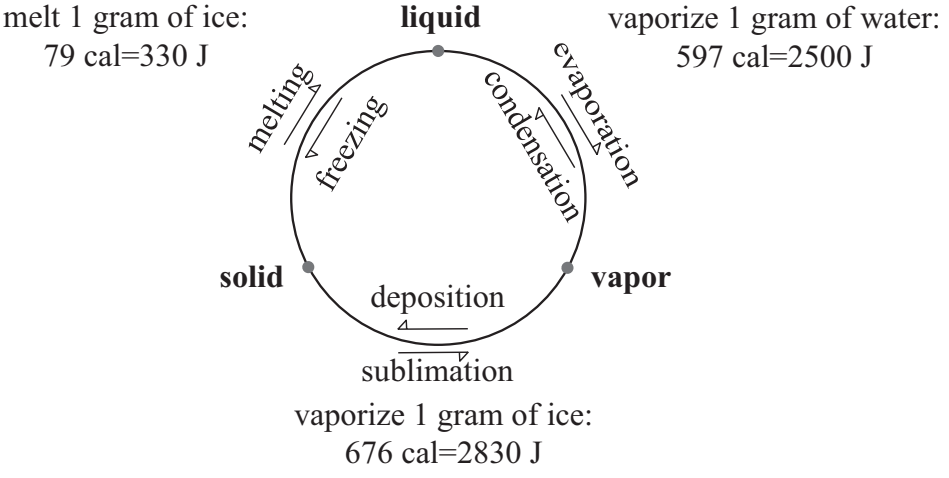

Fig. 3.2.2: Terminology defining phase changes and associated energies required for the phase changes (latent heats) under atmospheric pressure.

Table 3.2.3: Energy required to increase by 1 °C the temperature of 1 gram of the water substance under atmospheric pressure.

State	cal	J
Ice just below 0 °C	0.47	1.96
Water between 0 °C and 100 °C	1.008	4.22
Vapor just above 100 °C	0.50	2.08

For water at 35 °C, the mass densities of vapor and liquid, saturation pressure and latent heat of vaporization take the following values [IAPWS 2009]

$$\begin{aligned} &\rho_v = 0.0396\,\mathrm{kg/m^3}, \quad \rho_l = 994\,\mathrm{kg/m^3}, \quad p_{\mathrm{sat}} = 5.623\,\mathrm{kPa}, \\ &\mathcal{L}_{\mathrm{vap}} = 2418\,\mathrm{kJ/kg} = 43.52\,\mathrm{kJ/mole}\,. \end{aligned} \tag{3.2.8}$$

A specific terminology is used for the phase changes as indicated in Fig. 3.2.2. Numbers indicate that phase changes are path independent. Table 3.2.3 displays some typical heat capacities for the water substance.

Clapeyron formula can also be derived by considering a mixture of saturated vapor and liquid in equilibrium, with mass proportions of λ and $1-\lambda$ respectively. A reversible heat supply is used mainly to produce vapor. However, generally heat supply is also used to increase the temperature of the system,

$$T\,ds = \mathcal{L}_{\mathrm{vap}}\,d\lambda + (c_{pl}\,(1-\lambda) + c_{pv}\,\lambda)\,dT\,, \tag{3.2.9}$$

where the c_{p}'s are the heat capacities at constant pressure. The associated variation of enthalpy per unit mass of the mixture can be cast in the format,

$$dh \;=\; \frac{dp_{\mathrm{sat}}}{\rho_l}\,(1-\lambda) + \frac{dp_{\mathrm{sat}}}{\rho_v}\,\lambda + T\,ds\,. \tag{3.2.10}$$

The phase transition pressure $p_{\mathrm{sat}} = p_{\mathrm{sat}}(T)$ depends only on temperature T. Requiring the two expressions of entropy and enthalpy above to define exact differentials with respect to temperature T and mass ratio λ yields the two relations,

$$\begin{aligned} c_{pl} - c_{pv} \qquad\qquad\qquad &= \; T\,\frac{d}{dT}\Big(\frac{\mathcal{L}_{\mathrm{vap}}}{T}\Big) \\ c_{pl} - c_{pv} + (\frac{1}{\rho_v} - \frac{1}{\rho_l})\,\frac{dp_{\mathrm{sat}}}{dT} \;&=\; \frac{d}{dT}\Big(\mathcal{L}_{\mathrm{vap}}\Big)\,. \end{aligned} \tag{3.2.11}$$

Subtraction of these two relations yields again the 2nd Clapeyron formula. The first equation in (3.2.11) is of interest in itself.

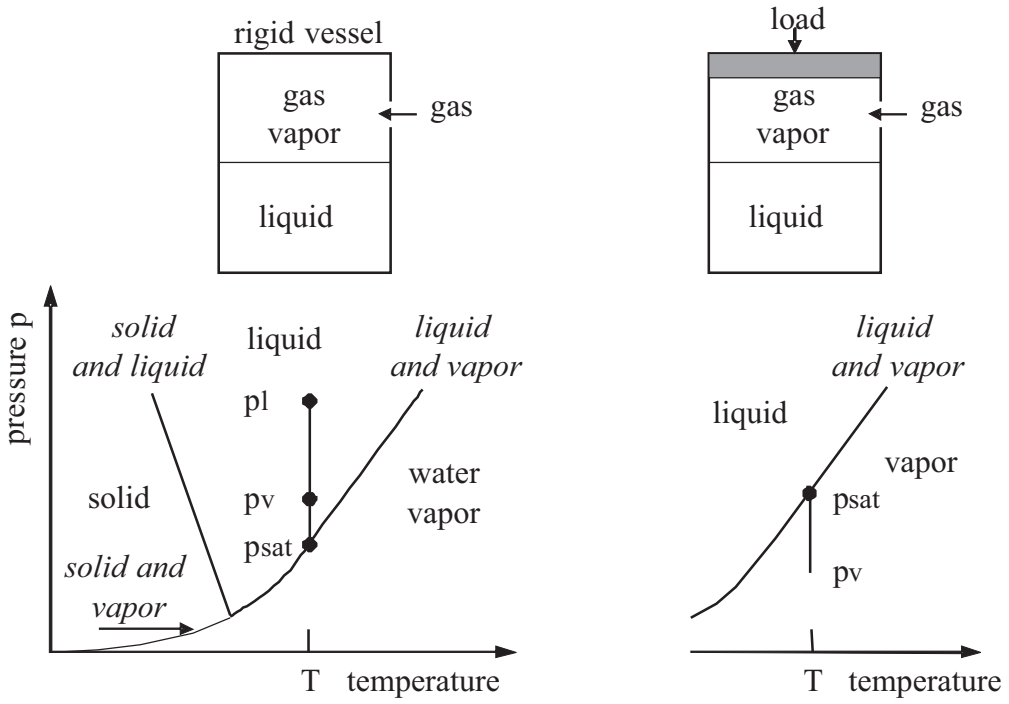

Fig. 3.2.3: Filling a rigid vessel (at constant volume) by an inert gas leads to metastable vapor bubbles (left) or, if the pressure of the gas mixture is constant, to evaporation (right). Since the liquid and vapor are in equilibrium along a flat interface, the liquid pressure is equal to the pressure of the gas mixture. The latter is the sum of the vapor pressure p_v and gas pressure. In absence of inert gas, equilibrium of the liquid and its vapor along a flat interface implies their pressures to be equal to the saturating pressure.

3.2.2 The principle of Spite and the Kelvin-Helmholtz formula

The principle of Spite formulated by Kestin [1968] provides qualitative information on the response of a system to chemical or mechanical loadings. It states that the response to a stimulus is such as to weaken this stimulus.

Let us for example consider a rigid vessel containing a liquid at temperature T pressurized by an inert gas in such a way that the state lies on the phase transformation curve, Fig. 3.2.3. The liquid pressure p_l and vapor pressure p_v are thus equal to the saturating pressure $p_l = p_v = p_{\rm sat}(T)$ in absence of water drops and air bubbles. What happens if the pressure of the gas is increased at constant temperature, and constant volume ?

The principle of Spite indicates that, to contract, the liquid evaporates. This general principle is illustrated by the Kelvin-Helmholtz formula.

(a) *Chemical equilibrium*:

Indeed, the liquid and its vapor are in continuing equilibrium along the phase boundary, so that $d\mu_l = d\mu_v$. Since $d\mu_\alpha = dp_\alpha/\rho_\alpha - s_\alpha\, dT$, $\alpha = l, v$, and since the temperature is kept constant, then $dp_l/\rho_l = dp_v/\rho_v$. The vapor with molar mass $\widehat{m}_v = \widehat{m}_l$ can be considered a perfect gas, $p_v/\rho_v = RT/\widehat{m}_l$. Therefore,

$$\frac{dp_l}{\rho_l} = \frac{dp_v}{\rho_v} = \frac{dp_v}{p_v}\,\frac{RT}{\widehat{m}_l}\,. \tag{3.2.12}$$

(b) *Mechanical equilibrium*:

Considering the mass density of the liquid to remain constant, (3.2.12) may be integrated from the initial equilibrium to a current state,

$$\textbf{Kelvin-Helmholtz formula}: \quad \mathrm{Ln}\,\frac{p_v}{p_{v0}} = \frac{\widehat{v}_l}{RT}\,(p_l - p_{l0}) \simeq \frac{\widehat{v}_v}{RT}\,(p_v - p_{v0}) > 0\,, \tag{3.2.13}$$

where the relation $dp_l/\rho_l = dp_v/\rho_v$ or $\widehat{v}_l\, dp_l = \widehat{v}_v\, dp_v$ has been used in finite form.

Now, the liquid is assumed to be in equilibrium with the gas mixture. In the gas mixture, vapor and inert gas occupy the total volume, and, according to Dalton's law, each one contributes by its partial pressure, p_v and p_g

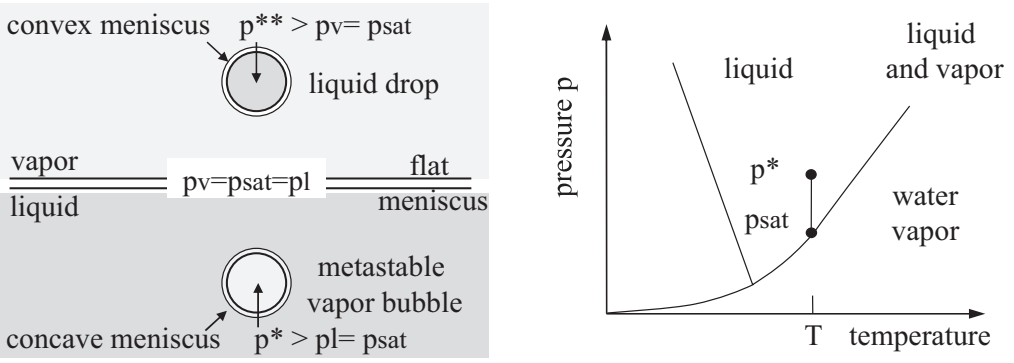

Fig. 3.2.4: Liquid in equilibrium with its vapor over a flat interface: the pressure is continuous across the interface due to Kelvin's law and equal to the saturating pressure, $p_l = p_v = p_{\rm sat}$. Because the meniscus can withstand only tension, pressures in liquid drop and vapor bubble are larger than in the vapor and liquid they bath in. Therefore the vapor bubble is in a metastable state.

respectively, to the pressure $p_v + p_g$ of the mixture. According to Laplace's law, the difference of pressures between two non miscible species is equal to the surface tension T_{lv} of the interface film (meniscus) times the total curvature $2/r$ of the interface. If the pressure in the liquid is p_l, the pressure of the inert gas p_g is thus equal to $p_l - p_v + 2\,T_{lv}/r$. The interface being flat ($r = \infty$), the pressures of the gas p_g is equal to $p_l - p_v$.

How do we interpret this experiment at constant volume? Since $dp_g = dp_l - dp_v = (\rho_l/\rho_v - 1)\,dp_v > 0$, the vapor pressure has increased while the volume available has remained practically identical, since the vessel is rigid. Therefore the mass of vapor has increased. However, since its pressure is larger than the saturating pressure at the prescribed temperature, it is in a so-called 'metastable state'. The concept is illustrated as well in Fig. 3.2.4.

The relation (3.2.13) can be viewed as providing the vapor pressure p_v in terms of the liquid pressure p_l. Now the pressure increase of the vapor is much smaller than the pressure increase of the liquid since $dp_l/dp_v = \rho_l/\rho_v \sim 25 \times 10^3$ at 35 °C according to the data above. Therefore, the vapor pressure remains close to the saturating pressure. Furthermore, if the initial equilibrium is realized over a flat surface, namely $p_{g0} + p_{v0} = p_{l0}$, then $p_{v0} = p_{l0} - p_{g0}$ and $p_v = p_l - p_g$ while $p_v \simeq p_{v0}$.

Kestin [1968], p. 353, also envisages the case where the inert gas is pumped into the vessel such that the pressure of the gas mixture is constant. Since this process reduces the vapor pressure, initially equal to $p_{\rm sat}$, the liquid will evaporate, Fig. 3.2.3.

3.2.3 The time course of a desiccation process

When the center of curvature of the liquid-air menisci is interior to the liquid (convex menisci), the contact angle between the liquid and the solid is larger than 90°. According to Laplace's law, the liquid pressure is larger than the vapor pressure and the suction $s \equiv p_v - p_l$ is negative.

Drying of a fluid saturated porous medium may be controlled by reducing the vapor pressure. A drying process typically proceeds along the following stages:

- in the initial configuration, the center of curvature of the liquid-air menisci is exterior to the liquid as sketched in Fig. 3.2.5: the contact angle θ between the liquid and the solid is smaller than 90° and, by Laplace's law, the suction $s = 2\,T_{lv}\cos\theta/r$ is positive. Here T_{lv} [unit : N/m] is the vapor-liquid tension. Then the liquid wets the pores and vapor begins penetrating the pores of representative radius r.
- drying proceeds with decreasing vapor pressure. For a vapor pressure much smaller (in algebraic value) than the saturation pressure $p_{\rm sat}$ (at 35 °C, $p_{\rm sat}$=5.6 kPa), the Kelvin-Helmholtz formula, namely $\widehat{v}_l\,(p_l - p_{l0}) = RT\,{\rm Ln}\,(p_v/p_{\rm sat})$ indicates that drying implies increasing liquid 'tension', i.e. negative pressure;
- the period during which the evaporation rate is virtually constant is termed constant rate period (CRP). This period ends up when the porous solid stops shrinking, evaporation decreases, vapor menisci enter the solid and suction increases;
- as the drying process continues by reducing the vapor pressure p_v, the suction increases by the Kelvin-Helmholtz formula. Since both the latter formula and Laplace's law should be satisfied, menisci enter the pore space from

the evaporation surface, the liquid recedes to the body and vapor invades pores of radii $2\,T_{lv}\,\cos\theta/s$ smaller and smaller.

According to this description, the larger pores drain first. For an actual porous solid, this general trend may be altered. Throats to the (larger) pores may be small, so that these throats constitute a bottleneck for evaporation. The large pores associated with these small throats drain only once the throats have drained.

If the body is kinematically constrained, fracture is likely because suction may create high tensile stresses. This description of desiccation qualitatively applies to gels [Scherer and Smith 1995] and to geomaterials like desiccating cements [Henkensiefken et al. 2009].

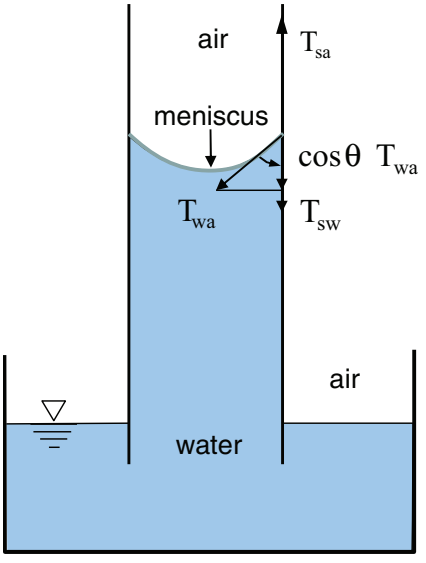

Fig. 3.2.5: The interface between a solid and a fluid develops a tension parallel to the interface. A similar tension parallel to the interface exists between a liquid, e.g., water, and a gas, e.g., air, which are not miscible. When the two non miscible fluids are in contact with a solid, the equilibrium configuration depends on the relative values of tension. For water and air, the actual configuration is indicated on the sketch: equilibrium implies that the projection of the water-air tension $T_{\rm wa}$ on the solid interface is equal to the tension resulting from the solid-water and solid-air interfaces, namely $T_{\rm wa}\cos\theta = T_{\rm sa} - T_{\rm sw}$ where θ is the contact angle between the water-air interface and the solid. The upward vertical force exerted on water inside a capillary (cylindrical tube) of radius r is thus equal to $2\,\pi\,T_{\rm wa}\cos\theta\,r$. This force is equilibrated by the weight of water in the tube, say $\rho_{\rm w}\,g\,h\,\pi\,r^2$. Thus the height of water is equal to $h = 2\,T_{\rm wa}\,\cos\theta/(\rho_{\rm w}\,g\,r)$ and the suction $p_{\rm a} - p_{\rm w} = \rho_{\rm w}\,g\,h$ is equal to $2\,T_{\rm wa}\,\cos\theta/r$. The water-air tension at ambient temperature is equal to 0.072 Pa×m and the contact angle θ is equal to 0°. For a capillary of radius $r = 10$ nm, the suction is thus equal to 14.4 MPa and water may theoretically (in absence of cavitation) ascent the tube over a height equal to 1440 m (the pressure due to a column of water of 10 m is equal to the atmospheric pressure).

3.2.4 Negative pressures, metastability and cavitation

In a porous medium, water is subjected to three types of physical forces: (1.) gravity, (2.) osmosis due to the presence of solutes, especially in fine pores and capillaries, and (3.) tension at the interfaces with air and solids.

Therefore, within tissues where water molecules establish strong bonds with other substances, some physical properties may be different from a pure substance. Water droplet suspended in air shows a convex meniscus (positive radius of curvature), as its pressure is larger than that of air. Conversely, capillary water bound to a solid displays a concave interface with air when its pressure is lower. Intrinsically negative pressures have been measured in water and liquids. The ascent of sap in the xylem conduits of trees is believed to be due to negative pressures, minus ten times the atmospheric pressure or more, generated by surface tension at the water-air interface of leaves. Indeed, the hydrostatic pressure decreases by about one atmosphere per dekameter. Under these circumstances, water is metastable with respect to its vapor (it remains liquid until a vapor bubble catastrophically develops), and the probability of cavitation (explosive liquid to vapor phase change) is large [Tardy and Duplay 1992, Mercury and Tardy 2001]. One way for nature to prevent cavitation might be to make use of a large number of redundant conduits with small diameters. However, too small conduits become hydraulically inefficient, because the permeability of tubes depends on their radius to the power 4, Table 15.7.1. The actual diameter of conduits is thought to be a trade-off between small conduits which are cavitation free (bubbles smaller than a certain critical size can not develop while larger ones do) but hydraulically inefficient, and large conduits which are hydraulically efficient but susceptible of cavitation [Tyree 2003].

The existence of negative pressures and the notion of metastability can be illustrated in the phase diagram [Kestin 1968, p. 238]. Indeed, let us follow an isotherm along which a liquid is expanded at constant temperature. When the experiment is performed in absence of foreign substances (impurities), the phase change actually does not take place at constant pressure, but at decreasing pressure up to some critical value of the specific volume, point A' in Fig. 3.2.6. Conversely, if the vapor is compressed, the phase change takes place at increasing pressure down to some

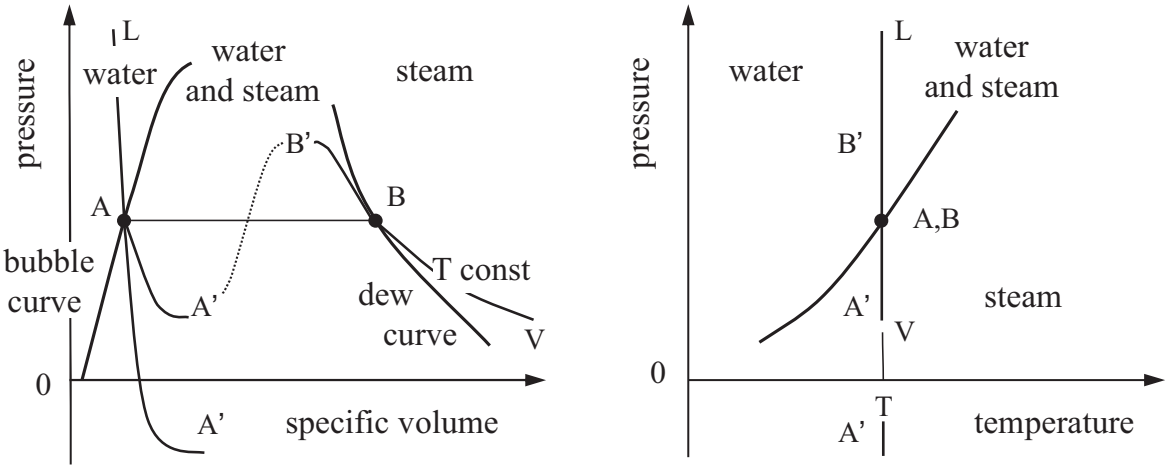

Fig. 3.2.6: In absence of impurities, part of the phase change at constant temperature and increasing specific volume takes place at decreasing pressure AA'. The values of pressure reached by water during volume expansion may be largely negative. Conversely, isothermal phase change at decreasing specific volume takes place in part at increasing pressure BB'. Along AA', the liquid is metastable with respect to its vapor, while, along BB', the vapor is metastable with respect to water.

critical value of the specific volume, point B' in Fig. 3.2.6. The path between A' and B' is *unstable* (not observable) since it would correspond to a negative isothermal bulk modulus. The paths AA' and BB' are termed *metastable*, that is, stable against small disturbances but instable again large ones. These notions of stability could be grasped by a colloquial example: a ball at the apex of a wedge $\wedge$ is in unstable equilibrium, it is in stable equilibrium in the inner edge of a V. Now if zooming the apex of the wedge, we discover a (even tiny) v, the ball will be said in metastable equilibrium at this apex.

Gas bubbles develop in liquids under very high negative pressure, or high suction. Cavitation may be viewed as the fracture of the liquid. An expression of the rate of nucleation of bubbles in terms of the liquid-vapor surface tension T_{lv} [unit : N/m], suction s, temperature T and vapor pressure p_v is proposed by Scherer and Smith [1995]. Inception of cavitation deduces by assuming a small rate of bubble formation, which provides the critical suction $s_{\rm cav}$ and the associated critical bubble radius $r_{\rm cav}$ by Laplace's law[3.8],

$$s_{\rm cav} = 3.9\sqrt{\frac{T_{lv}^3}{T}}, \quad r_{\rm cav} = 2\,\frac{T_{lv}}{s_{\rm cav}} = 0.51\,\sqrt{\frac{T}{T_{lv}}}\,. \tag{3.2.14}$$

In these formulas, the suction s is measured in MPa, the surface tension T_{lv} in erg/cm^2 and the radius in nm. For water and a particular gel, the liquid-vapor surface tension T_{lv} at $T = 300\,$K is typically equal to $72\,$erg/cm^2=$0.072\,$N/m. Therefore $s_{\rm cav}$=$137.5\,$MPa and $r_{\rm cav}$=$1.05\,$nm. Slightly different values are obtained for solvents other than water, like ethanol, etc.

3.3 Thermodynamic functions of fluids

The first part of this section is a short introduction to the thermomechanical properties for a single fluid species. The reader is referred to Kestin [1968] and Drumheller [1998], p. 321, for theoretical elaboration. The aim of the second part is to formulate constitutive restrictions that allow explicit expressions of the thermodynamic functions to be obtained.

The thermodynamic properties used here, namely internal energy u, free energy e, entropy s, are measured per unit mass. Let $v = 1/\rho$ be the specific volume of the species [unit : m^3/kg]. Since $-p\,dv - s\,dT$ is the differential of the free energy e, then

$$p = -\frac{\partial e}{\partial v}_{|T}, \quad s = -\frac{\partial e}{\partial T}_{|v}, \tag{3.3.1}$$

[3.8] The bubbles cannot form if the capillaries have a size smaller than $2\,r_{\rm cav}$.

and, assuming the free energy to be sufficiently smooth, the second order cross derivatives are equal,

$$\frac{\partial p}{\partial T}_{|v} = \frac{\partial s}{\partial v}_{|T} . \tag{3.3.2}$$

If one sets

$$T\,ds = \rho\,\mathcal{L}\,dv + c_{\rm v}\,dT\,, \tag{3.3.3}$$

with,
- $\mathcal{L}$ *latent heat of deformation* per unit mass [unit : J/kg],
- $c_{\rm v}$ heat capacity per unit mass at constant volume [unit : J/kg/K],

then

$$\rho\,\mathcal{L} = T\,\frac{\partial s}{\partial v}_{|T}\,, \quad c_{\rm v} = T\,\frac{\partial s}{\partial T}_{|v} = \frac{\partial u}{\partial T}_{|v}\,. \tag{3.3.4}$$

The last equality in the above relation results from the incremental definition of the internal energy $du = -p\,dv + T\,ds$. The terminology for the 'latent heat of deformation' is in analogy with the 'latent heat of phase change', a phenomenon that takes place at constant temperature. Truesdell [1984], p. 85, illustrates the idea by a simple example. If one compresses the air of a bike pump, its temperature increases and the pump itself becomes warmer. Now, one may submerge the pump in a large bath. Compressing the air no longer increases its temperature because the (latent) heat $dQ = T\,ds = \rho\,\mathcal{L}\,dv$ is absorbed by the bath.

The thermodynamic functions being Legendre transforms of one another, the knowledge of the free energy provides the energy, the enthalpy and the free enthalpy. However, we shall proceed in a different manner to build approximations of these functions for compressible and incompressible liquids.

3.3.1 The perfect or ideal gas

For a *perfect gas*[3.9], the constitutive relation may be expressed in the form $p\,\widehat{v} = RT$ or $p\,v = RT/\widehat{m}$, with $v = 1/\rho$ specific volume, $\widehat{m}$ the molar mass (equal to about 28.97 g/mole for dry air), $\widehat{v}$ the molar volume, and R the gas constant [unit : J/mole/K]. Then

$$\mathcal{L} = p\,v, \quad ds = \frac{R}{\widehat{m}}\,\frac{dv}{v} + c_{\rm v}\frac{dT}{T}, \quad du = -p\,dv + T\,ds = c_{\rm v}\,dT\,. \tag{3.3.8}$$

For u to be a total differential, $c_{\rm v}$ can depend only on T, $c_{\rm v} = c_{\rm v}(T)$. In addition, if $c_{\rm v}$ can be considered a constant, then

$$u - u_0 = c_{\rm v}\,(T - T_0), \quad s - s_0 = \frac{R}{\widehat{m}}\,{\rm Ln}\,\frac{v}{v_0} + c_{\rm v}\,{\rm Ln}\,\frac{T}{T_0}\,, \tag{3.3.9}$$

with the subscript index 0 denoting a reference configuration.

[3.9] The history of the ideal gas equation starts as far as from the 17th century and culminates in the first half of the 19th century with the current analytical expression by Clapeyron. Soon afterwards, measurements of the sound speed at high pressures indicated that the equation was inaccurate.

A significant contribution to a more realistic adjustment to data is due to the Dutch physicist Johannes van der Waals (1837-1923) who, in 1873, introduced two positive material constants a and b with appropriate dimensions that account for molecular attraction and molar volume respectively, so as to modify the state equation to the format,

$$\Big(p + \frac{a}{\widehat{v}^2}\Big)\,(\widehat{v} - b) = RT\,. \tag{3.3.5}$$

Using (3.3.1), the free energy, the internal energy and the enthalpy of the van de Waals gas deduce successively,

$$\begin{aligned}
s &= s_0 + c_{\rm v}\,{\rm Ln}\,\frac{T}{T_0} + \frac{R}{\widehat{m}}\,{\rm Ln}\,\frac{\widehat{v} - b}{\widehat{v}_0 - b};\\
e &= e_0 - s_0\,(T - T_0) - c_{\rm v}\Big(T\,{\rm Ln}\,\frac{T}{T_0} - T + T_0\Big) - \frac{RT}{\widehat{m}}\,{\rm Ln}\,\frac{\widehat{v} - b}{\widehat{v}_0 - b} - \frac{a}{\widehat{m}}\Big(\frac{1}{\widehat{v}} - \frac{1}{\widehat{v}_0}\Big);\\
u &= u_0 + c_{\rm v}\,(T - T_0) - \frac{a}{\widehat{m}}\Big(\frac{1}{\widehat{v}} - \frac{1}{\widehat{v}_0}\Big);\\
h &= h_0 + c_{\rm v}\,(T - T_0) + \frac{RT}{\widehat{m}}\Big(\frac{\widehat{v}}{\widehat{v} - b} - \frac{\widehat{v}_0}{\widehat{v}_0 - b}\Big) - 2\,\frac{a}{\widehat{m}}\Big(\frac{1}{\widehat{v}} - \frac{1}{\widehat{v}_0}\Big)\,.
\end{aligned} \tag{3.3.6}$$

A modern alternative to the van der Waals relation that introduces two constants as well goes by the name of Redlich-Kwong [Smith et al. 1996, p. 82], namely

$$\Big(p + \frac{a}{\sqrt{T}\,\widehat{v}\,(\widehat{v} + b)}\Big)\,(\widehat{v} - b) = RT\,. \tag{3.3.7}$$

The constants a and b express in terms of the pressure and temperature at the critical point [Smith et al. 1996, p. 83].
For *real* gases, the compressibility factor $Z = p\,\widehat{v}/RT$ takes values both below and above 1. It is larger than 1 for hydrogen.

It is instrumental to introduce the heat capacity at constant pressure $c_{\rm p} \equiv T\,(\partial s/\partial T)_{|p}$ and the adiabatic coefficient γ,

$$c_{\rm p}(T) \equiv c_{\rm v}(T) + \frac{R}{\widehat{m}}, \quad \gamma \equiv \frac{c_{\rm p}(T)}{c_{\rm v}(T)} = 1 + \frac{R}{\widehat{m}}\,\frac{1}{c_{\rm v}(T)} > 1, \quad c_{\rm p}(T) = \gamma\, c_{\rm v}(T) = \frac{R}{\widehat{m}}\,\frac{\gamma}{\gamma-1}\,. \tag{3.3.10}$$

The alternative set of variables (p, T),

$$T\,ds = -v\,dp + c_{\rm p}\,dT, \quad dh = v\,dp + T\,ds = c_{\rm p}\,dT\,, \tag{3.3.11}$$

yields, if $c_{\rm p}$ is a constant, explicit expressions of the enthalpy and entropy,

$$h - h_0 = c_{\rm p}\,(T - T_0), \quad s - s_0 = -\frac{R}{\widehat{m}}\,{\rm Ln}\,\frac{p}{p_0} + c_{\rm p}\,{\rm Ln}\,\frac{T}{T_0} = \frac{R}{\widehat{m}}\,{\rm Ln}\,\Big(\frac{p_0}{p}\big(\frac{T}{T_0}\big)^{\gamma/(\gamma-1)}\Big)\,. \tag{3.3.12}$$

Under isentropic conditions, i.e., s constant, the three sets of equivalent relations are easily established,

$$\begin{aligned}
\frac{T}{T_0} &= \Big(\frac{\rho}{\rho_0}\Big)^{\gamma-1} = \Big(\frac{p}{p_0}\Big)^{(\gamma-1)/\gamma};\\
\frac{p}{p_0} &= \Big(\frac{\rho}{\rho_0}\Big)^{\gamma} = \Big(\frac{T}{T_0}\Big)^{\gamma/(\gamma-1)};\\
\frac{\rho}{\rho_0} &= \Big(\frac{p}{p_0}\Big)^{1/\gamma} = \Big(\frac{T}{T_0}\Big)^{1/(\gamma-1)}.
\end{aligned} \tag{3.3.13}$$

3.3.2 Compressible and incompressible liquids

More generally, let us consider now fluids which are compressible, with a bulk modulus $K > 0$ [unit : Pa], and dilatable, with a cubic coefficient of thermal expansion $c_{\rm T}$ [unit : 1/K]), such that

$$\frac{dv}{v} = -\frac{dp}{K} + c_{\rm T}\,dT\,. \tag{3.3.14}$$

For a perfect gas,

$$K = p, \quad c_{\rm T} = 1/T\,. \tag{3.3.15}$$

Via (3.3.2), (3.3.4) the latent heat of deformation is found to be a function (in fact product) of the thermomechanical coefficients,

$$\rho\,\mathcal{L} = K\,c_{\rm T}\,T\,. \tag{3.3.16}$$

The entropy can be expressed in terms of the other variables once it is known in terms of one pair. Indeed, let

$$T\,ds = \rho\,\mathcal{L}\,dv + c_{\rm v}\,dT = \xi\,dp + c_{\rm p}\,dT = \zeta\,dv + \eta\,dp\,. \tag{3.3.17}$$

Then

$$c_{\rm p} - c_{\rm v} = K\,v\,c_{\rm T}^2\,T\ , \quad \xi = -v\,c_{\rm T}\,T, \quad \zeta = \frac{c_{\rm p}}{c_{\rm T}\,v}, \quad \eta = \frac{c_{\rm v}}{K\,c_{\rm T}}\,. \tag{3.3.18}$$

One may contrast the *isothermal bulk modulus*,

$$K = K^{\rm isoth} \equiv -v\,\frac{\partial p}{\partial v}_{|T}\,, \tag{3.3.19}$$

and the *isentropic* (or *adiabatic*) *bulk modulus*,

$$K^{\rm isen} \equiv -v\,\frac{\partial p}{\partial v}_{|s}\,. \tag{3.3.20}$$

Indeed,

$$-\,v\,\frac{dp}{dv} = K\begin{cases} 1 & \text{isothermal process,}\\ \gamma & \text{isentropic process.}\end{cases} \tag{3.3.21}$$

The adiabatic coefficient γ,

$$\gamma = \frac{c_p}{c_v} = \frac{K^{isen}}{K^{isoth}} = 1 + \frac{K\, v\, c_T^2\, T}{c_v}\,, \tag{3.3.22}$$

is about 1.3-1.7 for real gases at room temperature, close to 1 for water (1 at 4 °C, 1.024 at room temperature and 1.08 at 80 °C) and metals.

For a fluid which is neither compressible ($K = \infty$) nor dilatable ($c_T = 0$),

$$\xi = 0; \quad T\, ds = du = c\, dT; \quad c = c_v = c_p = c(T)\,. \tag{3.3.23}$$

It seems physically reasonable to restrict the heat capacities and bulk moduli to positive values,

$$c_p \geq c_v > 0; \quad K^{isen} \geq K = K^{isoth} > 0\,. \tag{3.3.24}$$

A positive bulk modulus implies the volume to decrease when the pressure increases. While the concept is not elaborated, these conditions are required for the *stability of the thermodynamic equilibrium* [Mandel 1974, p. 111].

It is important to note that the properties derived so far in this section are *tangent* properties, and not *secant* properties, since they are defined through differentials, and not finite increments.

Compressibility and thermal expansion

Incompressibility requires a vanishing coefficient of thermal expansion. Indeed, for the difference between heat capacities at constant pressure and constant volume to tend to 0, the product $K\, c_T^2$ should tend to 0 as well. On the other hand, since then $dp/dT = K\, c_T$, the product $K\, c_T$ is bounded.

Stability of equilibrium provides another argument against the existence of a fluid which would be incompressible but thermally dilatable. Indeed, then (3.3.14) and (3.3.17) would imply, under isentropic conditions, $dp = c_p/(v\, c_T)\, dT/T = c_p/(v\, c_T)^2\, dv/T$, that is, $dp/dv > 0$, or equivalently a negative isentropic bulk modulus, an inequality excluded by the stability conditions.

One would also expect the coefficient of thermal expansion to be positive, and, in fact, it does so for most substances. However, the fact that it might be negative or zero does not violate any principle. Indeed, water provides a conspicuous, although anomalous, example as illustrated by Figs. 3.2.1 and 3.3.1: the coefficient of thermal expansion changes sign and vanishes while the bulk modulus remains finite. The coefficient of thermal expansion of vitreous silica is negative at temperatures lower than 289 K. So do also the coefficients of thermal expansion of some tetrahedrally bonded materials at low temperatures, below 90 K for diamond.

3.3.3 Explicit thermodynamic functions for liquids

In order to build the thermodynamic functions in some ranges of pressure and temperature, we consider the specific volume and temperature as independent variables and we make successive assumptions, that will be seen to be appropriate for water [3.10]:

Assumption 3.1: constant bulk modulus K and coefficient of thermal expansion $c_T = c_T(T)$.

Note that the fact that the bulk modulus is constant implies the coefficient of thermal expansion to be independent of pressure, since the specific volume is a state variable, indeed $dp/K = -dv/v + c_T\, dT$. The integrability condition for the entropy $ds = K\, c_T\, dv + (c_v/T)\, dT$ implies

$$c_v(v, T) = c_v(v_0, T) + K\, (v - v_0)\, T\, \frac{dc_T}{dT}\,. \tag{3.3.25}$$

Then, with help of the relation (3.3.2) between partial derivatives,

$$\begin{aligned} v &= v_0\, \exp\big(-(p - p_0)/K + I_T(T, T_0)\big); \\ s - s_0 &= c_T\, K\, (v - v_0) + \int_{T_0}^{T} \frac{c_v(v_0, x)}{x}\, dx; \\ \mu - \mu_0 &= -K\, (v - v_0) - s_0\, (T - T_0) + K\, v_0\, I_T(T, T_0) - \int_{T_0}^{T} \int_{T_0}^{y} \frac{c_v(v_0, x)}{x}\, dx\, dy\,. \end{aligned} \tag{3.3.26}$$

[3.10] This simplified construction is left to be compared with the experimental measurements of the equation of state of distilled water and sea water, e.g., Fung [1977], p. 213. A comparison with the accurate formulation provided by the International Association for the Properties of Water and Steam (IAPWS) is presented in Section 3.3.4.

where

$$I_T(T,T_0) = \int_{T_0}^{T} c_\tau(x)\,dx\,. \tag{3.3.27}$$

The index 0 refers to the state ($p = p_0$, $T = T_0$). Therefore, a complete knowledge of the entropy and chemical potential requires the heat capacity $c_v = c_v(T)$ to be prescribed and the reference values of specific volume v_0, entropy s_0, and chemical potential μ_0 to be given. The reference value of chemical potential may be seen as containing some history of the species. In practice, it can be used as a degree of freedom to ensure chemical equilibrium of a species at the interface between two phases.

The status of the reference entropy is different : it affects the *variation* of the free energy and chemical potential as temperature varies. Kestin [1968] discusses the issue at length. He deduces from the third law of thermodynamics that the derivatives with respect to temperature of internal energy, free energy, enthalpy and free enthalpy should vanish as the temperature T tends to absolute zero, and so should the entropy, Kestin [1968], p. 364. Indeed for a reversible process, the change of entropy is equal to the heat supply per unit mass over absolute temperature, $ds = dq/T$. Since the heat capacity c is equal to dq/dT, then $ds = (c/T)\,dT$. For the entropy to be integrable from T=0 K onward, the heat capacity $c = c(T)$ should indeed vanish at T=0 K[Kestin 1968, p. 268]. Still, these considerations do not seem to be of much help at ambient temperature. In practice, a zero entropy at triple point is often assumed, e.g., Kestin [1978], p. 520. The current convention used by the thermodynamics community is made explicit in Section 3.3.4.

Assumption 3.2 : in addition, the heat capacity $c_v(v_0,T)$ is constant, $c_{v0} = c_v(v_0,T) = c_v(v_0,T_0)$.

Then

$$\begin{aligned}
s - s_0 &= c_\tau\,K\,(v - v_0) + c_{v0}\,\mathrm{Ln}\,\frac{T}{T_0},\\
\mu - \mu_0 &= -K\,(v - v_0) + (c_{v0} - s_0)(T - T_0) + K\,v_0\,I_T(T,T_0) - c_{v0}\,T\,\mathrm{Ln}\,\frac{T}{T_0},\\
h - h_0 &= -K\,(1 - T\,c_\tau)\,(v - v_0) + c_{v0}\,(T - T_0) + K\,v_0\,I_T(T,T_0)\,,\\
e - e_0 &= -(p - p_0)\,v - \big(p_0 + K\big)\,(v - v_0) + (c_{v0} - s_0)\,(T - T_0) + K\,v_0\,I_T(T,T_0) - c_{v0}\,T\,\mathrm{Ln}\,\frac{T}{T_0}\,,\\
u - u_0 &= -(p - p_0)\,v - (p_0 + K\,(1 - c_\tau\,T))\,(v - v_0) + c_{v0}\,(T - T_0) + K\,v_0\,I_T(T,T_0)\,,
\end{aligned} \tag{3.3.28}$$

with references expressed in terms of the quantities (p_0,T_0), v_0 and (s_0,μ_0), and

$$h_0 = \mu_0 + T_0\,s_0, \quad e_0 = \mu_0 - p_0\,v_0, \quad u_0 = \mu_0 + T_0\,s_0 - p_0\,v_0\,. \tag{3.3.29}$$

The chemical potential shows an affine dependence on the reference entropy, the internal energy shows an affine dependence on the reference pressure, and the free energy shows an affine dependence on both the reference entropy and the reference pressure.

Upon linearization to first order about the reference state (p_0,T_0), while maintaining the exact temperature dependence of the coefficient of thermal expansion,

$$\begin{aligned}
s - s_0 &= -c_\tau\,v_0\,(p - p_0) + \frac{c'_p}{T_0}\,(T - T_0),\\
\mu - \mu_0 &= v_0\,(p - p_0) - s_0\,(T - T_0),\\
h - h_0 &= (1 - T_0\,c_\tau)\,v_0\,(p - p_0) + c'_p\,(T - T_0)\,,\\
e - e_0 &= \frac{p_0 v_0}{K}\,(p - p_0) - s_0\,(T - T_0) - p_0\,v_0\,I_T(T,T_0)\,,\\
u - u_0 &= (\frac{p_0}{K} - c_\tau\,T_0)\,v_0\,(p - p_0) + c'_p\,(T - T_0) - p_0\,v_0\,I_T(T,T_0)\,.
\end{aligned} \tag{3.3.30}$$

The *secant* heat capacity c'_p

$$c'_p = c_{v0} + K\,v_0\,c_\tau\,T_0\,\frac{I_T(T,T_0)}{T - T_0}\,, \tag{3.3.31}$$

reduces to c_p if the coefficient of thermal expansion is a constant.

Under the above assumptions, the isothermal and isentropic bulk moduli, $K^{\text{isoth}} = K$ and K^{isen} respectively, relate as follows,

$$K^{\text{isen}} = \frac{c'_p}{c_{v0}} K \,, \tag{3.3.32}$$

and the pressure increment may be expressed in either format,

$$p - p_0 = \begin{cases} -K \dfrac{v - v_0}{v_0} & + \quad K \dfrac{I_T(T, T_0)}{T - T_0} (T - T_0); \\ -K^{\text{isen}} \dfrac{v - v_0}{v_0} & + \quad \dfrac{K}{c_{v0}} \dfrac{I_T(T, T_0)}{T - T_0} T_0 (s - s_0) \,. \end{cases} \tag{3.3.33}$$

If, in addition to the two first assumptions,

Assumption 3.3: the material is neither compressible ($K = \infty$) nor dilatable ($c_\tau = 0$), then, the heat capacities are equal and constant, $c_p = c_v = c_{v0} = c$, and

$$\begin{aligned} s - s_0 &= c \,\text{Ln}\, \frac{T}{T_0}, \\ \mu - \mu_0 &= v_0 (p - p_0) + (c - s_0)(T - T_0) - c\,T \,\text{Ln}\, \frac{T}{T_0} \,, \\ h - h_0 &= v_0 (p - p_0) + c (T - T_0) \,, \\ e - e_0 &= (c - s_0)(T - T_0) - c\,T \,\text{Ln}\, \frac{T}{T_0} \,, \\ u - u_0 &= c (T - T_0) \,. \end{aligned} \tag{3.3.34}$$

In this limit case, the pressure influence survives in the enthalpy and free enthalpy only.

The actual dependence of the thermodynamic functions with respect to pressure and temperature are quantified through contour levels in subsequent plots.

Table 3.3.1: Some physical properties of pure water at 1 atmosphere (101 325 Pa) calculated from (1) IAPWS [2009]; (2) IAPWS [1984].

Temperature T [°C]	Mass Density ρ [kg/m^3] (1)	Heat Capacity c_p [kJ/kg/K] (1)	Thermal Expansion c_τ [10^{-3}/K] (1)	Bulk Modulus K [GPa] (1)	Dynamic Viscosity [centipoise=10^{-3} Pa×s] (1), (2)
0 (ice)	916.8	1.96	0.158	∼10	$10^{16} - 10^{17}$
0 (liquid)	999.843	4.219	-0.068	1.965	1.791
2	999.943	4.213	-0.0326	1.994	1.674
4	999.975	4.207	0.3×10^{-6}	2.021	1.569
20	998.210	4.184	0.207	2.179	1.003
40	992.218	4.179	0.385	2.261	0.653
60	983.197	4.185	0.523	2.247	0.467
80	971.792	4.197	0.641	2.167	0.355
100 (liquid)	958.350	4.216	0.751	2.040	0.282
100 (steam)	0.598	2.080	2.902	10^{-4}	0.012

Table 3.3.1 displays a few physical properties of pure water over the range 0.01 °C to 100 °C. The dynamic viscosity of pure water is equal to 1 centipoise at 20 °C. The calorie (1 cal=4.185 J) is the energy required to increase the temperature of one gram of water from 14.5 °C to 15.5 °C under atmospheric pressure. The heat capacity of water is, after ammonia, the next largest among liquids. On the other hand, water is a poor conductor of heat, or equivalently a good insulator, Table 9.1.2. These properties confer to water and ice a significant resistance to changes of temperature. Heat capacities of biological tissues are of the same order, although a bit smaller [Duck 1990]:

- for blood: heat capacity c_p=3.84 kJ/kg/K; mass density 1.06 kg/m^3;

Table 3.3.2: Mass density and heat capacity of an aqueous solution at 20 °C and under atmospheric pressure with various concentrations of NaCl, obtained by interpolation from the data of de Marsily [1986], p. 417.

Concentration (mole/liter)	Mass/Volume of Solution [kg/m^3]	Heat Capacity c_p [kJ/kg/K]
0	998.2	4.182
0.15	1004.4	4.133
0.50	1018.7	4.028
1.0	1038.6	3.891

- for human liver: heat capacity c_p=3.60 kJ/kg/K; mass density 1.06 kg/m^3.

Similarly, heat capacity of sea water is slightly smaller than for pure water, Table 3.3.2.

Note the relation between cross-derivatives, $T\,\partial(-v\,c_\tau)/\partial T = \partial c_p/\partial p$. Therefore, in the range of temperatures of interest here, $\partial c_p/\partial p$ is about -2.75×10^{-6} m^3/kg/K, and the relative variation $\Delta c_p/c_p$ is equal to $-0.65\times10^{-9}\,\Delta p$, which is quite tiny for a change of a few atmospheres. Consequently, the model yields a heat capacity c_p fairly independent of pressure in the range of interest. However, this property should be manipulated with care since, if adopted from the start, it would have led to $v\,c_\tau$ independent of temperature, which is definitely inaccurate. Smith et al. [1996], p. 637, provide polynomial approximations of the heat capacities of a number of gases, liquids and solids, e.g., for water (the unit is that of the gas constant R),

$$\frac{c_p(T)}{R} = 8.712 + 1.25\times10^{-3}\,T - 0.18\times10^{-6}\,T^2, \quad T\in]273.16\,\mathrm{K},\ 373.125\,\mathrm{K}[\,. \tag{3.3.35}$$

The error induced by Assumption 3.2 can also be estimated: in view of (3.3.25), it amounts to a maximum error of about 10% on the heat capacities. Here, emphasis has been laid to accommodate an arbitrary temperature dependence of the coefficient of thermal expansion. If, on the other hand, accurate heat capacities are needed, alternative assumptions should be devised.

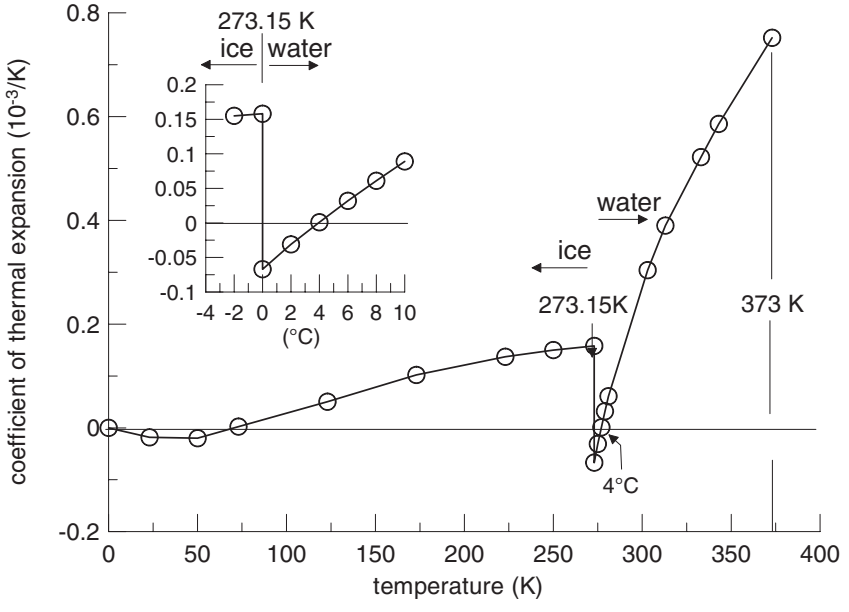

Fig. 3.3.1: Coefficient of thermal expansion of water at atmospheric pressure. The water substance presents an anomalous behavior. As temperature increases, the coefficient of thermal expansion undergoes a jump at 0 °C, from a positive value in the solid phase to a negative value in the liquid phase. It keeps this negative value from 0 °C to about 4 °C: in this interval, increase of temperature at constant pressure leads to volume decrease. From Kestin [1968], Table XXXIV, p. 541.

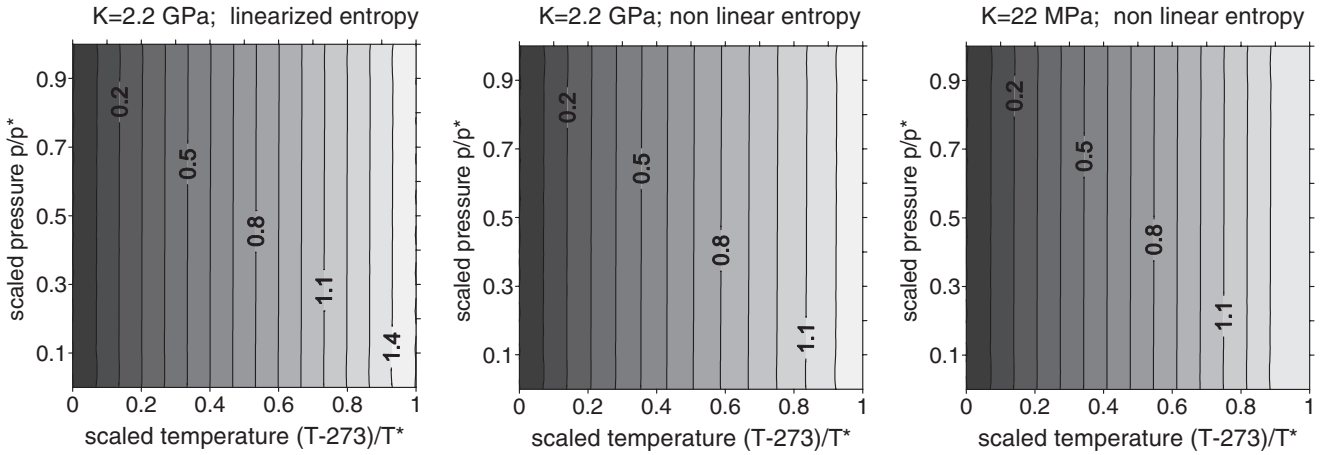

Fig. 3.3.2: Contours of entropy of water [unit : kJ/kg/K] for a coefficient of thermal expansion $c_{\mathrm{T}} = 0.4 \times 10^{-3}\,\mathrm{K}^{-1}$, a heat capacity $c_{\mathrm{v0}} = 4.02\,\mathrm{kJ/kg/K}$, and the reference values for pressure $p_0 = 611\,\mathrm{Pa}$, temperature $T_0 = 273.16\,\mathrm{K}$, specific volume $v_0 \sim 10^{-3}\,\mathrm{m^3/kg}$, entropy $s_0 = 0\,\mathrm{J/kg/K}$, and free enthalpy $\mu_0 = 0\,\mathrm{J/kg}$. The scaling temperature and pressure are respectively $T*$=100 K, and $p*$=10 MPa. The left and center contour plots display the linearized and nonlinear entropies respectively, for a bulk modulus $K = 2.2\,\mathrm{GPa}$, and the right contour plot displays the nonlinear entropy for $K = 0.022\,\mathrm{GPa}$.

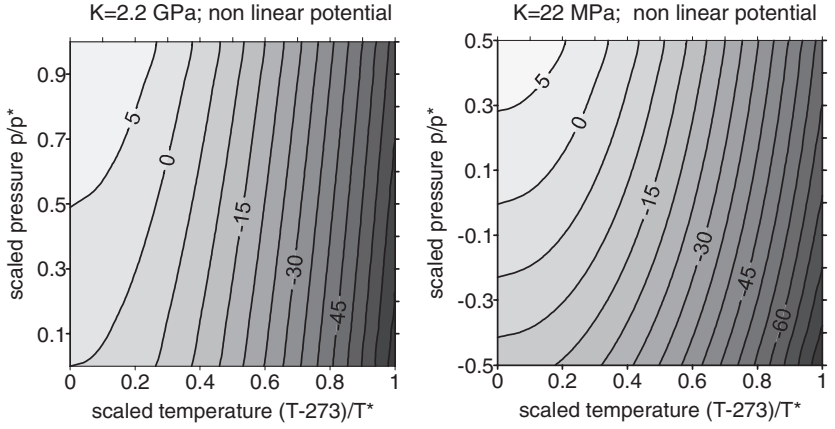

Fig. 3.3.3: Chemical potential of water [unit : kJ/kg] as a function of temperature and pressure.

The coefficient of thermal expansion of the water substance undergoes a negative jump at 0 °C, Fig. 3.3.1. It increases monotonically between 0 °C and 100 °C, passing through a null value just below 4 °C[Kestin 1968, p. 264]. In the liquid state, the affine expression [unit : 10^{-6}/K],

$$c_{\mathrm{T}}(T) = -67 + 8.19\,(T - 273.16), \quad T \in]273.16\,\mathrm{K}, 373.125\,\mathrm{K}[\,, \tag{3.3.36}$$

is exact at 0 °C and 100 °C, vanishes at 8 °C, and is below the actual value throughout the temperature interval. The quadratic expression [unit : 10^{-6}/K],

$$c_{\mathrm{T}}(T) = -67 + 15\,(T - 273.16) - 0.068\,(T - 273.16)^2, \quad T \in]273.16\,\mathrm{K},\ 373.125\,\mathrm{K}[\,, \tag{3.3.37}$$

is exact at 0 °C and 100 °C, and vanishes at 4.5 °C. Overall, it represents a reasonably good approximation between 0 °C and 50 °C, but slightly overestimates the actual expansion coefficient above 50 °C.

The analytical expressions (3.3.28), and the linearized expressions (3.3.30), are employed to obtain contour plots of the thermodynamic functions in a window of temperature and pressure, Figs. 3.3.2 to 3.3.6. The thermal dependence is much larger than the pressure dependence. This observation applies fully to the entropy but more moderately to

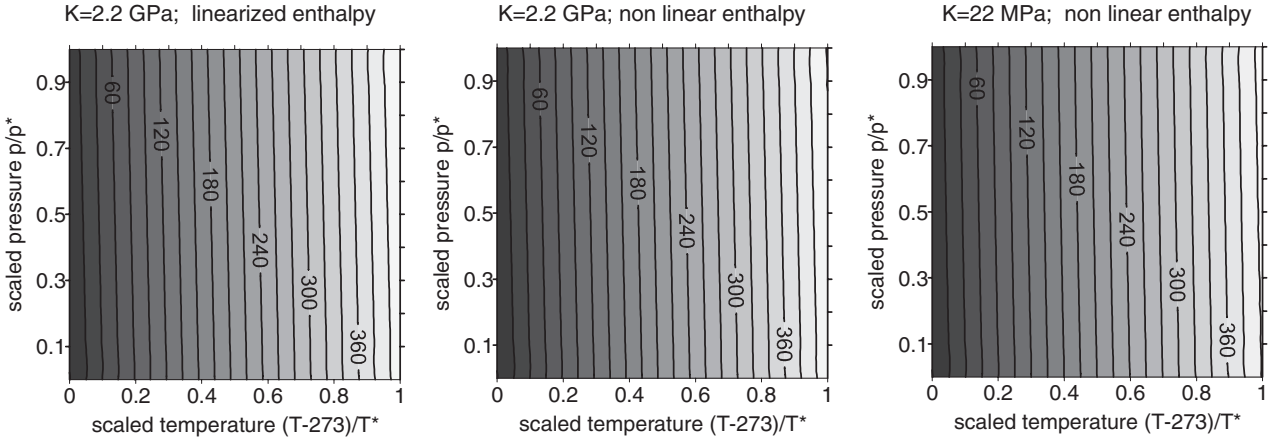

Fig. 3.3.4: Enthalpy of water [unit : kJ/kg] as a function of temperature and pressure.

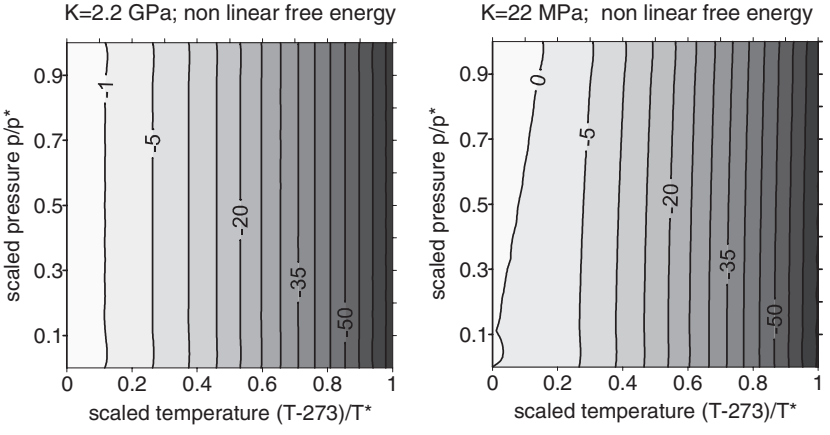

Fig. 3.3.5: Free energy of water [unit : kJ/kg] as a function of temperature and pressure.

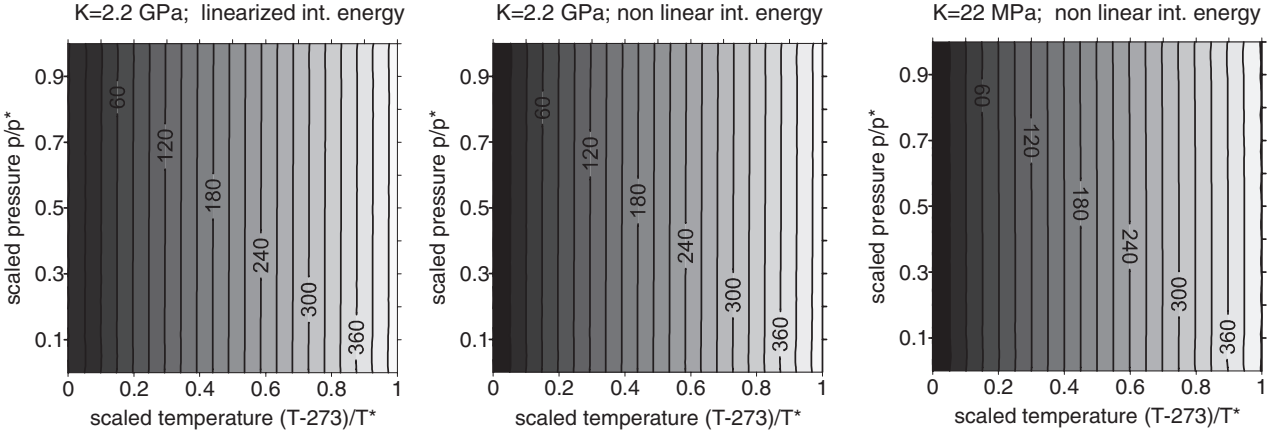

Fig. 3.3.6: Internal energy of water [unit : kJ/kg] as a function of temperature and pressure.

the chemical potential. Plots show that it holds true even if water contains air bubbles that reduce the bulk modulus by two orders of magnitude.

Figs. 3.3.2 to 3.3.6 also allow to assess the accuracy of the linearized expressions (3.3.30) with respect to the nonlinear relations (3.3.28). Entropy, internal energy and enthalpy are reasonably approximated by their linearized expressions. On the other hand, the first order linearized expressions of chemical potential and free energy are quite inaccurate and they are not displayed. These observations justify the developments of thermoelastic models in Chapter 9 where first order linearized expressions of the sole entropy and internal energy are used.

The thermal dependence of the chemical potential is encapsulated in

Proposition 3.2 on the dependence of chemical equilibrium with respect to pressure and temperature.

For temperatures in the range [0.01 °C, 100 °C], and pressures of a few atmospheres, chemical equilibrium is sensitive to disturbances of both pressure and temperature.

In the incompressible and inextensible limit, with reference values T_0=273.16 K and $s_0 = 0$, an increase of the temperature from 25 °C to 26 °C and an increase of pressure by 350 kPa have equal and opposite contributions to the chemical potential (3.3.34). The equivalent pressure differential falls to 7 kPa if the temperature changes from 0.01 °C to 1 °C, as can be observed in Fig. 3.3.3.

Indeed, consider a membrane to separate the fluid of a bucket in two parts. Each side of the membrane has its own pressure and temperature. Mass exchange between the two sides is controlled by the difference of chemical potentials (or free enthalpy), Section 3.1.3. A small difference in temperature results in a substantial difference of chemical potentials. If the membrane is permeable to the fluid, a fluid transfer will take place so as to equilibrate the chemical potentials. How exactly ? Well, to answer this question, a constitutive equation of mass transfer should be available. The conditions that control this physical phenomenon and specific linear and nonlinear laws are provided in Chapter 10.

Chemical equilibrium alone, namely equality of the chemical potentials, does not guarantee mechanical and/or thermal equilibria between two compartments. It simply provides a single relation between the two pressures and temperatures. As a very particular example, assume that the temperatures in the two compartments and the pressure in one compartment are controlled. Given reference values (which may well not be the same for the two compartments), chemical equilibrium will then provide the unknown pressure.

Thermal equilibrium may not hold in specific circumstances. Consider a porous medium with two types of porosities, one associated with transport, the other with fluid storage. In the context of soft tissues, vessels provide the first type of porosity[3.11] and pores of the interstitium the second type. Fast transport through the vessels may bring the two fluids at distinct temperatures in sudden local contact. A model of this flavor is developed in Section 10.6.

Thermal equilibrium may be reached if the membrane is a thermal conductor. Similarly, chemical equilibrium can be realized only if the membrane is permeable to the fluid.

At this point, as we are defining equilibria, it is of utmost importance to insist that these equilibria are *local*, that is, they are defined at a geometric point of the porous medium viewed as a continuum.

3.3.4 Liquid-vapor equilibrium curve: IAPWS and simplified formulations

Along the liquid-vapor equilibrium curve, the liquid (l) and vapor (v) phases are in thermal equilibrium (equal temperatures), mechanical equilibrium (equal pressures in absence of vapor bubbles in the liquid phase and liquid drops in the vapor phase) and chemical equilibrium (equal chemical potentials). On the other hand, the specific volumes, or mass densities, are distinct.

Two derivations of the thermodynamic properties of water along the equilibrium curve are considered:

- the first derivation uses the data provided by the International Association for the Properties of Water and Steam (IAPWS), IAPWS [2002] and IAPWS [2009]. The model is accurate over a wide range of temperatures and pressures from the triple point to the critical point, including in particular, but not restricted to, the equilibrium curve. It is unified, in the sense that the liquid and vapor phases use the same constitutive functions which are phrased in terms of mass density (or specific volume) and temperature;
- the second derivation considers vapor as an ideal gas described in Section 3.3.1 and uses the simplified model for the liquid phase exposed in Sections 3.3.2 and 3.3.3. These relations are expected to be reasonably accurate in a restricted domain of temperature and pressure, roughly between 0.01 °C and 100 °C and for a few MPa's;

[3.11] The term porosity is used to denote a certain type of pore geometry as well as the volume fraction associated with all porosity types.

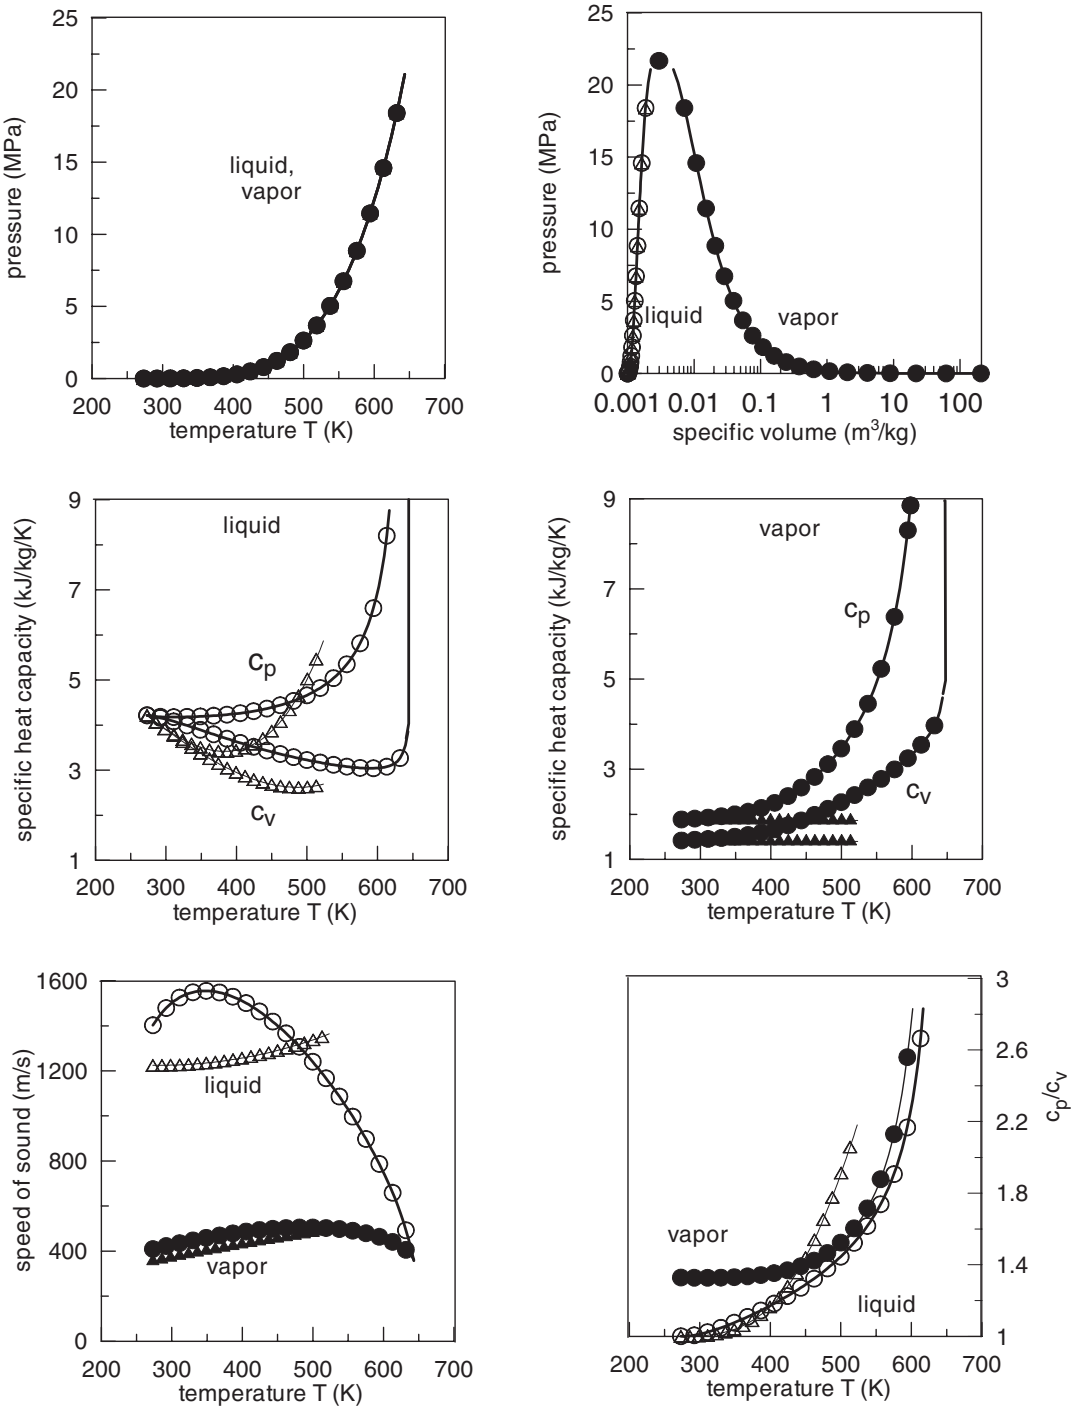

Fig. 3.3.7: A number of thermomechanical entities pertaining to the vapor and liquid along the equilibrium (saturation) curve from 0.01 °C to the critical point.
Open symbols: liquid; solid symbol: vapor; circles: IAPWS unified model; triangles: simplified model. Note that some curves of the IAPWS and simplified models almost superpose while some others are quite distinct.
At the critical point,
- the isobaric and isochoric heat capacities of liquid and vapor both tend to infinity but in such a way that the adiabatic coefficient c_p/c_v, which is always larger than 1, also tends to infinity;
- the isothermal speed of sound, $w^2 = \partial p/\partial \rho_{|T}$, vanishes and the isentropic speed of sound shown on the plot, namely $w^2_{\rm isen} = \partial p/\partial \rho_{|s}$, almost vanishes as well ($w_{\rm isen} = 7.79\,{\rm m/s}$).

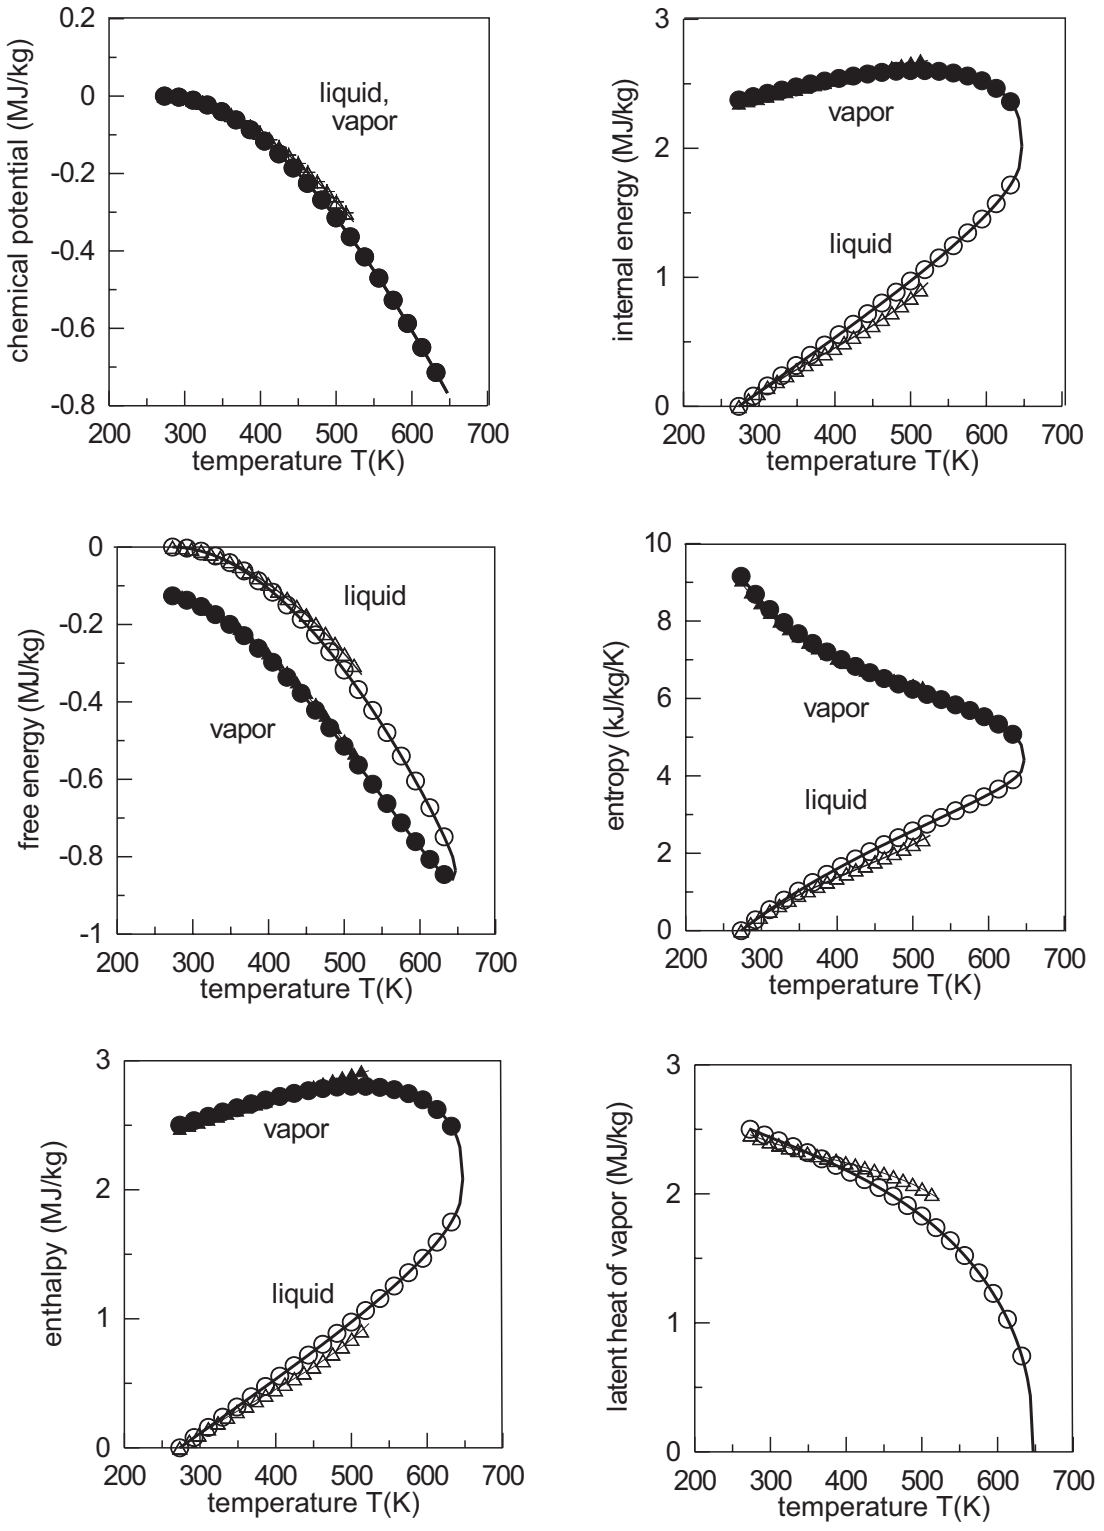

Fig. 3.3.8: Thermodynamic potentials, entropy and latent heat $h_v - h_l$.
- The latent heat decreases moderately with temperature;
- For the liquid, internal energy and entropy vanish at the triple point ($T = 273.16\,\mathrm{K}$). They are slightly negative at $0\,^\circ\mathrm{C}$ ($T = 273.15\,\mathrm{K}$). A sign change between $0\,^\circ\mathrm{C}$ and the triple point also takes place for the enthalpy and chemical potential.

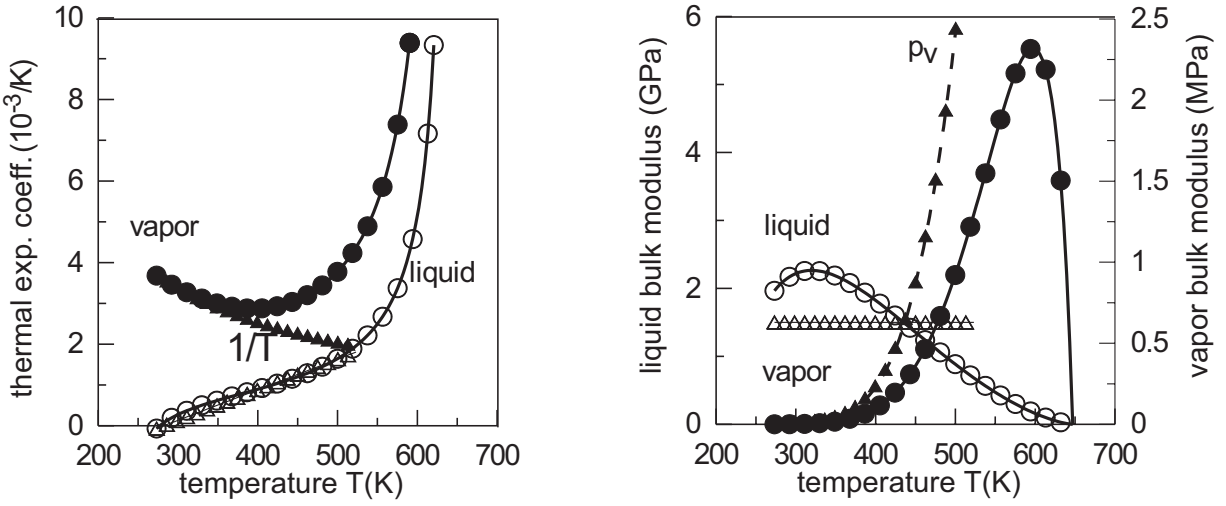

Fig. 3.3.9: Isothermal bulk modulus and coefficient of thermal expansion.
- The coefficient of thermal expansion of the liquid is negative between 0 and about 4 °C;
- At the critical point, the coefficient of thermal expansion becomes infinite and the bulk modulus vanishes.
Note: for an ideal gas, the isothermal bulk modulus is equal to the pressure and the coefficient of thermal expansion is equal to the coldness (inverse temperature).

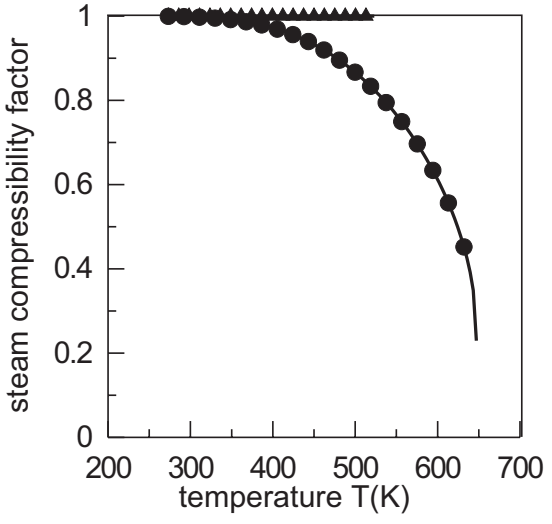

Fig. 3.3.10: The steam compressibility factor $Z \equiv p/(RT\,\widehat{v}_v)$ of the IAPWS model decreases monotonously along the equilibrium curve from the triple point to the critical point. It is equal to 1 for an ideal gas.

Both models provide other entities of interest, namely the isochoric heat capacity $c_v = T\,(ds/dT)_{|v}$ and

- the coefficient of thermal expansion,

$$c_{\rm T} = -\frac{1}{\rho}\left(\frac{d\rho}{dT}\right)_{|p};$$

- the isothermal and isentropic moduli,

$$K_T = \rho\left(\frac{dp}{d\rho}\right)_{|T}, \quad K_{\rm isen} = \rho\,(\frac{dp}{d\rho})_{|s} = K_T\left(1 + \frac{K_T\,c_{\rm T}^2\,T}{\rho\,c_v}\right);$$

- the isobaric heat capacity c_p,

$$c_p = c_v\left(1 + \frac{K_T\,c_{\rm T}^2\,T}{\rho\,c_v}\right);$$

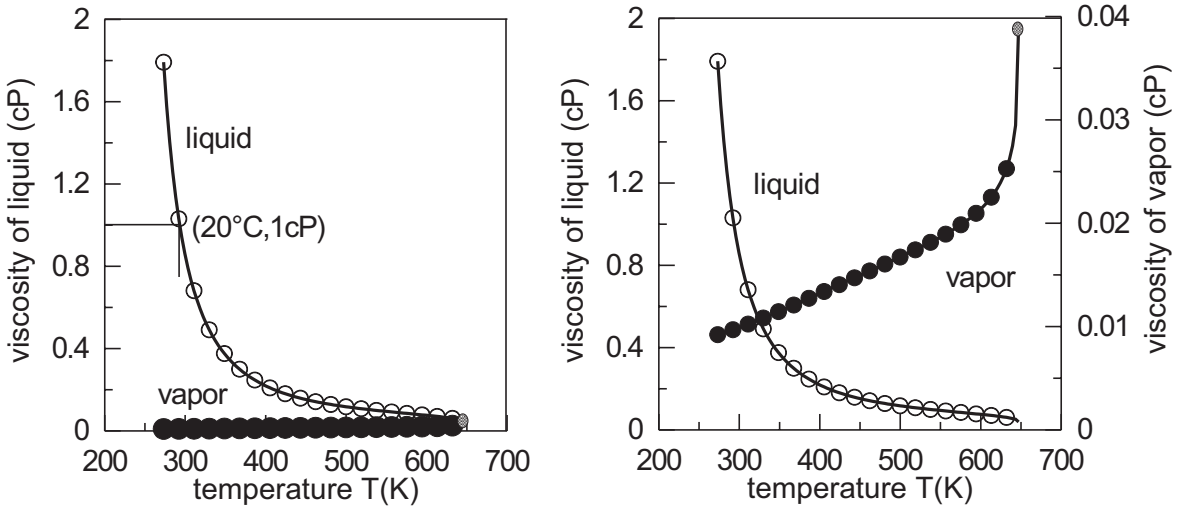

Fig. 3.3.11: The viscosity of the liquid decreases monotonously along the equilibrium curve from the triple point to the critical point. The opposite takes place for the steam. The common value of the viscosity at the critical point is equal to 0.038 990 cP.

- the isothermal and isentropic speeds of sound, defined respectively by their square as

$$w_T^2 = \left(\frac{dp}{d\rho}\right)_{|T} = \frac{K_T}{\rho}, \quad w_{\text{isen}}^2 = \left(\frac{dp}{d\rho}\right)_{|s} = \frac{K_{\text{isen}}}{\rho}\,.$$

.

3.3.4.1 The equilibrium curve

The equilibrium curve is sought by enforcing the liquid water and its steam to be simultaneously in thermal, mechanical and chemical equilibria,

$$T_l = T_v, \quad p_l = p_v, \quad \mu_l = \mu_v\,. \tag{3.3.38}$$

The equilibrium curve is obtained by varying the temperature over a given interval. At each point T of the interval, the constitutive equations for the pressures $p(v_l, T)$ and $p(v_v, T)$ and chemical potentials $\mu(v_l, T)$ and $\mu(v_v, T)$ inserted in the thermal and chemical equilibria provide the specific volumes v_l and v_v, and by the same token the common pressure.

3.3.4.2 Reference thermodynamic potentials along the IAPWS conventions

Along the conventions of the IAPWS, internal energy and entropy of the liquid are set to vanish at the triple point (subscript t),

$$s_{tl} = 0, \quad u_{tl} = 0\,, \tag{3.3.39}$$

which implies,

$$e_{tl} = 0, \quad h_{tl} = \mu_{tl} = p_t\, v_{tl}\,. \tag{3.3.40}$$

The equilibrium of the pressures and chemical potentials at $T_t = 273.16\,°\text{C}$ provides the pressure p_t and specific volumes v_{tl} and v_{tv} at the triple point t reported in Table 3.2.2. The entropy being provided directly by the IAPWS model, the other potentials of vapor at the triple point result in turn as,

$$\mu_{tv} = \mu_{tl}, \quad s_{tv} = 9.156\,\text{kJ/kg/K}, \quad h_{tv} = \mu_{tv} + T_t\, s_{tv}, \quad u_{tv} = h_{tv} - p_t\, v_{tv}, \quad e_{tv} = u_{tv} - T_t\, s_{tv}\,. \tag{3.3.41}$$

3.3.4.3 The simplified model for water and steam

For the simplified model, the following assumptions are adopted.

Liquid properties

Three properties need to be defined. The bulk modulus K_l is set to 1.5 GPa, and rough approximations are used for the coefficient of thermal expansion $c_{\tau l}$ and heat capacity $c_{vl}(v_0, T)$,

$$\begin{aligned} c_{\tau l} &= \big(-67 + 8.19 \times (T - T_t) \big) \times 10^{-6} / \mathrm{K}, \\ c_{vl}(v_0, T) &= 4217 - 11 \times (T - T_t) + 0.001 \times (T - T_t)^2 \quad \mathrm{J/kg/K}\,. \end{aligned} \tag{3.3.42}$$

The isochoric heat capacity $c_{vl}(v, T)$ is obtained from $c_{vl}(v_0, T)$ by (3.3.25) and the isobaric heat capacity $c_{pl}(v, T)$ derives from the latter by (3.3.18).

Vapor properties

A single entity needs to be fixed: the isochoric heat capacity c_{vv} is set to the constant value 1.418 kJ/kg/K.

3.3.4.4 Quantitative assessment of the simplified model

Figs. 3.3.7 to 3.3.10 show that some curves of the IAPWS and simplified models nicely superpose. The equilibrium curve provided by the simplified model is acceptable although some error with respect to the IAPWS model is visible. The principal source of error is due to the constant bulk modulus of the liquid. The heat capacities should be approximated more accurately than by a second order polynomial.

The viscosities along the equilibrium curve shown in Fig. 3.3.11 are derived from the expressions suggested in IAPWS [1984].

3.4 Laplace's law of mechanical equilibrium at the interface between two immiscible fluids

Laplace's law links the tension developed in the interface that separates two immiscible fluids to the pressures on each side of this interface. The interface is considered impervious to the fluids at the time scale of application of the law. Laplace's law is advocated in many circumstances. It applies to the meniscus separating two non miscible fluids in a tube, Section 3.2.3, or in a porous medium, Section 3.2.4. Controlling the surface tension of bubbles and droplets in emulsions through surfactants is a key issue in chemical engineering. Formally, it is also used for some solid structures: it provides the orthoradial stress in a solid vessel wall of given radius and thickness, the blood pressure and interstitium pressure being known, Section 15.9.2.

Laplace's law can be proved using work conservation or equilibrium of forces. Work conservation indicates that the work done by the tension T [unit : N/m] in an incremental change of the area of the membrane dS [unit : m^2] is equal to the work done by the pressure differential Δp [unit : $\mathrm{N/m}^2$] across the membrane in the associated incremental change of volume δV [unit : m^3] enclosed by the membrane. Therefore,

$$T\,\delta S - \Delta p\,\delta V = 0 \quad \Rightarrow \quad \Delta p = T\,\frac{\delta S}{\delta V}\,. \tag{3.4.1}$$

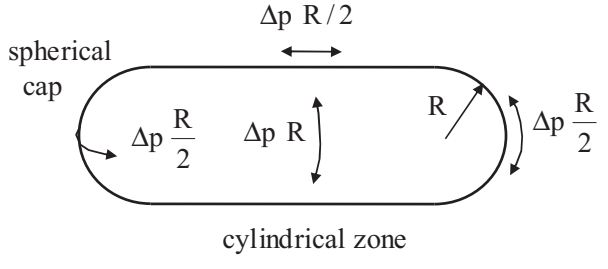

Fig. 3.4.1: In an elastic cylinder closed with two spherical caps, the orthoradial tension over the central part is twice the tension over the caps.

The area and volume of a spherical membrane of radius R are respectively equal to $S = 4\,\pi\,R^2$ and $V = 4/3\,\pi\,R^3$. For a cylindrical membrane of unit axial length, these quantities become $S = 2\,\pi\,R$ and $V = \pi\,R^2$. Therefore we have reached explicit expressions of Laplace's law,

$$\text{sphere}: \ \Delta p = 2\,\frac{T}{R}; \quad \text{cylinder}: \ \Delta p = \frac{T}{R}\,. \tag{3.4.2}$$

As an alternative to the energy method, these formulas can also be arrived at using the force equilibrium of a half sphere or of a half cylinder. Fig. 3.4.1 shows an immediate illustration.

A more general form of Laplace's law results by considering an infinitesimal surface, assuming its radii of curvature R_x and R_y to be known along two orthogonal directions (not necessarily the principal directions). The proof considers the two directions in turn, Fig. 3.4.2. Projecting onto the x-bisector the two forces $T\,dy$ inclined at an angle $dx/(2\,R_x)$ with respect to this bisector yields the component of the tension $T/R_x\,dx\,dy$ along the inward normal to the elementary surface. The orthogonal direction is treated similarly and the two contributions are summed. At equilibrium, the inward force of the membrane $T\,(1/R_x+1/R_y)\,dx\,dy$ counterbalances the outward contribution of the pressure $\Delta p\,dx\,dy$, yielding

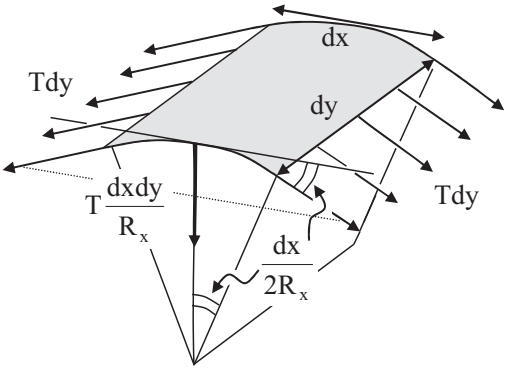

Fig. 3.4.2: Sketch to prove Laplace's law showing an elementary surface cut along two orthogonal directions.

$$\Delta p = T\,\Big(\frac{1}{R_x}+\frac{1}{R_y}\Big)\,. \tag{3.4.3}$$

The convention is that the pressure differential Δp is equal to the internal minus the external pressure. The curvature is counted positive if the center of curvature is located in the inner side delineated by the membrane.

Actually, Laplace's law assumes that the tension is identical in all directions of the surface. Therefore, it does not apply to an elastic cylinder: it provides the correct circumferential stress simply because the axial stress is elusive due to an infinite axial radius of curvature. As it has been stated, Laplace's law also assumes a continuous radius of curvature, excluding a priori the interface between a cylinder and a sphere. In fact, energy minimization implies small water droplets to be spherical, Eqn (3.4.1). Gravity and viscous friction tend to modify this shape. The aspiration of vesicles bounded by a fluid lipid membrane through micropipette techniques induces significant changes of curvature in the entrance of the pipette: a correct description of the induced geometry requires a modification of Laplace's law by the introduction of adhesion and curvature energies.

3.5 Henry's law and Raoult's law of chemical equilibrium between a liquid and a gas

Consider first a mixture of gases in a volume $V_{\rm G}$. Each gas occupies the *total* volume $V_{\rm G}$. Let us consider the gas noted g with $N_{\rm gG}$ moles, and let $N_{\rm G}$ be the total number of moles of gas in the volume $V_{\rm G}$. According to **Dalton's law**, each gas of the mixture contributes additively to the total gas pressure. The contribution $p_{\rm gG}$ of gas g, referred to as partial pressure, to the total pressure $p_{\rm G}$ is proportional to its molar fraction $x_{\rm gG}=N_{\rm gG}/N_{\rm G}$,

$$p_{\rm gG} = x_{\rm gG}\,p_{\rm G}\,. \tag{3.5.1}$$

For example, the molar fraction of oxygen in air is about 21% so that, under standard conditions, the pressure of oxygen is 0.21 atmosphere$\sim$160 mmHg.

Now let us consider the above gas mixture in equilibrium with a liquid phase L that contains the gas in dissolved form. Let $x_{\rm gL}=N_{\rm gL}/N_{\rm L}$ be the molar fraction of dissolved gas and $c_{\rm gL}=N_{\rm gL}/V_{\rm L}$ its concentration.

Henry's law sketched in Fig. 3.5.1 states that, at low gas solute molar fraction (less than 0.03), the molar fraction and concentration of the dissolved gas are proportional to its partial pressure in the gas phase and the gas concentrations in the liquid and gas phase are proportional,

$$x_{\rm gL} = H_{gx}\,p_{\rm gG},\quad c_{\rm gL} = H_{\rm gc}\,p_{\rm gG} = H_{gcc}\,c_{\rm gG}\,. \tag{3.5.2}$$

Here H_{gx} [unit : Pa^{-1}], $H_{\rm gc}=H_{gx}/\widehat{v}_{\rm L}$ [unit : mole/m^3/Pa] and $H_{gcc}=RT\,H_{\rm gc}$ [unit : 1] are Henry's coefficients for this gas and this liquid and $\widehat{v}_{\rm L}$ is the molar volume of the liquid, i.e., 18 cm^3/mole for water. At 25 °C, Henry's coefficient $H_{\rm gc}$ associated with the dissolution of oxygen in water is equal to 0.013 mmole/l/kPa=1.3×10^{-5} mole/m^3/Pa while it is more than 20 times higher for carbon dioxide, namely 0.34 mmole/l/kPa=34×10^{-5} mole/m^3/Pa. The associated coefficients H_{gcc} are thus equal to 0.032 and 0.83 respectively.

The partial pressure of carbon dioxide in carbonated drinks is high during bottling. When the can is opened, the gas pressure decreases and a great part of the dissolved gas is released. When the ascent of divers is too fast (larger

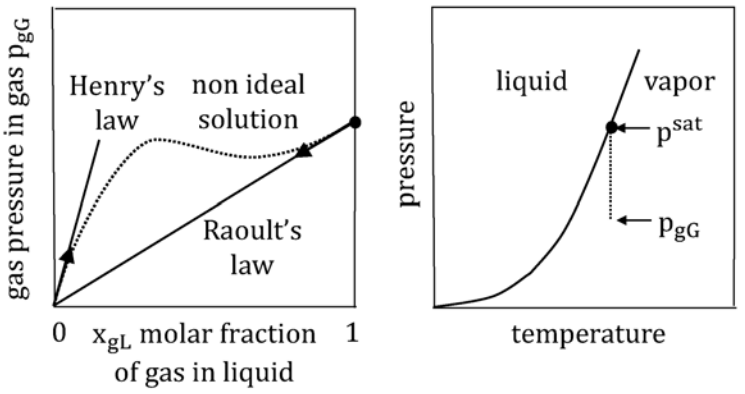

Fig. 3.5.1: At an interface between a gas phase and a liquid phase, the pressure differential is dictated by Laplace's law. At low value, the molar fraction of gas dissolved in the liquid follows Henry's law. At high value, according to Raoult's law, it is equal to the ratio of the pressure of the gas component in the gas phase divided by its saturating value.

than the popular 10 m per minute), bubbles of nitrogen, coming from the air that they breathe, form in their blood and can not vaporize. In fact, with $H_{gc} = 0.60 \times 10^{-5}$ mole/m^3/Pa Henry's coefficient for nitrogen dissolution in water/blood at 25 °C, the concentration of dissolved nitrogen decreases from 5.5 mM at a depth of 100 m to 0.48 mM at sea level, where the partial pressure of nitrogen is equal to 0.80 atmospheric pressure.

Henry's coefficient decreases with temperature: boiled water tastes 'flat' as it has lost its oxygen gas. The coefficient is roughly halved from 0 °C to 40 °C. Around $T_0 = 273.15$ K, the decrease is described by the analytic formula $H_{gx}(T) = H_{gx}(T_0)\exp(\beta\,(T^{-1} - T_0^{-1})$ with β equal to 1700 K for oxygen and 2400 K for carbon dioxide. In fact, the exponent β may be seen as linked to the change of enthalpy of the solution, $\beta = -(h_{gL} - h_{gG})/R = d\mathrm{Ln}\, H_{gx}(T)/d(1/T)$. For most gases, this exponent is positive, the enthalpy change during dissolution is negative and the reaction is exothermic.

Since H_{gc} is the nb of moles of gas per unit gas pressure (in the gas phase) per unit volume of liquid, and the molar volume of gas is equal to RT/p_{gG}, the volume of the gas at the pressure p_{gG} that is dissolved in the volume V_L of liquid is equal to

$$V_{\mathrm{g}}^{\mathrm{dissolved}} = H_{gc} \times RT/p_{\mathrm{gG}} \times p_{\mathrm{gG}} \times V_L = H_{gcc} \times V_{\mathrm{L}}\,. \tag{3.5.3}$$

At $T = 25$ °C, $RT = 8.3145 \times 298 = 2477$ J/mole and therefore $H_{gcc} = 2477 \times 1.3 \times 10^{-5} = 0.00322$ for oxygen dissolution in water. Therefore, about 16.1 ml of oxygen is dissolved in the 5 l of blood of the human body. This quantity is far from being sufficient to ensure survival as the human consumption of oxygen is about 250 ml per second. In fact, Section 15.11.1 highlights the fact that most of oxygen is transported by blood through devoted carriers, namely the red blood cells.

Raoult's law states that, even at high gas concentration, the partial gas pressure in the gas phase is proportional to the molar fraction of the dissolved gas times the saturating gas pressure,

$$p_{\mathrm{gG}} = x_{\mathrm{gL}}\, p^{\mathrm{sat}}\,. \tag{3.5.4}$$

Except for special ideal mixtures, Henry's law applies to low concentrations and Raoult's law to high concentrations so that H_{gx} is in general not the inverse of the saturating pressure $p^{\mathrm{sat}}(T)$. Henry's law provides an approximation of the real behavior of the solute while Raoult's law provides an approximation of the real behavior of the solvent.

For a more thorough thermodynamic treatment of adsorption of gases to a solid, the reader is directed to Smith, van Ness and Abbott [1996], p. 545.

3.6 Composition of fluids in plasma, interstitium, cell

Blood participates in

- the transport of gases, oxygen and carbon dioxide, nutrients, metabolic substances, vitamins, etc.;
- the transport of heat;
- the transport of signals, like hormones;
- maintaining a constant pH by providing a large buffer capacity;
- the defense of the body via plasma proteins.

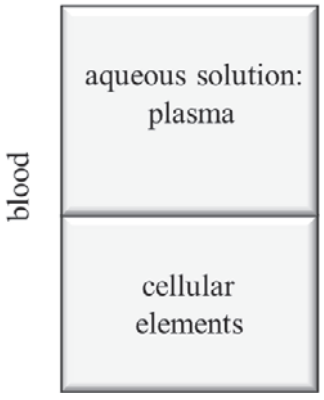

Fig. 3.6.1: Composition of blood, APB [1999], p. 261.
- Plasma proteins 60-80 g/l:
  albumin 45 g/l, α_1-, α_2-, β-, γ-globulins
- Serum = plasma - clotting factors (e.g., fibrinogen)
- Hematocrit = cellular elements/blood 45% vol.
- Cellular elements:
  - Erythrocytes (red blood cells, anucleated in blood)
  - Leukocytes (white blood cells):
    monocytes 6%, lymphocytes 27%, granulocytes 67%
  - Thrombocytes (platelets, anucleated)

Fig. 3.6.1 indicates that the aqueous part of blood, also called *plasma*, occupies about 55% of its volume. Plasma is obtained by centrifugation. Plasma contains water within which are dissolved charged proteins, neutral species (glucose, urea, etc.) and metallic ions. The composition of plasma, interstitium and cell are compared in Fig. 3.6.2.

The total concentration of plasma proteins is about 60 to 80 g/l. Albumin is the plasma protein with the largest concentration, Tables 3.6.1 and 3.6.2. The plasma proteins participate to the defense of the body, define the oncotic pressure, help in the transport of substances which are not soluble in water, and interact with drugs. Note that, for

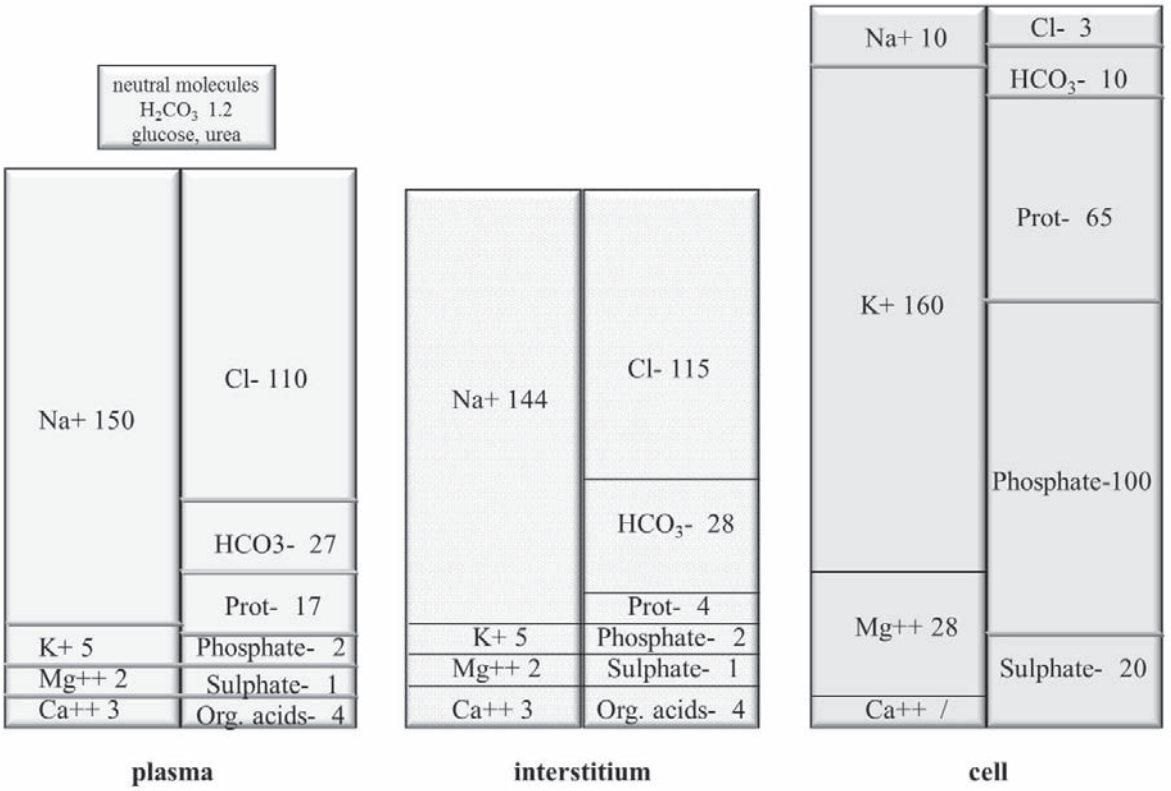

Fig. 3.6.2: Molar concentration [unit : mmole/l] in plasma, interstitium and cells, based on APP [2000], p. 65. Note that the calcium concentration depends on the cell type: even if it plays a major role in excitable cells (muscles), its concentration is tiny in the cytoplasm (10^{-7} mole/l) and it is stored in the sarcoplasmic reticulum (10^{-3} mole/l). Fung [1990], p. 276, gives similar information for the extravascular, extracellular and intracellular fluids of skeletal muscle cell and the normal blood plasma.

charged macromolecules, the entity that matters is not the concentration, but the effective concentration, that is the concentration times the electrical charge.

The concentrations of immunoglobulins which are γ-globulins are very low at birth, except that of IgG, which is easily transmitted by the mother, and after birth, by her milk.

Table 3.6.1: Some plasmic proteins.

Protein	g/l H_2O
Albumin	35-45
α_1-globulins	2.5
α_2-globulins	5
β-globulins	7.5
γ-globulins	10

Table 3.6.2: Immunoglobulins $\in \gamma$-globulins.

Protein	g/l H_2O
IgA	2.25
IgD	0.03
IgE	0.0002
IgG	11.00
IgM	1.150

To alleviate the low concentration of dissolved oxygen and carbon dioxide in blood, nature has created specific transporters dedicated to the transport of these gases. Indeed, erythrocytes are mainly aimed at transporting oxygen and carbon dioxide between lungs and tissues. They link the gases via an enzyme, the carbonic anhydrase, and a buffer, the hemoglobin.

Erythrocytes, usually called red blood cells, are disk-shaped of dimensions about $7.5\,\mu m \times 2\,\mu m$. They can diffuse through small capillaries and reach the interstitium. Their formation in the bone marrow is controlled by a hormone, the erythropoietin, and by the oxygen concentration of blood. While they have a nucleus during their formation, they become anucleated when circulating in blood.

The leukocytes participate to the immune defense of the body by secreting immunoglobulins : monocytes and granulocytes are involved in the non specific defense while lymphocytes address specific defense. Immunoglobulins are called *antibodies* while the foreign particles on the receptors of which they can fix are called *antigens* ($\equiv$ *anti*body *gen*erators).

Thrombocytes participate to hemostasis, a phenomenon by which a possible damage of the endothelium of blood vessels can be controlled quickly.

Chapter 4

Multi-species mixtures as thermodynamically open systems

4.1 The thermodynamically open system

Within a mixture, each species may in principle exchange mass, momentum and energy with the other species: these exchanges are referred to as (internal) *transfers*. Here, the mixture is viewed as a thermodynamically *open* system. Indeed, each point in the mixture or at the boundary may also exchange mass, momentum and energy directly with the surroundings: the latter exchanges correspond to *growth* processes. These ideas are sketched in Fig. 4.1.1 which is inspired by the model developed for articular cartilages in Loret and Simões [2004] [2005]a.

The balance equations of mass, momentum, energy, entropy for each species and for the mixture as a whole, as well as the dissipation inequality, need to be reviewed. This chapter proposes a general framework which serves as a repository where the various forms of these equations are exposed in view of their use in the subsequent chapters.

Various forms of energy can be exchanged between a tissue and its surroundings. Irradiation is known to increase the collagen content and also to decrease the permeability [Znati et al. 2003]. Recent fabrication methods of tissues have used external sources of heat or of light. Heat may be used for *in vitro* prefabrication: the temperature of the construct is elevated above its glass value and pressure is applied to assemble parts in a desired pattern. Light energy might be used under physiological temperature and pH in various techniques, e.g., photopolymerization, photocrosslinking, stereolithography. The energy radiated usually by ultraviolet frequencies is absorbed by the chromophore of a photolabile compound. The latter initiates next a series of reactions. *Photopolymerization* concerns discrete chains of polymers while *photocrosslinking* addesses a polymer network. Much effort has been devoted to form hydrogels by photopolymerization, e.g., the hydrophilic polyethylene glycol (PEG), and hard tissues for dental and orthopedic applications. The idea is to inject the compound in a soluble form and to turn it insoluble by photopolymerization. The compound may be a biodegradable scaffold used to help cell proliferation or to heal leaking tissues after surgery. As another use of light, radiation of an encapsulated gel in a damaged cartilage has been shown to excite extracellular matrix production, Elisseeff et al. [1999]. Thus light may be used for triggering both growth and structuration (crosslinking).

4.2 Chemomechanical behavior and growth of soft tissues

The developments presented here are intended to be used in a multi-phase multi-species mixture. Species can be solid particles, fluids, ions or macromolecules. However, at this stage, the separation of *species*, also referred to as *constituents*[4.1], into *phases* is not addressed. All species are considered here on an equal foot, except the solid skeleton which plays a special role. Tacitly, a chemical present in n phases will thus be modeled by n species.

For indications on species segregation into phases, the interested reader may consult Loret et al. [2004]a where the examples of chemically sensitive heteroionic clays and of articular cartilages are compared. Within phases, species

[4.1] The terms "species" and "constituent" are used almost interchangeably. Still, while the term "species" is generic, we may occasionally refer to the "solid constituent" and to the "fluid constituent" to contrast these species from species like salts, ions or macromolecules that diffuse in water.

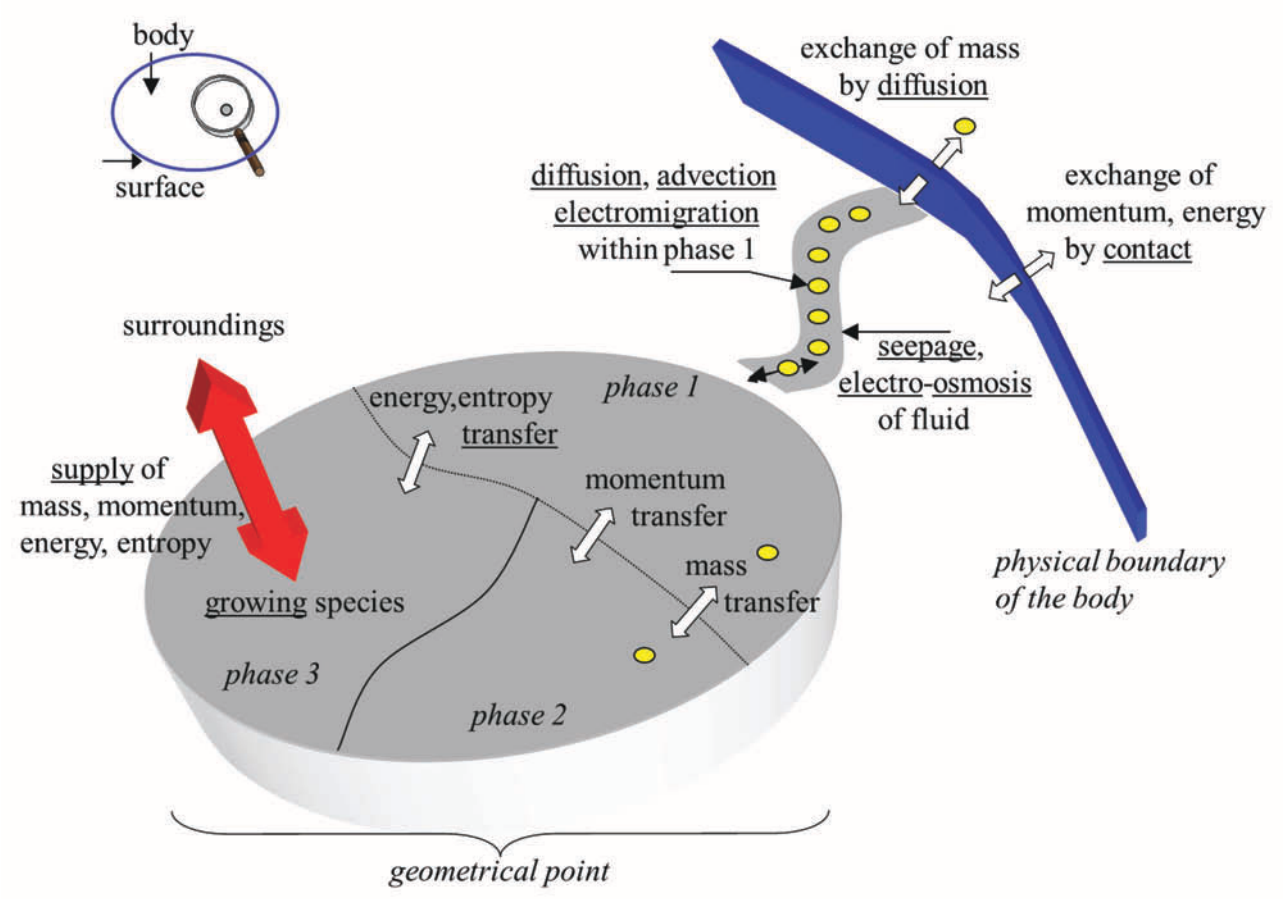

Fig. 4.1.1: Sketch of the exchanges that are accounted for in the multi-species multi-phase open system. For illustration, we have assumed that, at any geometrical point, the species can be segregated in three phases. (1) *Exchanges at the boundary.* Exchanges of various natures can take place at the boundary of the mixture. These exchanges affect only the species of phase 1, which is viewed as a fluid phase, that communicates with the exterior of the mixture. (2) *Transports.* Species of phase 1, are transported to, and from, the boundary by diffusion, advection, and electromigration, while the fluid itself flows through the solid skeleton by seepage and electroosmosis. (3) *Transfers.* Phases can exchange mass, momentum and energy. These exchanges are termed transfers. The characteristics of each exchange depend on both the concerned species (its molar mass, steric characteristics, electrical charge) and of the properties of the real or artificial membranes that separate the phases. Thus, typically, macromolecules are associated with a large transfer time. An infinite transfer time implies impermeability. A certain hierarchy of exchanges may be implied by considering that species of phase 2 that leave their phase have to transfer to phase 1: thus phase 2 can not be controlled directly from the boundary. (4) *Growth in an open system.* If, in addition, the system is thermodynamically open, supply and/or removal, directly from the surroundings, of mass, momentum and energy can take place at each geometrical point: these exchanges are referred to as growth processes. Interest is on the growth of the extracellular matrix, that is, essentially of collagen and proteoglycans.

diffuse. Across phases, they undergo a physico-chemical reaction, also termed mass transfer. Mass transfer can be viewed as a way for the tissue to adapt to mechanical and chemical loadings by modifying the internal repartition of its species.

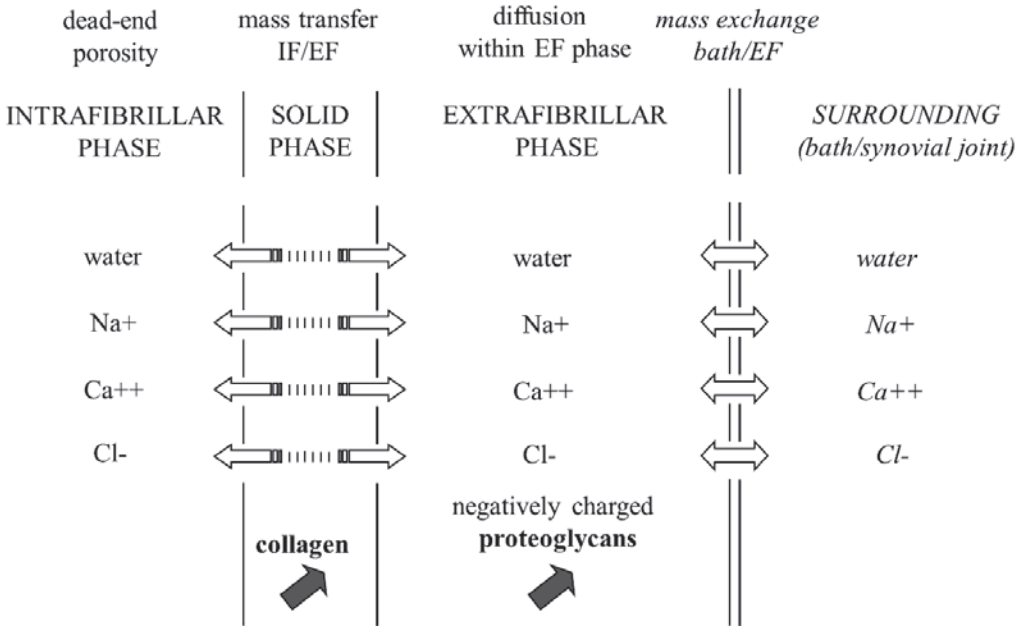

Fig. 4.2.1: An example of multi-phase multi-species biological material [Loret and Simões 2004, 2005]a. Any geometrical point, or representative elementary volume, of articular cartilage is partitioned in three phases: one solid phase and two fluid phases. Each fluid phase contains several species. Some of these species are mobile, at least partially: water and ions can enter and leave the intrafibrillar space defined by collagen fibrils. Proteoglycans which are macromolecules are too large to be admitted into that space, at least in absence of osteoarthritis. Water and ions can also be exchanged between the extrafibrillar phase and the exterior. Within their phase, extrafibrillar species *diffuse*. Across phases, species *transfer*. Mass transfer amounts to a physico-chemical reaction. While the mass transfer mechanism can be seen as a macroscopic mechanism, a zoom over the interface would show that it results from the upscaling of diffusion micromechanisms that take place at lower spatial scales. The modeling of growth (solid arrows) considers that the growing species, namely collagen and proteoglycans, are contributed directly by the surroundings. More generally, mass transfer within the mixture can contribute to growth as well.

In order to fix the ideas, the definition of phases in articular cartilages adopted by Loret and Simões [2004] [2005]a is shown in Fig. 4.2.1. The set of species in the solid phase is denoted by $\mathcal{S}$. The set of species that grow, e.g., collagen and proteoglycans in an articular cartilage, is denoted by $\mathcal{S}^*$. Some species which move with the collagen are not part of the solid phase, e.g., species of the intrafibrillar space: the set of all species which move with the velocity of the collagen is denoted by $\mathcal{S}^{**}$, so that $\mathcal{S} \subset \mathcal{S}^* \subset \mathcal{S}^{**}$.

Moreover, the set of all species is denoted by $\mathcal{K}$. The complements in $\mathcal{K}$ of the sets $\mathcal{S}^*$ and $\mathcal{S}^{**}$ are denoted by $\mathcal{K}^*$ and $\mathcal{K}^{**}$, and thus

$$\underbrace{\mathcal{K}}_{\substack{\text{complete}\\ \text{mixture}}} = \mathcal{K}^* + \underbrace{\mathcal{S}^*}_{\substack{\text{species}\\ \text{that grow}}} = \underbrace{\mathcal{K}^{**}}_{\substack{\text{species}\\ \text{that flow through}\\ \text{or diffuse wrt fluid phase}}} + \underbrace{\mathcal{S}^{**}}_{\substack{\text{species}\\ \text{that move}\\ \text{with the solid}}} . \tag{4.2.1}$$

The motivations for the developments below can be better appreciated if placed in a more general project:
(1) We have in mind to provide the thermodynamic arguments that have led to the modeling of multi-phase multi-species articular cartilages which accounts for deformation (chemomechanical couplings), mass transfer, momentum transfer, that generates generalized diffusion, as well as cation interaction. Constitutive equations are developed and

tested along equilibrium paths and in transient situations in the form of initial and boundary value problems solved either through analytical techniques or through the finite element method.

(2) An additional physical phenomenon is introduced, namely *growth*. This enlargement has two main consequences with respect to the previous model developments in Loret and Simões [2004] [2005]a:

(2.1) first, the system considered is *open*: the surroundings may contribute to the balance equations of mass, momentum, energy and entropy;

(2.2) as a second fundamental modification, the strain is decomposed into a growth component and an elastic (accommodating) component and the mechanical constitutive equations are based on the elastic part of the strain only, much like in elastoplasticity.

(3) Balance equations in the multi-species mixture context account for internal transfers across phases, and external contributions in terms of mass, momentum, energy and entropy. All four types of interactions have been considered within closed systems. As for open systems, most applications consider that they are open with respect to mass only. The external energy contributions are more seldom accounted for, with exceptions like Klisch and Hoger [2003], Lubarda and Hoger [2002]. In their pioneering continuum model of bone remodeling, Cowin and Hegedus [1976] describe a two species mixture that is open with respect to the momentum only. On the other hand, they view the bone matrix as another smaller system, open to the four types of interactions above, and they require balance and constitutive equations for this species only. By contrast, we will not view species as open systems with respect to other species. Species interact with the rest of the mixture via *transfer*. The whole mixture, and consequently each species, is open with respect to the surroundings and we generically refer to these latter interactions as *growth*. The constitutive equations that control the two phenomena are quite distinct.

(4) The constitutive equations of growth are restricted by the thermodynamic framework and indeed satisfaction of the dissipation inequality by growth motivates the structure of these equations.

(5) Four mechanisms of distinct physical natures are delineated to contribute to the dissipation inequality and therefore enforced to be positive individually. This segregation of the sources of dissipation simplifies the analysis and leads to specific relations, namely

(5.1) chemomechanical hyperelastic relations;

(5.2) coupled generalized diffusion including Darcy's law of seepage through the porous medium, Fick's law of diffusion of ions in water, Ohm's law of electrical flow, Fourier's law of thermal diffusion, electroosmosis, etc.;

(5.3) mass transfer of ions and water across fluid phases;

(5.4) growth in a multi-phase multi-species context where each species is able to evolve according to its own growth rate.

In a sense, the thermodynamic analysis is just an extension of the classical papers on mixtures by Truesdell and Toupin [1960], de Groot and Mazur [1962], Eringen and Ingram [1965], Atkin and Craine [1975], Bowen [1976], Truesdell [1984], Haase [1990]. They do not consider growth, while we precisely need to concentrate on the contributions by the surroundings in all the balance equations.

(6) The analysis is performed along Biot's [1973] point of view where the deformable solid plays a special role.

As an example, consider structuration of a tissue during the growth process. The phenomenon is governed by rate equations that involve mechanics and growth, that is, where mechanics and growth are the stimuli. In addition, chemical variables, indicating the concentrations of nutrients, cytokines and growth factors, may moderate or enhance the intensity of the process. At a later stage of the lifespan of the tissue, glycation induced stiffening of the cornea and annulus fibrosus provides a further example of chemomechanical coupling. The concentrations, or rather the mass contents, should be part of the state variables that define the chemomechanical state. Chemical fluxes have to be defined by generalized diffusion equations, to ensure that, in a boundary value problem, the local chemical content can be obtained by solving the field equations of mass balance.

Couplings versus interdependences

The segregation of the sources of dissipation is part of the framework that is developed. Attention should be paid to the fact this *segregation*, which we will avoid to term *decoupling*, does by no means imply that the four physical mechanisms *do not interact*, in the sense that they could for example be solved in independent initial and boundary value problems. For example, mechanics influences the actual diffusion processes via deformation since it is known that the hydraulic conductivity depends on the void space through which fluid can flow. These *interactions*, or *interdependences*, between the four physical mechanisms and the direct *couplings* that take place within each of these mechanisms as indicated in point (5.2) are distinct from a hierarchical point of view. They also differ from a formal point of view: indeed the couplings connect a set of rate equations associated with a set of driving forces.

4.3 General form of balance equations

In the standard approach to mixtures, the volume considered is the total volume of the mixture, the motion is described by the barycentric velocity $\mathbf{v}$ and by the associated deformation gradient. In Biot's approach, the solid skeleton is paid a special attention, and species are viewed as flowing through the solid skeleton. The volume considered is the volume V of the solid skeleton, the motion of a point $\mathbf{x}$ of the solid is described by the velocity $\mathbf{v}_s$ and by the associated deformation gradient $\mathbf{F}$ with velocity gradient $\mathbf{L} = (d\mathbf{F}/dt)\cdot\mathbf{F}^{-1}$, $d(\cdot)/dt$ denoting the time derivative following the solid particles.

Entities and operators reckoned from the reference configuration are underlined. The motion is considered to bring the point $\underline{\mathbf{x}} = (\underline{x}_i)$ in the reference configuration to its current position $\mathbf{x} = (x_i) = \mathbf{x}(\underline{\mathbf{x}}, t)$ at time t. Differential operators are reckoned from either configuration. For example, for a generic entity Ψ, the gradient with respect to the current configuration $\boldsymbol{\nabla}\Psi = \partial\Psi/\partial\mathbf{x}$ becomes $\underline{\boldsymbol{\nabla}}\Psi = \partial\Psi/\partial\underline{\mathbf{x}} = \boldsymbol{\nabla}\Psi\cdot\mathbf{F}$ with respect to the reference configuration.

Notation: in this chapter, unless stated otherwise, the convention of summation over the repeated index k which represents species of the mixture does *not* apply.

4.3.1 Partial, apparent and intrinsic properties

A generic species is denoted routinely by the index k. Some properties of the species refer either to the volume of the species or to the volume of the mixture. They are termed

- *intrinsic* when they refer to the volume or mass of the species;
- *partial* or *apparent*, when they refer to the volume or mass of the mixture.

The first situation is denoted by a **subscript** and the second one by a **superscript**. Key instances include

- the apparent mass density $\rho^k = n^k\,\rho_k$ versus the intrinsic mass density ρ_k;
- the partial stress $\boldsymbol{\sigma}^k = n^k\,\boldsymbol{\sigma}_k$ versus the intrinsic stress $\boldsymbol{\sigma}_k$;
- the thermodynamic functions, e.g., the internal energy per unit mass u_k versus the internal energy per unit volume of the mixture $U^k = \rho^k\,u_k$.

Apparent and intrinsic entities are linked by the volume fraction n^k defined below.

4.3.2 Mass, geometry and kinematical descriptors

At any point $\mathbf{x}$ of the porous medium, the present macroscopic approach endows the species k of mass M_k and volume V_k with properties like its absolute velocity $\mathbf{v}_k$, its volume fraction n^k, its *intrinsic* density ρ_k and its *partial* (or *apparent*) density ρ^k:

$$n^k = \frac{V_k}{V}\,; \quad \rho_k = \frac{M_k}{V_k}\,; \quad \rho^k = \frac{M_k}{V} = n^k\,\rho_k\,. \tag{4.3.1}$$

The lineal, areal and volume fractions are usually assumed to be equal, see e.g., Biot [1955], his Eqn (2.2), while the strict equality holds only when the species are distributed randomly. This assumption may be questionable for anisotropic materials in which the directional distribution of voids is not expected to be random. Oda et al. [1985] have attempted to characterize this directional distribution through a fabric tensor.

Therefore the mass flux per unit current area through the solid can be defined via the apparent mass density,

$$\mathbf{M}_k = \rho^k\,(\mathbf{v}_k - \mathbf{v}_s), \quad k \in \mathcal{K}\,. \tag{4.3.2}$$

By pure formalism, we also define $\mathbf{M}_s = \mathbf{0}$ so that summations that include the fluxes can be taken over all species $\mathcal{K}$ or only over species flowing through the solid $k = s$.

For any species $k \in \mathcal{K}$, we should distinguish the *filtration velocity* with respect to the solid which is involved in Darcy's law of seepage from the *diffusion velocity* with respect to the fluid phase that comes into the picture in Fick's law of diffusion, and from the *barycentric filtration velocity* with respect to the mass center,

$$\underbrace{\mathbf{v}_k - \mathbf{v}_s}_{\text{filtration velocity}} \quad ; \quad \underbrace{\mathbf{v}_k - \mathbf{v}_w}_{\text{diffusion velocity}} \quad ; \quad \underbrace{\overset{(b)}{\mathbf{v}}_k = \mathbf{v}_k - \mathbf{v}}_{\substack{\text{barycentric}\\ \text{filtration velocity}}} \quad . \tag{4.3.3}$$

To the mixture as a whole are attached entities like its density ρ, its barycentric velocity $\mathbf{v}$ and its barycentric body force $\mathbf{b}$, namely,

$$\rho = \sum_{k\in\mathcal{K}} \rho^k \,, \quad \rho\,\mathbf{v} = \sum_{k\in\mathcal{K}} \rho^k\,\mathbf{v}_k \,, \quad \rho\,\mathbf{b} = \sum_{k\in\mathcal{K}} \rho^k\,\mathbf{b}_k \;\;, \tag{4.3.4}$$

and therefore the barycentric filtration velocities satisfy the closure relation,

$$\sum_{k\in\mathcal{K}} \rho^k \overset{(b)}{\mathbf{v}}_k = \mathbf{0}\,. \tag{4.3.5}$$

Given a property of a species, there are different ways to define the property associated with the mixture as a whole. One way is by simple summation. A second way is by mass averaging, e.g., the barycentric velocity above and the body force per unit mass, Eqn (4.3.4). A third way is by volume averaging, e.g., Eqn (4.5.8) below for the stress. The property obtained by (weighted or unweighted) summation over species is sometimes called the *inner part* of the property in question, e.g., Eqn (4.5.8). In general, an *overall*, or global, property of the mixture as a whole may have to be defined through more involved procedures than simple averaging rules, e.g., the total stress of the mixture defined by Eqn (4.5.7). In fact the definition of overall, or global, properties is addressed in different ways in different theories of mixtures.

Finally, we have to reiterate the following convention stated in Section 2.6. Certain properties Ψ of the mixture as a whole are measured per unit (current or reference) volume, while the corresponding properties ψ_k attached to the species $k \in \mathcal{K}$ are measured per unit mass. Instances are internal energy, enthalpy, entropy, etc. For these entities, the property at the level of the mixture is defined *not* by $\rho\,\psi = \sum_{k\in\mathcal{K}} \rho^k\,\psi_k$ *but* by $\Psi = \sum_{k\in\mathcal{K}} \rho^k\,\psi_k$.

4.3.3 Integral and local balance equations

The generalized Reynolds theorem of Section 2.7.1 states that the rate of change of an integral is equal to the rate of change as if the volume was moving with the solid velocity to which should be added the contributions in terms of fluxes of the individual species through the solid surface. The solid being taken as control, Reynolds theorem, applied to the generic field $\Psi_k = \Psi_k(\mathbf{x}, t)$, $k \in \mathcal{K}$, can be cast in the format,

$$\begin{aligned} \frac{d}{dt}\int_V \Psi_k\; dV &= \int_V \frac{\partial \Psi_k}{\partial t}\; dV + \int_{\partial V} \Psi_k\,\mathbf{v}_k \cdot d\mathbf{S} \\ &= \int_V \frac{d\Psi_k}{dt} + \Psi_k \operatorname{div}\mathbf{v}_s + \operatorname{div}\left(\frac{\Psi_k}{\rho^k}\,\mathbf{M}_k\right)\; dV\,. \end{aligned} \tag{4.3.6}$$

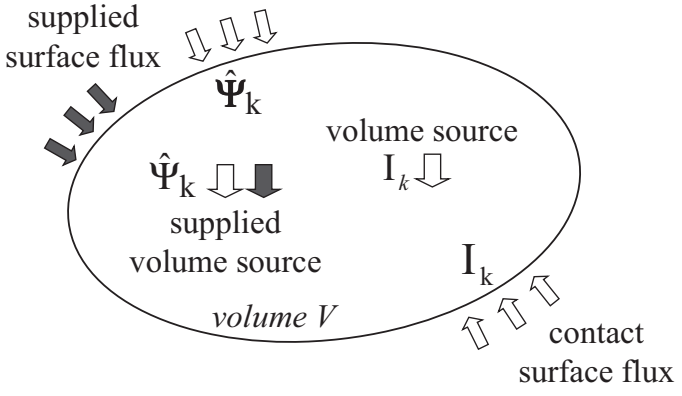

Fig. 4.3.1: The rate of change of an arbitrary function is generically set equal to the sum of two volume and two surface integrals. One set of integrals is standard while the other set represents supplies, which will be further split into internal transfers and external contributions.

This rate of change is generically set to the sum of two volume and two surface integrals, Fig. 4.3.1,

$$\frac{d}{dt}\int_V \Psi_k\; dV = \int_V I_k\; dV + \int_{\partial V} \mathbf{I}_k \cdot d\mathbf{S} + \int_V \hat{\Psi}_k\; dV + \int_{\partial V} \hat{\mathbf{\Psi}}_k \cdot d\mathbf{S}\,, \tag{4.3.7}$$

with

$\Psi_k = \Psi_k(\mathbf{x}, t)$	generic field;
$I_k = I_k(\mathbf{x}, t)$	a volume source per unit current volume;
$\mathbf{I}_k = \mathbf{I}_k(\mathbf{x}, t)$	a surface source (flux) per unit current area;
$\hat{\Psi}_k = \hat{\Psi}_k(\mathbf{x}, t)$	a volume source due to a mass transferred between phases within the mixture, and/or to a mass which is deposited in a growth process;
$\hat{\mathbf{\Psi}}_k = \hat{\mathbf{\Psi}}_k(\mathbf{x}, t)$	a surface source (flux) per unit current area contributed by the rest of the mixture and/or the surroundings.

Thus the overall contribution per unit current volume by the surroundings to the growth process sums to,

$$\sum_{k \in \mathcal{K}} \hat{\Psi}_k + \operatorname{div} \hat{\mathbf{\Psi}}_k = \hat{\Psi} \,. \tag{4.3.8}$$

In other words, $\hat{\Psi}$ is an entity that characterizes growth: it vanishes in absence of growth, that is when only transfers between phases take place.

In general, the velocities and the generic fields considered may undergo discontinuities within the volume V. Eringen and Ingram [1965] present a general treatment of discontinuities, used for example by Jabbour and Bhattacharya [2003] for the modeling of thin film deposition. Here however no such *discontinuity surfaces* crossing the volume V are assumed to exist. Therefore the local form of the balance equation for the species k may be cast in the following format,

$$\frac{d\Psi_k}{dt} + \Psi_k \operatorname{div} \mathbf{v}_s + \operatorname{div} \left(\frac{\Psi_k}{\rho^k} \mathbf{M}_k \right) - \; I_k - \operatorname{div} \mathbf{I}_k = \hat{\Psi}_k + \operatorname{div} \hat{\mathbf{\Psi}}_k, \quad k \in \mathcal{K} \,. \tag{4.3.9}$$

This equation can be expressed in a format that involves the derivative following the species k,

$$\frac{d^k \Psi_k}{dt} + \Psi_k \operatorname{div} \mathbf{v}_k - \; I_k - \operatorname{div} \mathbf{I}_k = \hat{\Psi}_k + \operatorname{div} \hat{\mathbf{\Psi}}_k, \quad k \in \mathcal{K} \,, \tag{4.3.10}$$

associated with the global balance statement akin to the species $k \in \mathcal{K}$,

$$\frac{d^k}{dt} \int_V \Psi_k \; dV = \int_V I_k \; dV + \int_{\partial V} \mathbf{I}_k \cdot d\mathbf{S} + \int_V \hat{\Psi}_k \; dV + \int_{\partial V} \hat{\mathbf{\Psi}}_k \cdot d\mathbf{S} \,, \tag{4.3.11}$$

with

$$\frac{d^k}{dt} \int_V \Psi_k \; dV = \int_V \frac{d^k \Psi_k}{dt} + \Psi_k \operatorname{div} \mathbf{v}_k \; dV \,. \tag{4.3.12}$$

Passman and McTigue [1989] and Manoussaki [2003] have used a flux supply in the momentum balance. Kuhl and Steinmann [2003] introduce flux supplies of mass and entropy, Section 21.6.3.3. Elements of comparison between volume growth and surface growth in the context of bone growth are presented in Rouhi et al. [2004], as indicated in Note 21.1. In the following however, these flux supplies $\hat{\mathbf{\Psi}}_k$, $k \in \mathcal{K}$, will be neglected to the exception of Section 4.5.4.

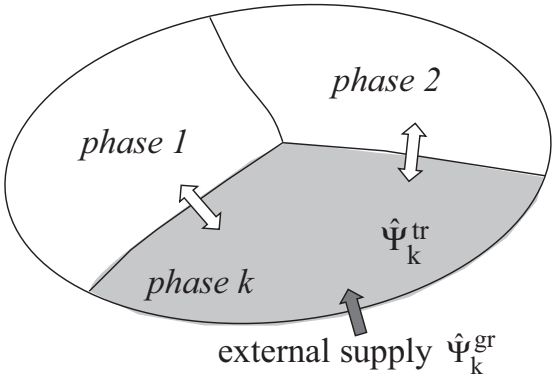

Fig. 4.3.2: Supplies to a phase k are split into internal transfers and external contributions.

As sketched in Fig. 4.3.2, the total volume supply to an individual species k,

$$\hat{\Psi}_k = \hat{\Psi}_k^{\rm tr} \; + \; \hat{\Psi}_k^{\rm gr}, \tag{4.3.13}$$

is contributed by (internal) transfers which are balanced per se, while external contributions contribute to growth (or resorption),

$$\sum_{k\in\mathcal{K}} \hat{\Psi}_k^{\rm tr} = 0, \qquad \sum_{k\in\mathcal{K}} \hat{\Psi}_k = \sum_{k\in\mathcal{K}} \hat{\Psi}_k^{\rm gr} \; \begin{cases} \hat{\Psi} \neq 0 & \text{growth or resorption,} \\ = 0 & \text{closed system.} \end{cases} \tag{4.3.14}$$

The transport relations established in Section 2.6 assume a pure change of configuration at constant mass. For growth processes in a mixture context, the evolution of mass is a central issue and it is important to delineate the following situations:

- if no mass transfer nor growth takes place, the mass of each species and the mass of the mixture are conserved;
- if there are mass transfers within the mixture, then the mass of each species is *not* conserved while the mass of the mixture does;
- if growth, or degradation, takes place, then neither the masses of the species nor the mass of the mixture are conserved.

The above considerations may be summarized in the invariance relations, for a species $k \in \mathcal{K}$, or for the mixture as whole,

$$M_k = \rho^k \, V = m^k \, \underline{V} \; \begin{cases} = \underline{M}_k = \underline{\rho}^k \, \underline{V} & \text{no transfer nor growth;} \\ \neq \underline{M}_k & \text{transfer or growth.} \end{cases} \tag{4.3.15}$$

The balance equation (4.3.9) can now be expressed in the reference configuration. Multiplying (4.3.9) by $\det \mathbf{F}$, using the transport relations (2.6.20) for the scalars I_k, Ψ_k, and $\hat{\Psi}_k$,

$$(\cdot) \quad \rightarrow \quad \underline{(\cdot)} = \det \mathbf{F} \, (\cdot),$$

and (2.6.13) for the vectors $\mathbf{I}_k$, $\mathbf{M}_k$ and $\hat{\mathbf{\Psi}}_k$,

$$(\cdot) \quad \rightarrow \quad \underline{(\cdot)} = \det \mathbf{F} \, \mathbf{F}^{-1}(\cdot),$$

and the rate relations (2.6.14) and (2.7.2), the local balance equation becomes in the reference configuration,

$$\frac{d\underline{\Psi}_k}{dt} + \underline{\rm div} \, \big(\frac{\underline{\Psi}_k}{m^k} \, \underline{\mathbf{M}}_k \big) - \; \underline{I}_k - \underline{\rm div} \, \underline{\mathbf{I}}_k = \underline{\hat{\Psi}}_k + \underline{\rm div} \, \underline{\hat{\mathbf{\Psi}}}_k, \quad k \in \mathcal{K}. \tag{4.3.16}$$

The generic relations listed in this section are applied in turn to the balances of mass, momentum, energy and entropy.

4.4 Balance of mass

The equations of balance of mass are stated in turn for the species and for the mixture. The phenomena of diffusion, mass transfer and growth are segregated subsequently. The kinematics of growth for the species in $\mathcal{S}^*$ susceptible of growth is deferred to the Section 21.3.4.

4.4.1 Balance of mass for species

The balance of mass for the species k is obtained by setting,

$$\underbrace{\Psi_k = \rho^k}_{\substack{\text{partial} \\ \text{mass density}}} \; , \quad I_k = 0, \quad \mathbf{I}_k = \mathbf{0}, \qquad \underbrace{\hat{\Psi}_k = \hat{\rho}^k}_{\substack{\text{rate of} \\ \text{volume supply}}} \; , \qquad \underbrace{\hat{\mathbf{\Psi}}_k = \mathbf{0}}_{\substack{\text{rate of} \\ \text{surface supply}}} \; . \tag{4.4.1}$$

The rate of mass supply $\hat{\rho}^k$ to the species $k \in \mathcal{K}$,

$$\underbrace{\hat{\rho}^k}_{\substack{\text{total rate} \\ \text{of mass supply}}} \; = \; \underbrace{\hat{\rho}^k_{\rm tr}}_{\substack{\text{internal supply} \\ \text{due to transfer}}} \; + \; \underbrace{\hat{\rho}^k_{\rm gr}}_{\substack{\text{external supply} \\ \text{due to growth}}} \; , \tag{4.4.2}$$

includes two contributions, namely

- the supply rate $\hat{\rho}^k_{\rm tr}$ by the rest of the mixture due to a *mass transfer*, which can be viewed as a physico-chemical reaction, and
- the supply rate $\hat{\rho}^k_{\rm gr}$ by the surroundings that participate to the growth process.

The contributions due to mass transfer sum to zero, while the total rate of mass supply due to growth does not vanish a priori,

$$\sum_{k\in\mathcal{K}} \hat{\rho}^k_{\rm tr} = 0\,, \quad \hat{\rho} \equiv \sum_{k\in\mathcal{K}} \hat{\rho}^k = \sum_{k\in\mathcal{K}} \hat{\rho}^k_{\rm gr}\,. \tag{4.4.3}$$

The rate of mass supply $\hat{\rho}^k$ is sometimes noted $\rho^k\,\hat{\rho}^k$, or $\rho\,\hat{\rho}^k$ by other authors.

The global balance of mass deduces from (4.3.11),

$$\frac{d^k}{dt}\int_V \rho^k\; dV = \int_V \hat{\rho}^k\; dV\,, \tag{4.4.4}$$

while Eqn (4.3.10) yields the local balance of mass in the current configuration,

$$\frac{d^k\rho^k}{dt} + \rho^k\,\mathrm{div}\,\mathbf{v}_k = \hat{\rho}^k, \quad k\in\mathcal{K}\,. \tag{4.4.5}$$

This local balance of mass can be used to obtain another form of the balance relation for the generic entity Ψ_k as,

$$\rho^k\,\frac{d^k}{dt}\Big(\frac{\Psi_k}{\rho^k}\Big) - \; I_k - \mathrm{div}\;\mathbf{I}_k = \hat{\Psi}_k + \mathrm{div}\,\hat{\mathbf{\Psi}}_k - \frac{\Psi_k}{\rho^k}\,\hat{\rho}^k, \quad k\in\mathcal{K}\,. \tag{4.4.6}$$

4.4.2 Balance of mass for the mixture

Let us sum (4.4.5) over species, using the definitions of overall density ρ and barycentric velocity $\mathbf{v}$, Eqn (4.3.4), the relation between the time derivatives (2.7.1) and the closure relations (4.4.3). Then the balance of mass of the whole mixture is seen to have the same format as that of a single body of density ρ, animated with the barycentric velocity $\mathbf{v}$, and endowed with the rate of mass supply $\hat{\rho}$,

$$\frac{D\rho}{Dt} + \rho\,\mathrm{div}\,\mathbf{v} = \hat{\rho}\,, \tag{4.4.7}$$

the barycentric time derivative $D(\cdot)/Dt$ being defined by (2.7.1).

4.4.3 Diffusion, mass transfer and growth

The following notations are introduced for the rates of mass supplies of the species and of the mixture

$$\hat{m}^k \equiv \hat{\rho}^k\,\det\mathbf{F}, \quad k\in\mathcal{K}; \quad \hat{m} \equiv \hat{\rho}\,\det\mathbf{F}\,. \tag{4.4.8}$$

With the mass flux defined by (4.3.2), insertion of (4.4.1) in (4.3.16) highlights the fact that the mass change is due to two physical phenomena namely flow, or filtration, of the species through the solid skeleton, and mass transfer or growth,

$$\frac{dm^k}{dt} = -\underline{\mathrm{div}}\;\underline{\mathbf{M}}_k + \hat{m}^k = \det\mathbf{F}\,(-\mathrm{div}\;\mathbf{M}_k + \hat{\rho}^k), \quad k\in\mathcal{K}\,. \tag{4.4.9}$$

The last relation is obtained via (2.6.14) and $(4.4.8)_1$.

Upon summation over *all* species, the rate of change of the mass content m of the mixture, Eqn (2.6.26), is seen to be due to fluxes on the boundary and to a growth contribution,

$$\frac{dm}{dt} = -\underline{\mathrm{div}}\Big(\sum_{k\in\mathcal{K}^{**}}\underline{\mathbf{M}}_k\Big) + \hat{m} = -\det\mathbf{F}\,\mathrm{div}\,\Big(\sum_{k\in\mathcal{K}^{**}}\mathbf{M}_k\Big) + \hat{\rho}\,\det\mathbf{F}\,. \tag{4.4.10}$$

The sum in Eqn (4.4.10) is restricted to the set $\mathcal{K}^{**}$ of species whose flux does not vanish a priori. Indeed, the analysis adopts the following assumption.

Assumption 4.1 : The species that grow move with the solid.

Then, the mass balances in terms of mass-contents, or masses, involve only the mass supplies. An explicit quantification of the rate of mass supply $\hat{\rho}^k$ is obtained in terms of the mass of the species $M_k = \rho^k V$, namely using the mass balance (4.4.9) and the rule of transformation of volumes,

$$\frac{\hat{\rho}^k}{\rho^k} = \frac{d}{dt}\mathrm{Ln}\, M_k \quad \Leftrightarrow \quad \frac{m^k(t)}{m^k(0)} = \frac{M_k(t)}{M_k(0)} = \exp\Big(\int_0^t \frac{\hat{\rho}^k}{\rho^k}\, d\tau\Big), \quad k \in \mathcal{S}^* . \tag{4.4.11}$$

A similar relation holds for the mass $M = \sum_{k\in\mathcal{K}} M_k = \rho V$ of the mixture: with ρ the overall density, Eqn (4.3.4), and $\hat{\rho}$ the rate of mass supply, Eqn (4.4.3),

$$\frac{\hat{\rho}}{\rho} = \frac{d}{dt}\mathrm{Ln}\, M \quad \Leftrightarrow \quad \frac{m(t)}{m(0)} = \frac{M(t)}{M(0)} = \exp\Big(\int_0^t \frac{\hat{\rho}}{\rho}\, d\tau\Big) . \tag{4.4.12}$$

Restrictions on the actual expression of the rate of mass supply may result from thermodynamic considerations. On another side, Drozdov and Khanina [1997] have suggested practical restrictions required to prevent the growth process to yield unexpected results. Indeed, they observed that a rate of mass supply depending linearly of the von Mises equivalent stress may lead to unbounded growth. A more general discussion on the dynamic behavior of the growth equation is presented in Hegedus and Cowin [1976]. In Chapters 22 and 23, bounded growth is achieved by allowing the homeostatic state to adapt.

4.5 Balance of momentum

The balance of momentum is considered, first for individual species and next for the mixture as a whole. The forms of the momentum supplies, of the interaction momenta and of the interaction stresses are commented.

4.5.1 Balance of momentum for species

The balance of momentum for the species $k \in \mathcal{K}$ is obtained by setting, Eringen and Ingram [1965],

$$\begin{aligned}
\Psi_k &= \underbrace{\rho^k \mathbf{v}_k}_{\text{momentum}} \\
I_k &= \underbrace{\rho^k \mathbf{b}_k}_{\text{body force}} \\
\mathbf{I}_k &= \underbrace{\boldsymbol{\sigma}^k}_{\text{partial stress}} \\
\hat{\Psi}_k &= \underbrace{\hat{\rho}^k \tilde{\mathbf{v}}_k}_{\substack{\text{supply due to} \\ \text{mass supplied}}} + \underbrace{\hat{\boldsymbol{\pi}}^k}_{\substack{\text{supply} \\ \text{by the rest} \\ \text{of the mixture}}} \\
\hat{\mathbf{\Psi}}_k &= \underbrace{\mathbf{0}}_{\substack{\text{supply rate of} \\ \text{surface momentum}}}
\end{aligned} \tag{4.5.1}$$

Just before being transferred and deposited, the masses are endowed with their own velocities $\tilde{\mathbf{v}}_k$, $k \in \mathcal{K}$. These velocities have to be specified by constitutive equations.

The net momentum supply,

$$\hat{\mathbf{p}} \equiv \sum_{k\in\mathcal{K}} \hat{\mathbf{p}}^k , \tag{4.5.2}$$

where

$$\hat{\mathbf{p}}^k \equiv \hat{\rho}^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k , \tag{4.5.3}$$

is contributed by the surroundings in the growth process. The term $\hat{\boldsymbol{\pi}}^k$ represents the momentum supply to the species k by the rest of the mixture, aside from the momentum $\hat{\rho}^k \tilde{\mathbf{v}}_k$ due to mass transfer and growth (once again,

notation varies with authors, and some authors embody the two contributions in a single term, e.g., Truesdell [1984], p. 219). Note 4.2 presents two ways of specifying the momentum supplies $\hat{\boldsymbol{\pi}}^k$, $k \in \mathcal{K}$.

The global balance of momentum of the species $k \in \mathcal{K}$ deduces from (4.3.11),

$$\frac{d^k}{dt}\int_V \rho^k \mathbf{v}_k \, dV = \int_V \rho^k \, \mathbf{b}_k \, dV + \int_{\partial V} \boldsymbol{\sigma}^k \cdot d\mathbf{S} + \int_V \hat{\rho}^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k \, dV \,, \tag{4.5.4}$$

while Eqn (4.4.6) yields, with a change of sign, the local balance of momentum in the current configuration, in terms of the partial stress $\boldsymbol{\sigma}^k$ and body force per unit mass $\mathbf{b}_k$,

$$\operatorname{div} \boldsymbol{\sigma}^k + \rho^k \, (\mathbf{b}_k - \frac{d^k \mathbf{v}_k}{dt}) = \hat{\rho}^k (\mathbf{v}_k - \tilde{\mathbf{v}}_k) - \hat{\boldsymbol{\pi}}^k \,. \tag{4.5.5}$$

On the right-hand side of (4.5.5), the *interaction* momentum due to mass transfer and growth, that contributes to the momentum balance, is an objective vector that is *not* the whole momentum supply. In fact, if the mass supplied is endowed with the velocity of the targeted species k, that is $\tilde{\mathbf{v}}_k = \mathbf{v}_k$, the first term of the interaction momentum vanishes, while the momentum of the transferred or deposited mass itself does not.

Note 4.1 on strongly interacting media.

In a theory of strongly interacting media applied to articular cartilages, a single balance of momentum is enforced for a phase where all species have the same velocity, but the balance of mass is imposed for each species, Loret and Simões [2004] [2005]a. Some papers, e.g., Klisch and Hoger [2003], Klisch et al. [2003]a [2003]b, impose the balance of momentum as such to all species: the requirement might be too constraining.

Note 4.2 on momentum supplies and generalized diffusion.

Momentum supplies are dealt with in two standard ways:

- when solving boundary value problems, the balances of momentum of individual species may be used directly if constitutive equations have been provided for the momentum supplies, e.g., Section 7.3.2;
- alternatively, the generalized diffusion equations are postulated first, motivated by and satisfying the Clausius-Duhem inequality, e.g., Eqn (4.7.32) below: in fact, the diffusion equation of the species k is nothing else than the balance of momentum of this species. The momentum supplies are then elusive, but, if necessary, they can be retrieved from the momentum balances.

4.5.2 Balance of momentum for the mixture

The balance of momentum for *the mixture as a whole* is obtained by summing (4.5.5) over all species,

$$\operatorname{div} \boldsymbol{\sigma} + \rho \, (\mathbf{b} - \frac{D\mathbf{v}}{Dt}) = \hat{\rho} \, \mathbf{v} - \hat{\mathbf{p}} \,, \tag{4.5.6}$$

where $\mathbf{v}$ and $\mathbf{b}$ are respectively the barycentric velocity and the overall body force defined by (4.3.4), and $\boldsymbol{\sigma}$ is the Cauchy stress of the mixture,

$$\boldsymbol{\sigma} = \sum_{k \in \mathcal{K}} \boldsymbol{\sigma}^k - \rho^k \, \overset{(b)}{\mathbf{v}}_k \otimes \overset{(b)}{\mathbf{v}}_k \,. \tag{4.5.7}$$

A detailed proof is deferred to the Appendix. The diffusion contribution to the stress is often neglected in applications so that the (total) stress $\boldsymbol{\sigma}$ is approximated by the 'inner' part obtained by summation of partial stresses

$$\boldsymbol{\sigma}^I = \sum_{k \in \mathcal{K}} \boldsymbol{\sigma}^k \,. \tag{4.5.8}$$

Another equivalent form is deduced by summing the individual balances of momentum (4.5.5) over all species and using the closure relation (4.5.2),

$$\operatorname{div} \boldsymbol{\sigma}^I + \rho \, \mathbf{b} - \sum_{k \in \mathcal{K}} \rho^k \, \frac{d^k \mathbf{v}_k}{dt} + \hat{\rho}^k \, \mathbf{v}_k = -\hat{\mathbf{p}} \,. \tag{4.5.9}$$

With help of the relation (2.6.18), the balance of momentum for the mixture as a whole in the reference configuration can be cast in the form,

$$\begin{aligned} \underline{\operatorname{div}} \, \underline{\boldsymbol{\tau}} + m \, (\mathbf{b} - \frac{D\mathbf{v}}{Dt}) &= \hat{m} \, \mathbf{v} - \underline{\hat{\mathbf{p}}} \,, \\ \frac{\partial \underline{\tau}_{iJ}}{\partial \underline{x}_J} + m \, (b_i - \frac{Dv_i}{Dt}) &= \hat{m} \, v_i - \underline{\hat{p}}_i \,, \quad i \in [1,3] \,. \end{aligned} \tag{4.5.10}$$

Note 4.3 on the symmetry of the stresses.

The current framework assumes that the partial stresses $\boldsymbol{\sigma}^k$, $k \in \mathcal{K}$, are symmetric. Unsymmetric stresses are introduced in some theories of granular or polycrystalline materials, where couple stresses are intended to represent the mechanical interactions at the particle level, Cosserat and Cosserat [1909].

In the context of mixture theories, several authors, e.g., Truesdell and Toupin [1960], Section 215, Eringen and Ingram [1965], Bowen [1976], suggest that species may also interact via moment of momentum supplies.

The stress of the mixture $\boldsymbol{\sigma}$ or $\boldsymbol{\sigma}^I$ is symmetric in a closed system if the sum over all species of the moments of momentum vanishes. For an open system, the surroundings may contribute a moment of momentum supply. In this text, all moment of momentum supplies are assumed to be null, so that the Cauchy stress tensors representing the partial stresses of individual species and the stress of the mixture are symmetric.

4.5.3 Interaction momenta

One might perhaps assume that matter supplied to growing species either internally, by mass transfer, or externally, is endowed with the velocity of the solid skeleton, i.e. $\mathbf{v}_k = \mathbf{v}_\mathrm{s}$, $k \in \mathcal{S}^*$.

In general however, the interaction momentum $\hat{\rho}^k\,(\mathbf{v}_k - \tilde{\mathbf{v}}_k)$ in the momentum balance (4.5.5) due to mass transfer or growth does not vanish. For example, our model of articular cartilage defines three phases, one solid phase and two fluid phases, Loret and Simões [2004]. A species of the intrafibrillar phase is assumed to move with the same velocity as the solid, $\tilde{\mathbf{v}}_k = \mathbf{v}_{k\mathrm{I}} = \mathbf{v}_\mathrm{s}$, while a species k in the extrafibrillar phase is endowed with its own velocity, $\tilde{\mathbf{v}}_k = \mathbf{v}_{k\mathrm{E}}$ so as to be able to diffuse in water through the mixture. Thus upon transfer from the extrafibrillar phase to the intrafibrillar phase, the velocity of a species k undergoes the discontinuity $\mathbf{v}_\mathrm{s} - \mathbf{v}_{k\mathrm{E}}$.

4.5.4 Interaction stresses

When loosely spread over a scaffold, cells do not interact mechanically. On the other hand, as the cell density increases, a mechanical interaction develops that ultimately, as cells get into contact, reaches a large value that limits the macroscopic cellular density. To model this phenomenon, a cell-cell interaction stress can be introduced that, in absence of external loading, would imply cells to get apart and the tissue to expand. To be specific, let us consider an elastic material in a one-dimensional setting whose stress σ is equal to the product of the Young's modulus E by the strain ϵ. Let us introduce the compressive interaction stress $\hat{\sigma} < 0$ and modify the constitutive equation to $\sigma - \hat{\sigma} = E\,\epsilon$. At zero applied stress σ, the strain due to interaction is positive and the material expands. Conversely, at zero strain, the applied stress is compressive. Under the notation $-\hat{\sigma} = E\,\hat{\epsilon}$, the interaction stress can be transformed into a growth strain $\hat{\epsilon} > 0$, and the constitutive equation then becomes $\sigma = E\,(\epsilon - \hat{\epsilon})$.

Breward et al. [2002] introduce directly such an interaction term between tumor cells viewed as linear viscoelastic materials. In their study, this type of interaction concerns a single species, the tumor cells in the example, and has purely mechanical effects.

In this mixture framework, we consider now the existence of an interaction stress due to momentum supplies. For that purpose, we shall adapt an idea of Passman and McTigue [1989] used to model non-homogeneous mixtures where the supply terms do not balance each other. Specifically let us first rewrite the closure of the momentum supplies in a modified form, namely

$$\sum_{k\in\mathcal{K}} \hat{\rho}^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k \;+\; \mathrm{div}\;\hat{\boldsymbol{\sigma}} \;=\; \hat{\mathbf{p}}\,, \tag{4.5.11}$$

which involves the interaction stress $\hat{\boldsymbol{\sigma}}$. To discover the effects of this stress, let us consider two situations (a) and (b) defined by the stresses $\hat{\boldsymbol{\sigma}}_{(a)} = \mathbf{0}$ and $\hat{\boldsymbol{\sigma}}_{(b)} = \hat{\boldsymbol{\sigma}}$, respectively, the other data being identical. Then the momentum supplies $\hat{\boldsymbol{\pi}}^k$ and partial stresses $\boldsymbol{\sigma}^k$, $k \in \mathcal{K}$, in the two systems can be obtained by the correspondence,

$$\hat{\boldsymbol{\pi}}^k_{(a)} \to \hat{\boldsymbol{\pi}}^k_{(b)} = \hat{\boldsymbol{\pi}}^k_{(a)} - \mathrm{div}\;(\lambda_k\,\hat{\boldsymbol{\sigma}}), \quad \boldsymbol{\sigma}^k_{(a)} \to \boldsymbol{\sigma}^k_{(b)} = \boldsymbol{\sigma}^k_{(a)} + \lambda_k\,\hat{\boldsymbol{\sigma}}, \quad k \in \mathcal{K}\,, \tag{4.5.12}$$

where the λ_k's are arbitrary quantities that satisfy $\sum_{k\in\mathcal{K}} \lambda_k = 1$. Thus, for the mixture as a whole,

$$\hat{\boldsymbol{\pi}}_{(a)} \to \hat{\boldsymbol{\pi}}_{(b)} = \hat{\boldsymbol{\pi}}_{(a)} - \mathrm{div}\;\hat{\boldsymbol{\sigma}}, \quad \boldsymbol{\sigma}_{(a)} \to \boldsymbol{\sigma}_{(b)} = \boldsymbol{\sigma}_{(a)} + \hat{\boldsymbol{\sigma}}\,. \tag{4.5.13}$$

All data being fixed, let us consider variations of the λ_k's that satisfy $\sum_{k\in\mathcal{K}} \Delta\,\lambda_k = 0$. Then we see, by (4.5.12), that variations of the momentum supplies imply variations of the partial stresses even if the mixture properties (4.5.13) are kept constant.

Incidentally, note that the momentum supply for the species k in situation (b) associated with (4.5.11) can be cast, in integral form, as the sum of a volume integral and a surface integral,

$$\int_V \hat{\rho}^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k \, dV + \int_{\partial V} \lambda_k \, \hat{\boldsymbol{\sigma}} \cdot \, d\mathbf{S} \,, \tag{4.5.14}$$

and therefore, with the notation set in Section 4.3.3,

$$\hat{\Psi}_k = \hat{\rho}^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k, \quad \hat{\boldsymbol{\Psi}}_k = \lambda_k \, \hat{\boldsymbol{\sigma}} \,. \tag{4.5.15}$$

4.6 Balance of energy

The balance of energy is considered first for each species, and next for the mixture as a whole. Electrolytes are addressed as well.

4.6.1 Notation of thermodynamic functions in a mixture context

In agreement with the notations set by (2.6.23), the internal energy of an elementary volume may be expressed through several equivalent representations,

$$U^k \, V = \underline{U}^k \, \underline{V} = u_k \, M_k, \quad U^k = \rho^k \, u_k, \quad \underline{U}^k = m^k \, u_k \,. \tag{4.6.1}$$

In words, for any species k,

- u_k is the internal energy per unit current mass;
- U^k the internal energy per current volume of the mixture, and
- $\underline{U}^k$ the internal energy per reference volume of the mixture.

The internal energy of the body $\mathbb{U}$ [unit : J] is defined by integration over the volume of the internal energy U measured per current volume of the mixture, namely $\mathbb{U} = \int_V U \, dV$. The internal energy U is the sum over species k of the apparent internal energies $U^k = \rho^k \, u_k$. In summary, in the current and reference configurations,

$$\underbrace{u_k}_{\substack{\text{internal energy}\\ \text{of the species k}\\ \text{per unit mass}\\ \text{of that species}}} \mapsto \underbrace{\left\{ \begin{array}{l} U^k = \rho^k \, u_k \\ \underline{U}^k = m^k \, u_k \end{array} \right.}_{\substack{\text{internal energy}\\ \text{of the species k per}\\ \text{unit current/reference}\\ \text{volume of the mixture}}} \mapsto \underbrace{\left\{ \begin{array}{l} U = \sum_{k \in \mathcal{K}} U^k \\ \underline{U} = \sum_{k \in \mathcal{K}} \underline{U}^k \end{array} \right.}_{\substack{\text{internal energy}\\ \text{of the mixture per}\\ \text{unit current/reference}\\ \text{volume of the mixture}}} \mapsto \mathbb{U} = \underbrace{\left\{ \begin{array}{l} \int_V U \, dV \\ \int_{\underline{V}} \underline{U} \, d\underline{V} \end{array} \right.}_{\substack{\text{internal energy}\\ \text{of the body}}} . \tag{4.6.2}$$

An identical notation applies to the free energy, enthalpy, free enthalpy and entropy. Let us record the dimensions of internal energy, free energy, enthalpy and free enthalpy,

$$u \ [\text{unit} : \text{J/kg} = \text{m}^2/\text{s}^2], \quad U \ [\text{unit} : \text{Pa} = \text{J/m}^3 = \text{kg/m/s}^2] \,, \tag{4.6.3}$$

and of entropy,

$$s \ [\text{unit} : \text{J/kg/K} = \text{m}^2/\text{s}^2/\text{K}], \quad S \ [\text{unit} : \text{Pa/K} = \text{J/m}^3/\text{K} = \text{kg/m/s}^2/\text{K}] \,. \tag{4.6.4}$$

Additional notation is required to distinguish e.g., the free enthalpy per unit mass and per unit mole. Incidentally, the free enthalpy is also referred to as chemical potential.

4.6.2 First principle of thermodynamics

The concept of state variables is at the root of the thermomechanical analysis that is pursued in this work. Rather than attempting a general definition, we shall be content to proceed via examples. It suffices for now to indicate that they provide in an approximative manner the history of the material in terms of stress, of some representative strain, of temperature, etc. Memory effects may reduce to the current instant, or may be of short range or may require a time integral representation. In a *local state* or *local action* approach, only entities that take values at the geometrical point of interest are involved. Spatial interactions between a point and its neighborhood are introduced in a so called *non local action* approach through space derivatives, gradients of various orders or space integrals.

The first principle of thermodynamics relies on the existence of a function of the state of the body, called internal energy. It can be enounced as follows: for any incremental process, the sum of this internal energy and of the kinetics energy is balanced by the sum of the mechanical energy supplied by the surroundings and of the heat supply,

$$\underbrace{d\,\mathbb{U}}_{\substack{\text{internal}\\ \text{energy}}} + \underbrace{d\mathbb{C}}_{\substack{\text{kinetic}\\ \text{energy}}} = \underbrace{\delta\mathbb{W}_{\text{ext}}}_{\substack{\text{energy supplied}\\ \text{by the surroundings}}} + \underbrace{\delta\mathbb{Q}}_{\substack{\text{heat}\\ \text{supply}}}. \tag{4.6.5}$$

The differential in front of the internal energy and kinetic energy is meant to stress the fact that these entities are functions of the state of the material, while the entities on the right-hand side are not. Indeed, while, for a cycle $C = C(\mathcal{V})$ in the state space $\mathcal{V}$,

$$0 = \oint_C d\,\mathbb{U} + \oint_C d\mathbb{C} = \oint_C \delta\mathbb{W}_{\text{ext}} + \oint_C \delta\mathbb{Q}\,, \tag{4.6.6}$$

each of the two integrals of the left-hand side vanishes, the two integrals on the right-hand side do not, but they cancel each other.

4.6.3 Balance of energy for species

The balance of energy for the species $k \in \mathcal{K}$ is obtained by setting, Eringen and Ingram [1965] (the sign of the heat fluxes used here is opposite to that of these authors),

$$\begin{aligned}
\Psi_k &= \underbrace{\rho^k\, u_k}_{\text{internal energy}} + \underbrace{\tfrac{1}{2}\,\rho^k\,\mathbf{v}_k^2}_{\text{kinetic energy}}\\
I_k &= \underbrace{\Theta_k}_{\text{heat source}} + \underbrace{\rho^k\,\mathbf{b}_k\cdot\mathbf{v}_k}_{\text{mechanical source}}\\
\mathbf{I}_k &= \underbrace{-\mathbf{Q}_k}_{\text{heat flux}} + \underbrace{\boldsymbol{\sigma}^k\cdot\mathbf{v}_k}_{\text{mechanical flux}}\\
\hat{\Psi}_k &= \underbrace{\hat{\rho}^k\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2)}_{\substack{\text{supply rate due to}\\ \text{mass supply}}} + \underbrace{\hat{\boldsymbol{\pi}}^k\cdot\mathbf{v}_k}_{\substack{\text{supply rate due to}\\ \text{momentum supply}}} + \underbrace{\hat{\mathcal{U}}^k}_{\substack{\text{supply rate}\\ \text{in other forms}}}\\
\hat{\mathbf{\Psi}}_k &= \underbrace{\mathbf{0}}_{\substack{\text{supply rate}\\ \text{of surface energy}}}
\end{aligned} \tag{4.6.7}$$

The net power supply, namely

$$\hat{U} \equiv \sum_{k\in\mathcal{K}} \hat{U}^k\,, \tag{4.6.8}$$

with

$$\hat{U}^k \equiv \hat{\rho}^k\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2) + \hat{\boldsymbol{\pi}}^k\cdot\mathbf{v}_k + \hat{\mathcal{U}}^k\,, \tag{4.6.9}$$

characterizes the growth process, i.e. $\hat{U}$ is zero if only (internal) energy transfers take place.

The contribution due to mass transfer and growth is endowed with an independent velocity $\tilde{\mathbf{v}}_k$ and an independent internal energy $\tilde{u}_k$. Cowin [2004], p. 94, presents physical arguments intended to justify that the deposited bone, when interpreted in the proper time scale, can be endowed with the same internal energy as the existing bone at the deposition site. Energy supply to the species k by the rest of the mixture and by the surroundings may take place also via kinetic energy and momentum supply, as well as in other arbitrary forms gathered in the term $\hat{\mathcal{U}}^k$.

The global balance of energy for the species $k \in \mathcal{K}$ deduces from (4.3.11),

$$\begin{aligned} &\frac{d^k}{dt}\int_V \rho^k\, u_k + \tfrac{1}{2}\,\rho^k\,\mathbf{v}_k^2\; dV \\ = &\int_V \Theta_k + \rho^k\,\mathbf{b}_k\cdot\mathbf{v}_k\; dV + \int_{\partial V}\; \big(-\mathbf{Q}_k + \boldsymbol{\sigma}^k\cdot\mathbf{v}_k\big)\cdot d\mathbf{S} + \int_V\; \hat{\rho}^k\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2) + \hat{\boldsymbol{\pi}}^k\cdot\mathbf{v}_k + \hat{\mathcal{U}}^k\; dV\,, \end{aligned} \tag{4.6.10}$$

while its local expression can be cast in the format,

$$\rho^k\,\frac{d^k u_k}{dt} - \boldsymbol{\sigma}^k : \boldsymbol{\nabla}\mathbf{v}_k + \operatorname{div}\,\mathbf{Q}_k - \Theta_k = \hat{\rho}^k\,\big(\tilde{u}_k - u_k + \tfrac{1}{2}\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\big) + \hat{\mathcal{U}}^k\,. \tag{4.6.11}$$

Eqn (4.6.11) is obtained by insertion of the terms appearing in (4.6.7) in the generic balance equation (4.4.6) and use of the balance of momentum of species (4.5.5). As observed for the latter relation, the energy (rate) interaction is not equal to the total supply of energy rate.

An equivalent expression, obtained by using the balances of mass and momentum, which highlights the internal energy per unit volume,

$$\frac{d}{dt}(\rho^k\,u_k) + \rho^k\,u_k\operatorname{div}\mathbf{v}_{\rm s} + \operatorname{div}\,(-\boldsymbol{\sigma}^k\cdot\mathbf{v}_{\rm s} + \mathbf{Q}_k + \mathbf{h}_k\cdot\mathbf{M}_k) - \Theta_k - \rho^k\,(\mathbf{b}_k - \frac{d^k\mathbf{v}_k}{dt})\cdot\mathbf{v}_k + \frac{1}{2}\hat{\rho}^k\,\mathbf{v}_k^2 - \hat{U}^k = 0\,, \tag{4.6.12}$$

makes use of the enthalpy tensor $\mathbf{h}_k$ introduced by Bowen [1976],

$$\mathbf{h}_k \equiv u_k\,\mathbf{I} - \frac{\boldsymbol{\sigma}^k}{\rho^k}\,. \tag{4.6.13}$$

If the partial stress $\boldsymbol{\sigma}^k = -n^k\,p_k\,\mathbf{I}$ is spherical and proportional to the intrinsic pressure p_k, then $\mathbf{h}_k = h_k\,\mathbf{I}$ with h_k the enthalpy per unit mass,

$$h_k \equiv u_k + \frac{p_k}{\rho_k}\,. \tag{4.6.14}$$

4.6.4 Balance of energy for the mixture: direct derivation

As already mentioned, in the standard approach of balance equations for the whole mixture, attention is paid to the motion of the mass center of the mixture which is endowed with the barycentric velocity. Along Eringen and Ingram [1965], the balance of energy for the mixture can be obtained by summation of the individual equations (4.6.11), a detailed derivation being provided in the Appendix. Here instead, the motion of the solid plays a central role. The alternative derivation shown below is in fact slightly more general as it includes internal body forces. The entities that appear in (4.6.5) are defined and considered in turn. This procedure motivates the definitions (4.6.7), as in fact it could be used to derive the balance of energy of individual species.

(1) Internal energy:

The time derivative, following the solid particles, of the internal energy of the body $\mathbb{U}$ is obtained via (4.3.6). If, in addition, internal body forces per unit mass are included, namely $\mathbf{b}_{k,\rm int}$ for species k, then

$$\frac{d\mathbb{U}}{dt} = \int_V\; \frac{dU}{dt} + U\operatorname{div}\mathbf{v}_{\rm s} + \sum_{k\in\mathcal{K}}\operatorname{div}\,(u_k\,\mathbf{M}_k) - \rho^k\,\mathbf{b}_{k,\rm int}\cdot\mathbf{v}_k\; dV\,. \tag{4.6.15}$$

(2) Kinetic energy:

The kinetic energy of the body is obtained according to the scheme displayed by (4.6.2),

$$\underbrace{c_k = \tfrac{1}{2}\,\rho^k\mathbf{v}_k^2}_{\substack{\text{kinetic energy}\\ \text{of the species k}}} \;\mapsto\; \underbrace{C = \sum_{k\in\mathcal{K}} c_k}_{\substack{\text{kinetic energy}\\ \text{of the mixture}\\ \text{per current volume}}} \;\mapsto\; \underbrace{\mathbb{C} = \int_V C\,dV}_{\substack{\text{kinetic energy}\\ \text{of the body}}}\,. \tag{4.6.16}$$

The time derivative following the solid particles can be transformed to, see the Appendix for a details,

$$\begin{aligned}\frac{d\mathbb{C}}{dt} &= \int_V -\boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_\mathrm{s} + \mathbf{v}_\mathrm{s}\cdot(\rho\,\mathbf{b} + \hat{\mathbf{p}} - \hat{\rho}\,\frac{\mathbf{v}_\mathrm{s}}{2})\;dV \\ &+ \sum_{k\in\mathcal{K}}\int_V \mathbf{M}_k\cdot\frac{d^k\mathbf{v}_k}{dt} + \frac{\hat{\rho}^k}{2}\Big(\frac{\mathbf{M}_k}{\rho^k}\Big)^2 + \mathrm{div}\,(\mathbf{v}_\mathrm{s}\cdot\boldsymbol{\sigma}^k)\;dV\,.\end{aligned} \tag{4.6.17}$$

(3) Energy supplied by the surroundings:

The power supplied by the surroundings includes, next to the standard contributions of external body forces, namely $\mathbf{b}_{k,\mathrm{ext}}$ for species k, and of the traction over the boundary, the power supply $\hat{U}$,

$$\frac{\delta\mathbb{W}_\mathrm{ext}}{\delta t} = \int_V \hat{U}\;dV + \sum_{k\in\mathcal{K}}\int_V \rho^k\,\mathbf{b}_{k,\mathrm{ext}}\cdot\mathbf{v}_k\;dV + \sum_{k\in\mathcal{K}}\int_{\partial V}\mathbf{v}_k\cdot\boldsymbol{\sigma}^k\cdot\;d\mathbf{S}\,. \tag{4.6.18}$$

(4) Heat supply:

The heat power is contributed by

- a heat source per unit current volume Θ,
- the heat transmitted by conduction.

By application of the lemma of the tetrahedron, the latter is obtained in the format $-\mathbf{Q}\cdot\mathbf{n}$ where $\mathbf{Q}$ is the heat flux and $\mathbf{n}$ is the local outward unit normal to ∂V. Hence

$$\frac{\delta\mathbb{Q}}{\delta t} = \int_V \Theta\;dV - \int_{\partial V}\mathbf{Q}\cdot\;d\mathbf{S}\,. \tag{4.6.19}$$

For this direct derivation to be consistent with the sum of the individual balances of energy (4.6.11), the heat source and heat flux of the mixture have to be the inner parts, namely

$$\mathbf{Q} = \mathbf{Q}^I = \sum_{k\in\mathcal{K}}\mathbf{Q}_k, \quad \Theta = \Theta^I = \sum_{k\in\mathcal{K}}\Theta_k\,. \tag{4.6.20}$$

The energy equation will involve two additional entities, namely the total body force per unit mass.

$$\mathbf{b} = \mathbf{b}_\mathrm{int} + \mathbf{b}_\mathrm{ext}\,, \tag{4.6.21}$$

and the enthalpy tensor $\mathbf{h}_k$ defined by (4.6.13).

Collecting Eqns (4.6.15)–(4.6.21), the local forms of the first principle (4.6.5) in the current and reference configurations can be cast in the respective formats,

$$\begin{aligned}&\frac{dU}{dt} + U\,\mathrm{div}\,\mathbf{v}_\mathrm{s} - \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_\mathrm{s} - \Theta + \mathrm{div}\;\mathbf{Q} + \sum_{k\in\mathcal{K}}\mathrm{div}\;(\mathbf{M}_k\cdot\mathbf{h}_k) + \mathbf{M}_k\cdot\big(\frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\big) \\ &\qquad + \sum_{k\in\mathcal{K}}\frac{1}{2}\,\hat{\rho}^k\,\big(\mathbf{v}_k - \mathbf{v}_\mathrm{s}\big)^2 + \hat{\mathbf{p}}\cdot\mathbf{v}_\mathrm{s} - \frac{1}{2}\,\hat{\rho}\,\mathbf{v}_\mathrm{s}^2 \;=\; \hat{U}\,,\end{aligned} \tag{4.6.22}$$

and

$$\begin{aligned}&\frac{d\underline{U}}{dt} - \underline{\boldsymbol{\tau}}^I : \frac{d\mathbf{E}_\mathrm{G}}{dt} - \underline{\Theta} + \underline{\mathrm{div}}\;\underline{\mathbf{Q}} + \sum_{k\in\mathcal{K}}\underline{\mathrm{div}}\;(\underline{\mathbf{M}}_k\cdot\mathbf{h}_k) + \mathbf{F}\cdot\underline{\mathbf{M}}_k\cdot\big(\frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\big) \\ &\qquad + \sum_{k\in\mathcal{K}}\frac{1}{2}\,\hat{m}^k\,\big(\mathbf{v}_k - \mathbf{v}_\mathrm{s}\big)^2 + \underline{\hat{\mathbf{p}}}\cdot\mathbf{v}_\mathrm{s} - \frac{1}{2}\hat{m}\,\mathbf{v}_\mathrm{s}^2 \;=\; \underline{\hat{U}}\,.\end{aligned} \tag{4.6.23}$$

A proof of this expression in the current configuration is detailed in the Appendix. The result in the reference configuration follows by multiplying the balance of energy in the current configuration (4.6.22) by $\det\mathbf{F}$, using the transformation rule (2.6.20) for U and Θ, the transformation rule (2.6.13) for the fluxes $\mathbf{M}_k$'s and $\mathbf{Q}$, the definitions of mass supplies (4.4.8), the work invariance relation (2.8.7), and the differential relations (2.7.2).

Note 4.4 on alternative definitions for a mixture.

Here we have defined the internal energy, free energy, entropy, heat flux and volume heat source of the mixture per unit current or initial volume. These entities are defined by simple summations. Moreover, the rate involved in the balances of the mixture is the time derivative following the solid particles.

There are other ways of defining global entities at the mixture level, each designed to cast the balance equations of energy and entropy in the familiar forms of a solid. In relation with the derivative associated with the barycentric velocity, Eringen and Ingram [1965] define the following entities,

$$\begin{aligned} \rho\, u &= \sum_{k\in\mathcal{K}} \rho^k \,(u_k + \tfrac{1}{2}\overset{(b)}{\mathbf{v}}_k \cdot \overset{(b)}{\mathbf{v}}_k) = \sum_{k\in\mathcal{K}} \rho^k \,(u_k + \tfrac{1}{2}\mathbf{v}_k^2) - \tfrac{1}{2}\,\rho\mathbf{v}^2\,, \\ \mathbf{Q} &= \sum_{k\in\mathcal{K}} \mathbf{Q}_k - \boldsymbol{\sigma}^k\cdot \overset{(b)}{\mathbf{v}}_k + \rho^k \left(u_k + \tfrac{1}{2}\overset{(b)}{\mathbf{v}}_k \cdot \overset{(b)}{\mathbf{v}}_k\right) \overset{(b)}{\mathbf{v}}_k\,, \\ \Theta &= \sum_{k\in\mathcal{K}} \Theta_k + \rho^k\, \mathbf{b}_k\cdot \overset{(b)}{\mathbf{v}}_k\,, \end{aligned} \tag{4.6.24}$$

and provide similar redefinitions for the entities entering the entropy balance[4.2].

4.6.5 The case of an electrolyte

Some species, like ions and charged macromolecules, are not electrically neutral. Let ϕ be the electrical potential, ζ_k the valence of the species k and N_k the number of moles of this species in the volume V. An electrical contribution has to be added to the external work (4.6.18), namely

$$-\int_{\partial V} \phi\,\mathrm{F}\,\frac{N_k}{V}\,\zeta_k \mathbf{v}_k\cdot d\mathbf{S}\,. \tag{4.6.25}$$

Here F is Faraday's equivalent charge. We shall assume the mixture as a whole to be electrically neutral,

$$\sum_{k\in\mathcal{K}} N_k\,\zeta_k = 0\,. \tag{4.6.26}$$

Therefore the electrical work can be cast in the format

$$-\int_{\partial V} \phi\,\mathrm{F}\,\frac{\zeta_k}{\widehat{m}_k}\,\mathbf{M}_k\cdot d\mathbf{S}\,, \tag{4.6.27}$$

where $\widehat{m}_k$ is the molar mass of the species k. Consequently, a charged species is endowed with the additional specific energy $\phi\,\mathrm{F}\,\zeta_k/\widehat{m}_k$ (specific $\equiv$ per unit mass).

More generally, as described in Loret et al. [2004]a for both geological materials and biological tissues, the existence of natural or artificial membranes that separate phases may imply as many independent electroneutrality conditions as there are electrical potentials.

4.7 Balance of entropy and Clausius-Duhem inequality

The balance of entropy is stated first for each species. However, the temperature $T > 0$ is considered to be uniform over all species and a single condition on the entropy production is required for the whole mixture. The terms entering the inequality are next split into three contributions of distinct physical natures, each of which is required to be positive. These three contributions concern the mechanical and growth aspects, generalized diffusion and mass transfer. The unravelling of the mechanics and growth aspects are considered in Section 21.4. The framework built in that way motivates and structures constitutive equations associated with the four physical phenomena of interest. Within each of them, couplings are allowed, while some degrees of interdependence between them are possible.

The assumption of *local thermal equilibrium* (identical temperature for all species of the mixture) is relaxed in Chapter 10. A constitutive thermomechanical model where the solid skeleton and two immiscible fluids are endowed each with its own temperature is developed as an extension of so-called doubled porosity model.

[4.2] While writing his balance equations in terms of redefined entities (4.6.24) and barycentric time derivative, Bowen [1976] finally uses the free energy per unit current volume as a thermodynamic potential. Bowen [1982], Eqns 3.14 et seq., also notes that the use of the free energy per unit initial volume simplifies the expressions.

4.7.1 Balance of entropy for species

The balance of entropy for the species $k \in \mathcal{K}$ is obtained by setting, Eringen and Ingram [1965],

$$\begin{array}{rcccl}
\Psi_k &=& \underbrace{\rho^k\, s_k}_{\text{entropy}} & & \\
I_k &=& \underbrace{\Theta_k/T}_{\text{heat source}} & + & \underbrace{\hat{S}^k_{(\mathrm{i})}}_{\substack{\text{internal}\\ \text{entropy production}}} \\
\mathbf{I}_k &=& \underbrace{-\mathbf{Q}_k/T}_{\text{heat flux}} & & \\
\hat{\Psi}_k &=& \underbrace{\hat{\rho}^k\, \tilde{s}_k}_{\substack{\text{supply rate}\\ \text{due to mass supply}}} & + & \underbrace{\hat{\mathcal{S}}^k}_{\substack{\text{supply rate}\\ \text{in other forms}}} \\
\hat{\mathbf{\Psi}}_k &=& \underbrace{\mathbf{0}}_{\substack{\text{supply rate}\\ \text{of surface entropy}}} & &
\end{array} \tag{4.7.1}$$

The contribution to species k due to mass transfer and growth is endowed with its own entropy per unit mass $\tilde{s}_k$. Entropy supply to the species k by the rest of the mixture and by the surroundings arises also in other arbitrary forms gathered in the term $\hat{\mathcal{S}}^k$. The net rate of entropy supply

$$\hat{S} \equiv \sum_{k\in\mathcal{K}} \hat{S}^k\,, \tag{4.7.2}$$

with

$$\hat{S}^k \equiv \hat{\rho}^k\, \tilde{s}_k + \hat{\mathcal{S}}^k\,, \tag{4.7.3}$$

is contributed by the surroundings in the growth process: $\hat{S}$ is zero if only (internal) mass transfers occur.

Inserting the above quantities (4.7.1) in the generic balance equation (4.4.6), the balance of entropy for the species $k \in \mathcal{K}$ can be cast in the formats,

$$\begin{aligned}
\hat{S}^k_{(\mathrm{i})} &= \rho^k\, \frac{d^k s_k}{dt} + \operatorname{div}\, \frac{\mathbf{Q}_k}{T} - \frac{\Theta_k}{T} + \hat{\rho}^k\, (s_k - \tilde{s}_k) - \hat{\mathcal{S}}^k \\
&= \frac{d^k}{dt}(\rho^k s_k) + \rho^k s_k \operatorname{div} \mathbf{v}_k + \operatorname{div} \frac{\mathbf{Q}_k}{T} - \frac{\Theta_k}{T} - \hat{\rho}^k\, \tilde{s}_k - \hat{\mathcal{S}}^k\,,
\end{aligned} \tag{4.7.4}$$

the latter expression being readily deduced from the global statement,

$$\frac{d^k}{dt}\int_V \rho^k\, s_k\, dV = \int_V \frac{\Theta_k}{T} + \hat{S}^k_{(\mathrm{i})}\, dV - \int_{\partial V} \frac{\mathbf{Q}_k}{T}\cdot d\mathbf{S} + \int_V \hat{\rho}^k\, \tilde{s}_k + \hat{\mathcal{S}}^k\, dV\,. \tag{4.7.5}$$

As observed for the balances of momentum and of energy, the entropy interaction (rate) is not equal to the total entropy supply rate. With the balance of mass (4.4.5) and the relation between time derivatives (2.7.1), the local balance of entropy (4.7.4) for the species $k \in \mathcal{K}$ may also be cast in the format,

$$\hat{S}^k_{(\mathrm{i})} = \frac{d}{dt}(\rho^k s_k) + \rho^k s_k \operatorname{div} \mathbf{v}_{\mathrm{s}} + \operatorname{div}\big(\frac{\mathbf{Q}_k}{T} + s_k \mathbf{M}_k\big) - \frac{\Theta_k}{T} - \hat{\rho}^k\, \tilde{s}_k - \hat{\mathcal{S}}^k\,. \tag{4.7.6}$$

4.7.2 Internal and external entropy productions for a species

In view of comparison with the case of a single solid, it is useful to record the alternative forms of entropy production of a species k using either a free energy per unit (current) mass or a free energy per unit (current) volume (at this point, we refrain to remove the index k because of the time derivative). Substituting div $\mathbf{Q}_k - \Theta_k$ obtained from

the balance of energy (4.6.11) in the balance of entropy (4.7.4) yields with help of the balance of mass (4.4.5) two possible expressions of the entropy production,

$$\begin{aligned} T\,\hat{S}^k_{(\mathrm{i})} &= -\rho^k\,\frac{d^k e_k}{dt} + \boldsymbol{\sigma}^k : \boldsymbol{\nabla}\mathbf{v}_k - \rho^k\,s_k\,\frac{d^k T}{dt} - \frac{\mathbf{Q}_k}{T}\cdot\boldsymbol{\nabla}T \\ &+ \hat{\rho}^k\left(\tilde{e}_k - \underline{\underline{e_k}} + \tfrac{1}{2}\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\right) + \hat{\mathcal{U}}^k - T\,\hat{\mathcal{S}}^k\,; \\ T\hat{S}^k_{(\mathrm{i})} &= -\frac{d^k}{dt}(\rho^k\,e_k) - \underline{\underline{\rho^k\,e_k\,\mathrm{div}\,\mathbf{v}_k}} + \boldsymbol{\sigma}^k : \boldsymbol{\nabla}\mathbf{v}_k - \rho^k\,s_k\,\frac{d^k T}{dt} - \frac{\mathbf{Q}_k}{T}\cdot\boldsymbol{\nabla}T \\ &+ \hat{\rho}^k\left(\tilde{e}_k + \tfrac{1}{2}\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\right) + \hat{\mathcal{U}}^k - T\,\hat{\mathcal{S}}^k\,. \end{aligned} \tag{4.7.7}$$

For the mixture as a whole, where a common derivative with respect to the solid is used, the rate of the specific free energy introduces a convective term,

$$\begin{aligned} \rho^k\,\frac{d^k e_k}{dt} &= \rho^k\,\frac{de_k}{dt} + \mathbf{M}_k\cdot\boldsymbol{\nabla}e_k\,, \\ \frac{d^k}{dt}(\rho^k e_k) + \rho^k e_k\,\mathrm{div}\,\mathbf{v}_k &= \frac{d}{dt}(\rho^k e_k) + \mathrm{div}\,(\mathbf{M}_k\,e_k) + \rho^k e_k\,\mathrm{div}\,\mathbf{v}_{\mathrm{s}}\,. \end{aligned} \tag{4.7.8}$$

The last line of the above relation (4.7.7) introduces the external entropy production $\hat{S}^k_{(\mathrm{e})}$, namely

$$-\,T\hat{S}^k_{(\mathrm{e})} = \hat{\rho}^k\left(\tilde{e}_k + \tfrac{1}{2}\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\right) + \hat{\mathcal{U}}^k - T\,\hat{\mathcal{S}}^k\,. \tag{4.7.9}$$

Now let us assume that the net supplies of momentum, of power and of rate of entropy to the species k, defined by (4.5.2), (4.6.8) and (4.7.2), respectively, are formally known. Then, in turn,

$$\begin{aligned} &\hat{\mathbf{p}}^k \equiv \hat{\rho}^k\tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k && \Rightarrow\quad \hat{\boldsymbol{\pi}}^k = \hat{\mathbf{p}}^k - \hat{\rho}^k\tilde{\mathbf{v}}_k\,, \\ &\hat{U}^k \equiv \hat{\rho}^k\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2) + \hat{\boldsymbol{\pi}}^k\cdot\mathbf{v}_k + \hat{\mathcal{U}}^k && \Rightarrow\quad \hat{\mathcal{U}}^k = \hat{U}^k - (\hat{\mathbf{p}}^k - \hat{\rho}^k\,\tilde{\mathbf{v}}_k)\cdot\mathbf{v}_k - \hat{\rho}^k\,\tilde{u}_k - \tfrac{1}{2}\,\hat{\rho}^k\,\tilde{\mathbf{v}}_k^2\,, \\ &\hat{S}^k \equiv \hat{\rho}^k\,\tilde{s}_k + \hat{\mathcal{S}}^k && \Rightarrow\quad \hat{\mathcal{S}}^k = \hat{S}^k - \hat{\rho}^k\,\tilde{s}_k\,. \end{aligned} \tag{4.7.10}$$

Consequently the external entropy production (4.7.9) may be rephrased in terms of the total supply rates,

$$-T\hat{S}^k_{(\mathrm{e})} = \tfrac{1}{2}\,\hat{\rho}^k\,\mathbf{v}_k^2 - \hat{\mathbf{p}}^k\cdot\mathbf{v}_k + \hat{U}^k - T\,\hat{S}^k\,. \tag{4.7.11}$$

The expressions (4.7.9) and (4.7.11) are strictly equivalent. The former expression displays the rates of mass supply and the rates of independent supply of internal energy and entropy not associated with mass supply nor momentum supply. While included in the formulation, the independent supply of momentum $\hat{\boldsymbol{\pi}}^k$ is elusive in (4.7.9). Expression (4.7.11) highlights the four net supplies associated with the balance equations. It should be emphasized that these supplies are contributed by mass, momentum, energy and entropy.

As an example, a species might be open to mass only, in the sense that it may gain/loose mass, while its *independent* supplies in momentum $\hat{\boldsymbol{\pi}}^k$, internal energy $\hat{\mathcal{U}}^k$ and entropy $\hat{\mathcal{S}}^k$ are zero. By the same token, the species gains/looses momentum, energy and entropy,

$$\begin{aligned} \hat{\mathbf{p}}^k &= \hat{\rho}^k\tilde{\mathbf{v}}_k\,, \\ \hat{U}^k &= \hat{\rho}^k\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2)\,, \\ \hat{S}^k &= \hat{\rho}^k\,\tilde{s}_k\,, \end{aligned} \tag{4.7.12}$$

which together contribute to the total external entropy production,

$$-\,T\hat{S}^k_{(\mathrm{e})} = \hat{\rho}^k\,\tilde{e}_k + \tfrac{1}{2}\,\hat{\rho}^k\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\,, \tag{4.7.13}$$

a result which was blatant from (4.7.9).

4.7.3 Second principle of thermodynamics

The second principle is stated as follows: There exist
- a scalar $T > 0$ [unit : K] called temperature and
- a function of the state of the material $\mathcal{S} = \int_V S dV$, called entropy of the body and obtained by integration of the local entropy $S = S(\mathbf{x}, t)$ [unit : Pa/K = J/m^3/K = kg/m/s^2/K],

such that, for any process consistent with the balance equations,

$$\int_V \hat{S}_{(\mathrm{i})}\, dV = \frac{d}{dt}\int_V S\, dV - \int_V \frac{\Theta}{T}\, dV + \int_{\partial V} \frac{\mathbf{Q}}{T}\cdot d\mathbf{S} - \int_V \hat{S}\, dV \geq 0\,. \tag{4.7.14}$$

Summing the derivatives (4.3.6), the ensuing local inequality may be phrased in terms of the local entropy production $\hat{S}_{(\mathrm{i})} = \hat{S}_{(\mathrm{i})}(\mathbf{x}, t)$, namely in the current and reference configurations, respectively,

$$\begin{aligned} \hat{S}_{(\mathrm{i})} &= \frac{dS}{dt} + S\,\mathrm{div}\,\mathbf{v}_{\mathrm{s}} + \mathrm{div}\,\Big(\frac{\mathbf{Q}}{T} + \sum_{k\in\mathcal{K}} s_k\,\mathbf{M}_k\Big) - \frac{\Theta}{T} - \hat{S} \geq 0\,,\\ \underline{\hat{S}}_{(\mathrm{i})} &= \frac{d\underline{S}}{dt} + \underline{\mathrm{div}}\,\Big(\frac{\mathbf{Q}}{\underline{T}} + \sum_{k\in\mathcal{K}} s_k\,\underline{\mathbf{M}}_k\Big) - \frac{\Theta}{\underline{T}} - \underline{\hat{S}} \geq 0\,. \end{aligned} \tag{4.7.15}$$

The global statement (4.7.14) of the second principle stands on its own. The local statement (4.7.15) is also obtained by summing the species entropy productions (4.7.6), provided that

1. The entropy is obtained along the same scheme as the internal energy, namely in the current and reference configurations,

$$\underbrace{s_k}_{\substack{\text{entropy}\\ \text{of the species k}\\ \text{per unit mass}}} \mapsto \underbrace{\begin{cases} S^k = \rho^k\, s_k \\ \underline{S}^k = m^k\, s_k \end{cases}}_{\substack{\text{entropy}\\ \text{of the species k}\\ \text{per unit current/reference}\\ \text{volume of the mixture}}} \mapsto \underbrace{\begin{cases} S = \sum_{k\in\mathcal{K}} \rho^k\, s_k \\ \underline{S} = \sum_{k\in\mathcal{K}} m^k\, s_k \end{cases}}_{\substack{\text{entropy of the mixture}\\ \text{per unit current/reference}\\ \text{volume of the mixture}}} \mapsto \mathcal{S} = \underbrace{\begin{cases} \int_V S\, dV \\ \int_{\underline{V}} \underline{S}\, d\underline{V} \end{cases}}_{\substack{\text{entropy}\\ \text{of the body}}}\,. \tag{4.7.16}$$

2. The total internal entropy production is built additively from the internal entropy production of the species,

$$\hat{S}_{(\mathrm{i})} = \sum_{k\in\mathcal{K}} \hat{S}^k_{(\mathrm{i})}, \quad \underline{\hat{S}}_{(\mathrm{i})} = \sum_{k\in\mathcal{K}} \underline{\hat{S}}^k_{(\mathrm{i})}\,, \tag{4.7.17}$$

with the convention $\underline{\hat{S}}_{(\mathrm{i})} = \det\mathbf{F}\,\hat{S}_{(\mathrm{i})}$ and $\underline{\hat{S}}^k_{(\mathrm{i})} = \det\mathbf{F}\,\hat{S}^k_{(\mathrm{i})}$, $k \in \mathcal{K}$.

3. The heat flux $\mathbf{Q}$ and heat source Θ in (4.7.15) are equal to the inner parts of their species properties as described by (4.6.20).

Note 4.5 on the number of dissipation inequalities for a mixture.

We require a single inequality for the whole mixture. This requirement seems consistent with the local thermal equilibrium assumption (a uniform temperature over all species). Theories assuming a local thermal nonequilibrium assumption may or may not be more demanding. Eringen and Ingram [1965] require an entropy inequality per temperature/species $\hat{S}^k_{(\mathrm{i})} \geq 0$, their Eqn (8.5), which of course implies $\hat{S}_{(\mathrm{i})} \geq 0$ at the mixture level. On the other hand, Atkin and Craine [1975] require a single inequality for the whole mixture, their Eqn (2.40), namely $\hat{S}_{(\mathrm{i})} \geq 0$.

Note 4.6 on local thermal non equilibrium.

For a system in local thermal equilibrium where the temperatures of all species are equal, $T_k = T$, $\forall k \in \mathcal{K}$, the second principle $\hat{S}_{(\mathrm{i})}$ is often expressed in the equivalent format $T\hat{S}_{(\mathrm{i})} \geq 0$. For mixtures where local thermal equilibrium does not hold, where each species is endowed with its own temperature, the entropy inequality at the mixture level is contributed by the species in the format $\sum_k \hat{S}^k_{(\mathrm{i})} \geq 0$, and not $\sum_k T_k\hat{S}^k_{(\mathrm{i})} \geq 0$.

4.7.4 The Clausius-Duhem inequality

4.7.4.1 Free energy of the mixture, electrochemical potentials of species

The Clausius-Duhem inequality (CD) is obtained by insertion of the balance of energy into the second principle. It expresses in terms of

- the free energy of the mixture per unit current volume

$$E = U - T\,S\,, \tag{4.7.18}$$

- and of the free enthalpies, also called electrochemical potentials, of the species per unit mass,

$$\mu_k^{\rm ec} = h_k - T\,s_k = e_k + \frac{p_k}{\rho_k}, \quad k \in \mathcal{K}\,, \tag{4.7.19}$$

where

$$e_k = u_k - T\,s_k, \quad k \in \mathcal{K}, \tag{4.7.20}$$

is the free energy per unit mass of the species k.

For further reference, it is instrumental to define the electrochemical potential per unit mole g_k,

$$g_k^{\rm ec} = \widehat{m}_k\,\mu_k^{\rm ec} = \rho_k\,\widehat{v}_k\,\mu_k^{\rm ec}, \quad k \in \mathcal{K}\,, \tag{4.7.21}$$

where $\widehat{m}_k$ and $\widehat{v}_k$ are respectively the molar mass and molar volume of the species k.

If the partial stress is not isotropic, then, instead of the scalar electrochemical potential (4.7.19), the electrochemical potential tensor $\boldsymbol{\mu}_k^{\rm ec}$ appears,

$$\boldsymbol{\mu}_k^{\rm ec} = \mathbf{h}_k - T\,s_k\,\mathbf{I} = e_k\,\mathbf{I} - \frac{\boldsymbol{\sigma}^k}{\rho^k}, \quad k \in \mathcal{K}\,. \tag{4.7.22}$$

The tensor $-\rho^k\,\boldsymbol{\mu}_k^{\rm ec} = \boldsymbol{\sigma}^k - \rho^k\,e_k\,\mathbf{I}$ is sometimes referred to as the Eshelby stress of the species.

The electrochemical potentials have still to be defined by constitutive equations. This issue is pursued in Chapters 13 and 14. The electrochemical potentials contain, besides a mechanical and an electrical component, a chemical component as well as a term that represents an energy of formation. The latter is capital for the transfer equations, as it generates equilibrium constants. Instances for clays and articular cartilages can be found in our previous works, Gajo et al. [2002], Loret and Simões [2007].

The chemical potentials are denoted by the symbol μ and the *electro*chemical potentials by the symbol $\mu^{\rm ec}$. Of course, the chemical and electrochemical potentials are one and the same if the species is electrically neutral.

4.7.4.2 Internal entropy production, equilibrium, stationary state

The (CD) inequality states that the internal entropy production should be positive,

$$\hat{S}_{\rm (i)} \geq 0\,. \tag{4.7.23}$$

The external entropy production $\hat{S}_{\rm (e)}$, that is the entropy production contributed by the surroundings to the body, and the total entropy production $\hat{S} = \hat{S}_{\rm (i)} + \hat{S}_{\rm (e)}$ may have any sign.

The internal entropy production is a sum of work-conjugated fluxes and driving forces. It is convenient to delineate the fluxes for which no constraint is placed on the associated driving forces: their asymptotic values vanish. On the other hand, the fluxes whose driving forces are subjected to a constraint tend asymptotically to a constant (non zero) value. The asymptotic state may be called an *equilibrium* in the first case, and a *stationary state* in the second case. In both cases, since the state is constant, so do functions of the state, and in particular the (total) entropy,

$$\hat{S} = 0 \quad \text{for a stationary state and for an equilibrium}\,. \tag{4.7.24}$$

However, both internal and external entropy productions vanish in an equilibrium,

$$\hat{S}_{\rm (i)} = 0, \quad \hat{S}_{\rm (e)} = 0 \quad \text{for an equilibrium}\,, \tag{4.7.25}$$

while

$$\hat{S}_{\rm (i)} \geq 0, \quad \hat{S}_{\rm (e)} = -\hat{S}_{\rm (i)} \leq 0 \quad \text{for a non equilibrium stationary state}\,, \tag{4.7.26}$$

that is, entropy is *supplied* to the surroundings. Consequently, non equilibrium stationary states associated with, e.g., active transports require the system to be thermodynamically open, Katchalsky and Kedem [1962], p. 59.

Thus Clausius-Duhem implies an increasing disorder, Fig. 4.7.1. On the other hand, biological systems tend to increase order, e.g., by active transports, and thus to decrease entropy. These two points of view seem opposite. According to Glansdorff and Prigogine [1971], they correspond to different settings: close to equilibrium $\hat{S}_{\rm (e)} = 0$, structures disappear according to (CD), namely $\hat{S}_{\rm (i)} \geq 0$. On the other hand, biological structures are created through nonlinear kinetics far from equilibrium, where $\hat{S}_{\rm (e)} \leq 0$ and $\hat{S} \leq 0$.

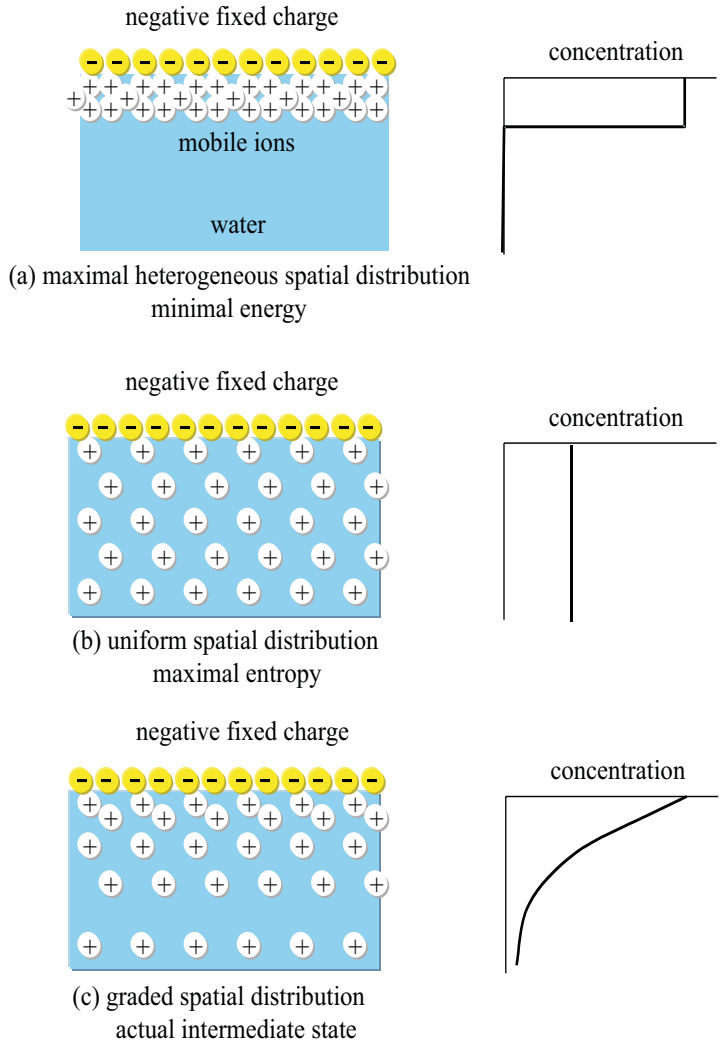

Fig. 4.7.1: Negative fixed electrical charges attract mobile cations. The three thought spatial distributions of mobile ions illustrate the notions of energy, entropy and the intermediate actual solution. Modified from Appelo and Postma [1993], p. 184.

4.7.4.3 Additive split of the (CD) inequality

In deriving the (CD) inequality, the thermal contribution $\Theta - \operatorname{div} \mathbf{Q}$ is first obtained from the first principle (4.6.22), and next substituted in the local statement of the second principle (4.7.15).

The (CD) inequality can be split into three terms of distinct physical natures,

$$\hat{S}_{(\mathrm{i})} = \hat{S}_{(\mathrm{i},1,4)} + \hat{S}_{(\mathrm{i},2)} + \hat{S}_{(\mathrm{i},3)} \geq 0\,. \tag{4.7.27}$$

It is sufficient (but by no means necessary a priori) to require each of them to be positive or zero. As indicated in Section 4.2, this point of view certainly restricts the interactions between the physical phenomena but it does not preclude some interdependence:

1. $\hat{S}_{(\mathrm{i},1,4)}$ represents the contributions to $\hat{S}_{(\mathrm{i})}$ due to **mechanics** and **growth**:

$$\begin{aligned} T\hat{S}_{(\mathrm{i},1,4)} &= -\frac{dE}{dt} - E \operatorname{div} \mathbf{v}_{\mathrm{s}} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - S\frac{dT}{dt} + \frac{1}{\det \mathbf{F}} \sum_{k\in\mathcal{K}^*} \mu_k^{\mathrm{ec}} \frac{dm^k}{dt} - T\,\hat{S}_{(\mathrm{e})}\,, \\ T\underline{\hat{S}}_{(\mathrm{i},1,4)} &= -\frac{d\underline{E}}{dt} + \underline{\boldsymbol{\tau}}^I : \frac{d\mathbf{E}_{\mathrm{G}}}{dt} - \underline{S}\frac{dT}{dt} + \sum_{k\in\mathcal{K}^*} \mu_k^{\mathrm{ec}} \frac{dm^k}{dt} - T\,\underline{\hat{S}}_{(\mathrm{e})}\,, \end{aligned} \tag{4.7.28}$$

with the external entropy production per unit current volume $\hat{S}_{(\mathrm{e})}$ and per unit reference volume $\underline{\hat{S}}_{(\mathrm{e})}$,

$$\begin{aligned} -T\,\hat{S}_{(\mathrm{e})} &= \tfrac{1}{2}\,\hat{\rho}\,\mathbf{v}_{\mathrm{s}}^2 - \hat{\mathbf{p}}\cdot\mathbf{v}_{\mathrm{s}} + \hat{U} - T\hat{S}\,, \\ -T\,\underline{\hat{S}}_{(\mathrm{e})} &= \tfrac{1}{2}\,\hat{m}\,\mathbf{v}_{\mathrm{s}}^2 - \underline{\hat{\mathbf{p}}}\cdot\mathbf{v}_{\mathrm{s}} + \underline{\hat{U}} - T\underline{\hat{S}}\,. \end{aligned} \tag{4.7.29}$$

The fact that the system is open is blatant in $\hat{S}_{(\mathrm{e})}$, where the contributions $\hat{\rho}$, $\hat{\mathbf{p}}$, and $\hat{U}$, $\hat{S}$ by the surroundings to the mass, momentum, internal energy and entropy respectively, are recognized.

The unravelling between mechanics and growth is realized in Section 21.4. A vanishing mechanical dissipation $\hat{S}_{(\mathrm{i},1)} = 0$ gives rise to coupled chemo-hyperelasticity in terms of a generalized stress and a generalized strain that are motivated by the equality. Examples are provided in the modeling of articular cartilages in Chapter 14 and of cornea in Chapter 19.

The surface contributions to the growth process by the surroundings have not been considered, except in Section 4.5.4. If they are accounted for, the overall supplies of mass, momentum, energy and entropy should be understood as accounting for the volume and surface contributions, namely along (4.3.8),

$$\begin{aligned} \hat{\rho}^k &\rightarrow \hat{\rho}^k + \operatorname{div} \hat{\mathbf{R}}^k, \\ \hat{\boldsymbol{\pi}}^k &\rightarrow \hat{\boldsymbol{\pi}}^k + \operatorname{div} \hat{\boldsymbol{\Pi}}^k, \\ \hat{\mathcal{U}}^k &\rightarrow \hat{\mathcal{U}}^k + \operatorname{div} \hat{\mathbf{U}}^k, \\ \hat{\mathcal{S}}^k &\rightarrow \hat{\mathcal{S}}^k + \operatorname{div} \hat{\mathbf{S}}^k . \end{aligned} \tag{4.7.30}$$

2. $\hat{S}_{(\mathrm{i},2)}$ is the contribution due to (internal) **mass transfers**:

$$\begin{aligned} T\hat{S}_{(\mathrm{i},2)} &= -\sum_{k\in\mathcal{K}^*} \left(\mu_k^{\mathrm{ec}} + \tfrac{1}{2}\left(\mathbf{v}_k - \mathbf{v}_{\mathrm{s}}\right)^2\right) \hat{\rho}^k , \\ T\underline{\hat{S}}_{(\mathrm{i},2)} &= -\sum_{k\in\mathcal{K}^*} \left(\mu_k^{\mathrm{ec}} + \tfrac{1}{2}\left(\mathbf{v}_k - \mathbf{v}_{\mathrm{s}}\right)^2\right) \hat{m}^k . \end{aligned} \tag{4.7.31}$$

Constitutive equations of mass transfer are guided by satisfaction of the inequality $\hat{S}_{(\mathrm{i},2)} \geq 0$. Thus mass transfers are driven by differences in electrochemical potentials. To realize this point, consider a closed system with two species/compartments: then $\hat{\rho}^1 + \hat{\rho}^2 = 0$, and therefore $T\hat{S}_{(\mathrm{i},2)} = -(\mu_1 - \mu_2)\,\hat{\rho}^1 \geq 0$. In words, mass transfers from the compartment of higher electrochemical potential to the compartment of lower electrochemical potential. Linear and nonlinear constitutive equations of mass transfer are proposed in Chapter 10.

3. $\hat{S}_{(\mathrm{i},3)}$ gives rise to **coupled generalized diffusion**:

$$\begin{aligned} T\hat{S}_{(\mathrm{i},3)} &= -\Big(\frac{\mathbf{Q}}{T} + \sum_{k\in\mathcal{K}^{**}} s_k\,\mathbf{M}_k\Big)\cdot\boldsymbol{\nabla}T - \sum_{k\in\mathcal{K}^{**}} \mathbf{M}_k\cdot\Big(\boldsymbol{\nabla}\mu_k^{\mathrm{ec}} + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big), \\ T\underline{\hat{S}}_{(\mathrm{i},3)} &= -\Big(\frac{\underline{\mathbf{Q}}}{T} + \sum_{k\in\mathcal{K}^{**}} s_k\,\underline{\mathbf{M}}_k\Big)\cdot\underline{\boldsymbol{\nabla}}T - \sum_{k\in\mathcal{K}^{**}} \underline{\mathbf{M}}_k\cdot\underline{\boldsymbol{\nabla}}\mu_k^{\mathrm{ec}} + \mathbf{F}\cdot\underline{\mathbf{M}}_k\cdot\Big(\frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big). \end{aligned} \tag{4.7.32}$$

The species which move with the solid velocity are definitely not involved in (4.7.32), so that summation extends over the set $\mathcal{K}^{**}$. The term

$$\frac{\mathbf{Q}}{T} + \sum_{k\in\mathcal{K}^{**}} s_k\,\mathbf{M}_k , \tag{4.7.33}$$

is referred to as total entropy flux. Uniform body forces $\mathbf{b}_k$ can be viewed as introducing a sedimentation contribution into the electro-chemomechanical potentials.

The species that have the same velocity as the solid have to be eliminated, or kept, in (4.7.28) and (4.7.31) according to the same rule. A priori, we would like to involve the maximum number of species, even those that move with the solid velocity. One possibility is to consider only the species that transfer, and then the set for the summation in (4.7.28) is $\mathcal{K}^*$. But in that way, we tacitly imply that the species that are not involved in (4.7.31) do not transfer, because we will not have constitutive equations for their transfer. Conversely, if the latter were subjected to transfer, they would have to be endowed with a chemical potential, either in scalar form, or in tensorial form (Eshelby stress). In the framework we have in mind, Eshelby stresses would appear for species that grow. The latter are assumed to move with the same velocity as the solid, so that their fluxes relative to the solid vanish. Thus Eshelby stresses do not appear here, because they are conjugated to vanishing fluxes, Section 6.3 of Loret and Simões [2005]b. We will summarize the state of affairs in Section 21.4.1 later.

The inequality $\underline{\hat{S}}_{(\mathrm{i},3)} \geq 0$ is used to formulate the constitutive equations of generalized diffusion, with possible couplings between Darcy's, Fick's, Fourier's and Ohm's laws. Examples are provided in Section 9.3.3 which addresses thermoosmosis and in Chapter 16 which addresses coupled fluid flow, ionic diffusion and electromigration.

Note 4.7 on a more general formulation with electrochemical potentials in tensor form.

In the above decomposition of the dissipation in three terms, use has been made of the fact that the non growing species are endowed with an isotropic partial stress, leading to an isotropic chemical potential tensor. If this assumption is not used, then we are to be content with a decomposition in two parts only,

$$\begin{aligned} T\hat{S}_{(\mathrm{i},1,2,4)} &= -\frac{dE}{dt} - E\,\mathrm{div}\,\mathbf{v}_\mathrm{s} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_\mathrm{s} - S\,\frac{dT}{dt} - \sum_{k\in\mathcal{K}^{**}} \Big(\boldsymbol{\nabla}\mathbf{M}_k : \boldsymbol{\mu}_k^{\mathrm{ec}} + \tfrac{1}{2}\,\hat{\rho}^k\,\big(\mathbf{v}_k - \mathbf{v}_\mathrm{s}\big)^2\Big) - T\,\hat{S}_{(\mathrm{e})}\,, \\ T\hat{S}_{(\mathrm{i},3)} &= -\Big(\frac{\mathbf{Q}}{T} + \sum_{k\in\mathcal{K}^{**}} s_k\,\mathbf{M}_k\Big)\cdot\boldsymbol{\nabla}T - \sum_{k\in\mathcal{K}^{**}} \mathbf{M}_k\cdot\Big(\mathrm{div}\,\boldsymbol{\mu}_k^{\mathrm{ec}} + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big)\,. \end{aligned} \tag{4.7.34}$$

For the species whose partial stress is isotropic, the electrochemical potential tensor $\boldsymbol{\mu}_k^{\mathrm{ec}}$ becomes equal to $\mu_k^{\mathrm{ec}}\,\mathbf{I}$. Then the term $\mathbf{M}_k\cdot\mathrm{div}\,\boldsymbol{\mu}_k^{\mathrm{ec}}$ becomes $\mathbf{M}_k\cdot\boldsymbol{\nabla}\mu_k^{\mathrm{ec}}$ while $\boldsymbol{\nabla}\mathbf{M}_k : \boldsymbol{\mu}_k^{\mathrm{ec}}$ simplifies to $\mu_k^{\mathrm{ec}}\,\mathrm{div}\,\mathbf{M}_k$. The divergence term $\mathrm{div}\,\mathbf{M}_k$ can be eliminated in favor of dm^k/dt and $\hat{\rho}^k$ using the balance of mass (4.4.9), and this manipulation gives rise to the decomposition of the dissipation in three parts.

Note 4.8 on a more general formulation with active transports.

We have split the (single) entropy inequality into three or four parts, each one being in turn required to be positive or zero. This formalism is not as drastic as it could be thought a priori. Indeed, a redefinition of the various entities can be called for, if necessary. For example, we have tacitly assumed that the contribution by the surroundings $\hat{S}_{(\mathrm{e})}$ is completely diverted to mechanics and growth.

Let us consider active transfer or active diffusion, with energy providers (cells delivering ATP) being exterior to the system. Then the individual contributions to mechanics, transfer, diffusion and growth emanating from the total $\hat{S}_{(\mathrm{e})}$ should be delineated. This split embodies a competition for energy among the physical phenomena at hand.

4.8 Dissipation mechanisms

Constitutive assumptions are needed to split the thermomechanical part from the growth contribution in the dissipation (4.7.28). Constitutive assumptions for the growth rate can then be deduced.

In presence of chemomechanical couplings in geomechanics and biomechanics, the entropy production is contributed by mechanics via viscous effects, and plastic effects in the case of geomaterials, by mass transfer and by generalized diffusion. Following the standard thermodynamic approach, e.g., Kestin [1968], each of these phenomena contributes additively to the entropy production in the form of the product of a thermodynamic force f and of a flux $d\xi/dt$, of appropriate tensorial nature,

$$\hat{S}_{(\mathrm{i})} = \cdots - f\,\frac{d\xi}{dt}\cdots\,. \tag{4.8.1}$$

The entropy productions $\hat{S}_{(\mathrm{i},2)}$ due to mass transfer and $\hat{S}_{(\mathrm{i},3)}$ due to generalized diffusion are almost in this standard format, namely a sum of such products. Constitutive equations motivated by these expressions have been developed in Gajo and Loret [2003] [2004], Loret et al. [2004]b for geomaterials and in Loret and Simões [2004] [2005]a for articular cartilages.

4.8.1 Dissipation due to generalized diffusion and transfer

Generalized diffusion includes thermal effects (Fourier's law), seepage of water through the solid skeleton (Darcy's law), diffusion of species in water (Fick's law) and electrical flow (Ohm's law). The couplings between the different diffusion phenomena that occur in an electrolyte can not be neglected. As an algebraic consequence, the associated diffusion matrix is not diagonal. In fact, parameter identification requires a rewriting of the dissipation due to diffusion in terms of entities more accessible to measurements than electrochemical potentials, as stressed in the above papers and in Chapter 16. The coupled constitutive equations for generalized diffusion express the fluxes in terms of the driving forces via a symmetric matrix which has to be positive (semi-)definite, but that may well depend on the material state.

These equations apply in continua but they may be used as well to describe passive transport across a cellular membrane. If only a single ionic species is allowed to cross the membrane, equilibrium implies the electrochemical potentials on both sides of the membrane to be equal and the rest potential is the Nernst potential. On the other hand,

for an electrogenic membrane crossed by several ionic species, the rest potential is provided either by the Huxley-Hodgkin-Katz (HHK) formula phrased in terms of permeabilities and concentrations, or by the chord conductance equation, phrased in terms of conductances and Nernst potentials, Sperelakis [2001]. In a passive transport, the motion takes place *against* a gradient. On the other hand, active transport, where the motion using available energy (in the form of ATP) may take place *along* a gradient, is usually described empirically by kinematics associated with reversible or irreversible enzymatic reactions, Section 15.12.2.

The dissipation associated with mass transfer simply indicates that the rate of mass transfer is a function of the out-of-balance between electrochemical potentials. In fact, due to electroneutrality, the out-of-balance driving force can be expressed in terms of chemical potentials of electroneutral salts, Loret and Simões [2007]. In our previous works, linear and exponential constitutive equations of mass transfer have been proposed, and the coupling between species has been ignored, so that the transfer matrix was diagonal.

4.8.2 Spontaneous reactions and stable configurations

It is appropriate to highlight here the connections between these continuum thermodynamic developments and chemical thermodynamics and in particular the interpretation of mass transfer as a physico-chemical reaction, possibly involving several species endowed with distinct free enthalpies of formation, resulting in an equilibrium constant nonequal to unity.

In agreement with the above constitutive equation of mass transfer, chemical equilibrium between two thermodynamic states is defined by a vanishing variation of *free enthalpy* ΔG. If the free enthalpy of the final state is lower than initially, $\Delta G < 0$, the reaction is said exergonic, and *spontaneous* at fixed pressure and temperature. Otherwise, i.e., if $\Delta G > 0$, some form of energy should be provided for the reaction to occur and the reaction is said endergonic[4.3]. In continuum thermodynamics, the free enthalpy of species is called (electro)chemical potential because it is the chemical work that a substance can provide.

The variation of free enthalpy ΔG, at constant temperature T, is equal to $\Delta H - T\,\Delta S$, where ΔH is the variation of *enthalpy* and ΔS the variation of *entropy*. Enthalpy is a measure of heat content. Depending whether the reaction takes place with $\Delta H < 0$ or $\Delta H > 0$, it is said exothermic or endothermic. For example, the reaction $H_2 + \frac{1}{2}O_2 \rightarrow H_2O$ is exothermic and $\Delta H = -287\,\mathrm{kJ/mole}$. When NaCl is dropped in a reservoir filled with water, the reservoir cools because it has given heat for the dissolution to take place, $\Delta H = +3.8\,\mathrm{kJ/mole}$.

Entropy is usually viewed as a measure of *molecular disorder*. It is larger for systems whose order is low, as shown in Section 3.2.1 in relation to phase change. If, during a reaction, the order increases, then the associated $\Delta S < 0$ is negative. For example, the gas mixture of H_2 and O_2 has a larger entropy than water H_2O and the reaction $H_2 + \frac{1}{2}O_2 \rightarrow H_2O$ has $-T\,\Delta S = 49\,\mathrm{kJ/mole}$ at T=20 °C. Therefore the reaction is spontaneous since $\Delta G = -238\,\mathrm{kJ/mole}$ is negative.

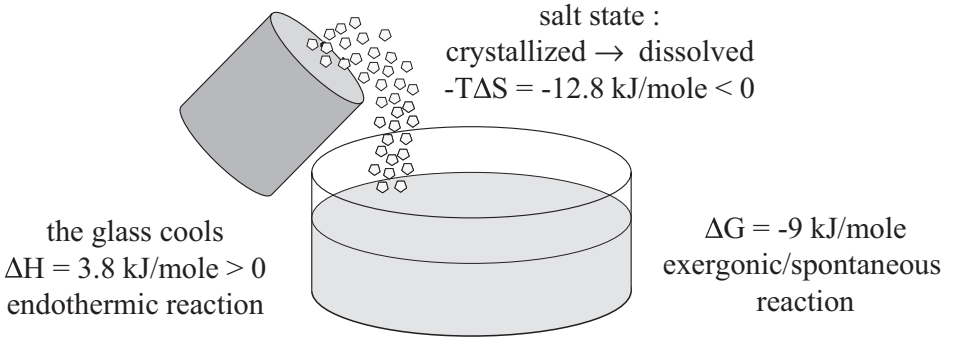

Fig. 4.8.1: An endothermic chemical reaction may be spontaneous if it is sufficiently entropy-driven.

[4.3] A heat engine receives heat from a heat source (like a boiler, or a device burning fossil or nuclear fuels), produces mechanical work, and transfers some remaining heat to a heat sink. Conversely, heat pumps receive work and transfer heat from a source at lower temperature to a source at higher temperature: there is no contradiction with the second principle of thermodynamics because the thermal flow is no longer spontaneous, but mechanically activated. Refrigerators and geothermal heat pumps are instances of heat pumps. Refrigerators aim primarily at extracting heat from the source at lower temperature, while geothermal heat pumps are designed to transfer heat to the source at higher temperature.

Let us consider again the dissolution of NaCl in water, Fig. 4.8.1. NaCl initially crystallized has a high order of organization while, when dissolved in water, the ions Na^+ and Cl^- move randomly. Therefore dissolution of NaCl in water is associated with $\Delta S > 0$, in fact, at ambient temperature, $-T\,\Delta S = -12.8\,\text{kJ/mole}$.

This example of dissolution of salt in water is a bit peculiar because it is exergonic, i.e. spontaneous, $\Delta G = -9\,\text{kJ/mole} < 0$, while endothermic, $\Delta H = +3.8\,\text{kJ/mole} > 0$. Therefore, even if quite often $\Delta G \sim \Delta H$, *an endothermic reaction may occur spontaneously if it is (sufficiently) entropy-driven.*

Table 4.8.1: Variations of enthalpy ΔH and free enthalpy ΔG [unit : kJ/mole] associated with the formation of two sequences of amino-acids, Pálfi and Perczel [2008].

	ΔH		ΔG	
Sequence	Triple Helix	β-Pleated Sheet	Triple Helix	β-Pleated Sheet
-Gly-Gly-Gly	-129.3	-286.7	113.8	-68.6
-Gly-Hyp-Pro	-169.9	-65.7	-5.4	54.8

The existence and stability of certain biological structures in preference to others are often dictated by energetic considerations. These structures may differ by their composition or by their spatial conformation. Collagen chains are formed by the repetition of basic units of three amino-acids, -Gly-X-Y, where Gly is the amino-acid glycine, and X and Y may be one of the twenty amino-acids. For example, we consider the sequences -Gly-Gly-Gly, and -Gly-Hyp-Pro where Hyp is hydroxyproline and Pro proline. These two sequences aggregate into chains that form triple helices or triple stranded β-pleated sheets. The changes of enthalpy and free enthalpy associated with the formation of these structures starting from the individual chains are listed in Table 4.8.1.

The entropy variation corresponding to a higher organization is negative. The sequence -Gly-Gly-Gly is more likely to exist under the form of β-pleated sheets, while the sequence -Gly-Hyp-Pro is more likely to exist as a triple helix. β-pleated sheets are known to be associated with diseases that affect the central nervous system.

At a higher scale, the assembly of collagen molecules into fibrils is again both endothermic and exergonic (spontaneous), possibly due to entropy increase associated with loss of water from bound monomers or to hydrophilic interactions. At still higher scales, collagen fibrils organize into various spatial structures that serve best the physiological role of the tissues, e.g., parallel arrays in tendons and ligaments. The cornea and annulus fibrosus are made of a number of lamellae in which the collagen fibers adopt a strictly identical direction. This direction changes abruptly from lamella to lamella. This organization is thought to optimize transparency in the cornea and to resist clockwise and anticlockwise torsion in the annulus fibrosus. In the central zone of articular cartilages the directional distribution of collagen fibers is roughly random, while fibers are aligned normal to the subchondral bone in the lower zone and parallel to the synovial joint in the upper zone.

In a thermodynamic approach to mixture, the key role of the free enthalpy, or chemical potential, of a chemical species is made clear when we introduce the second principle and the Clausius-Duhem inequality. Chemical potentials are basic entities to the development of the chemomechanical constitutive equations and of the constitutive equations of mass transfer, Chapter 10, and for generalized diffusion, Chapter 16.

4.8.3 Coupled chemical reactions

While it may not be spontaneous by itself, a chemical reaction may turn so when coupled with one or several other reactions. In the context of chemistry, coupling between two reactions implies that the reactions share, perhaps temporarily, some chemicals. Indeed, the existence of a source of energy is not enough. A key issue is to find out a device to make use of this energy (perhaps only a part of it, as its efficiency will probably, and even certainly, not be complete).

The concept of *coupling* may be also explained via a mechanical analogy. Consider two identical masses 1 and 2, which are subjected to gravity, Fig. 4.8.2. The issue is to lift mass 1: this experiment requires energy to be provided to the mass. The question is: how to use the energy provided by dropping mass 2 ? Dropping mass 2 alone won't help. Some device should be invented to transfer directly this energy (or perhaps part of it only due to dissipation) to mass 1. Connecting the two masses through a rope attached to a pulley will solve the problem ... The energy released by mass 2 is used by mass 1.

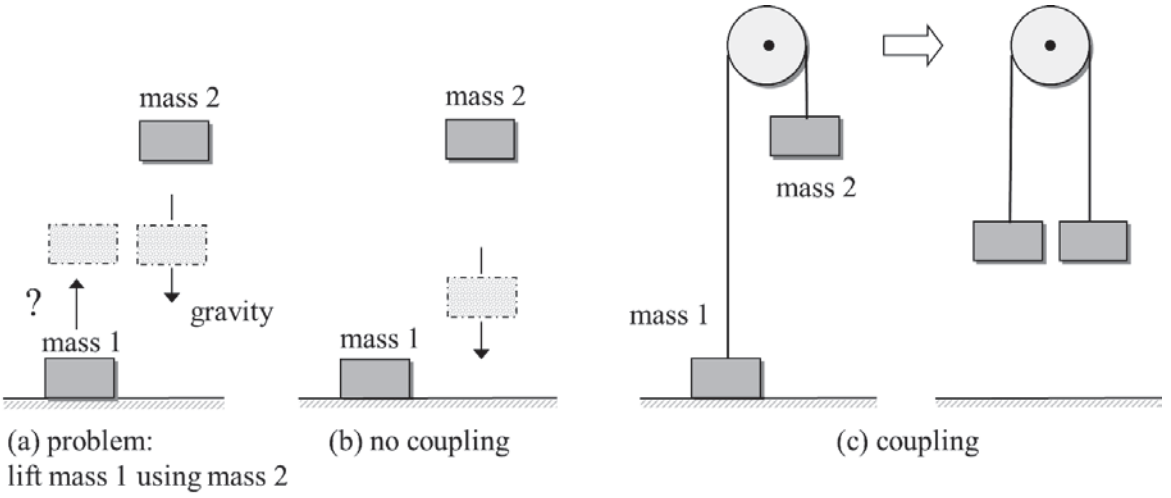

Fig. 4.8.2: Illustrative strategy of mechanical coupling, from APB [1999], p. 15.

As an example, consider two independent reactions,

$$\begin{aligned} \mathrm{A} \quad &\rightleftharpoons \quad \mathrm{B}, \quad \Delta g_1^0 > 0, \\ \mathrm{C} \quad &\rightleftharpoons \quad \mathrm{D}, \quad \Delta g_2^0 < 0\,, \end{aligned} \tag{4.8.2}$$

the first one being endergonic (and therefore not spontaneous), while the second one is exergonic (and therefore spontaneous)[4.4]. This information is delivered by the sign of the change of the standard chemical potential Δg_k^0, $k = 1, 2$. Indeed, the equilibria of these two reactions expressed in terms of concentrations point to the left and to the right respectively,

$$\frac{c_B}{c_A} = K_1^{\mathrm{eq}} = \exp\big(-\frac{\Delta g_1^0}{RT}\big) < 1, \quad \frac{c_D}{c_C} = K_2^{\mathrm{eq}} = \exp\big(-\frac{\Delta g_2^0}{RT}\big) > 1\,. \tag{4.8.3}$$

Assume that we can couple the two reactions (ideally, that is without loss of energy),

$$\mathrm{A} + \mathrm{C} \quad \rightleftharpoons \mathrm{B} + \mathrm{D}, \quad \Delta g_{1+2}^0 = \Delta g_1^0 + \Delta g_2^0\,. \tag{4.8.4}$$

The *new* equilibrium is defined by

$$\frac{c_B}{c_A}\frac{c_D}{c_C} = K_{1+2}^{\mathrm{eq}} = \exp\big(-\frac{\Delta g_{1+2}^0}{RT}\big) = K_1^{\mathrm{eq}}\, K_2^{\mathrm{eq}}\,. \tag{4.8.5}$$

This equilibrium is shifted to the right with respect to the first independent reaction,

$$\frac{c_B}{c_A} = K_{1+2}^{\mathrm{eq}}\,\frac{c_C}{c_D} > K_1^{\mathrm{eq}}\,, \tag{4.8.6}$$

if the concentrations of the species involved in the second reaction which are thought to be clamped satisfy the condition,

$$\frac{c_C}{c_D} > \frac{1}{K_2^{\mathrm{eq}}}\,. \tag{4.8.7}$$

Typically, in biological systems, the second reaction involves ATP. The inequality means that the concentration of ATP should be sufficiently large so that ATPase can take place, as argued in Section 20.2.2. Another example with an electrogenic ionic pump is exposed in Section 19.3.3.3.

[4.4] The distinction between endergonic and endothermic reactions, and exergonic and exothermic reactions, is highlighted in Section 4.8.2.

4.8.4 Dissipation associated with a chemical reaction

The contribution due to mass transfers to the dissipation inequality (4.7.31) can be used to estimate the dissipation associated with chemical reactions. Indeed, if the kinetic terms are neglected and if the (electro)chemical potentials per unit mole are used rather than per unit mass, refer to (3.1.6) or (4.7.21) for definitions, the dissipation (4.7.31) may be brought to the format (3.1.19),

$$-\sum_{j=1}^{n} g_j^{\rm ec}\, dN_j = -\mathcal{G}\, d\xi \geq 0\,, \tag{4.8.8}$$

where n is the number of chemicals involved in the reaction, and $\mathcal{G}$ and ξ are respectively the chemical affinity and advancement of the reaction defined in Section 3.1.5.

The dissipation inequality requires this quantity to be positive. According to (3.1.4) and (3.1.19), this requirement is equivalent to a negative change of the Gibbs energy during the reaction at constant pressure and temperature.

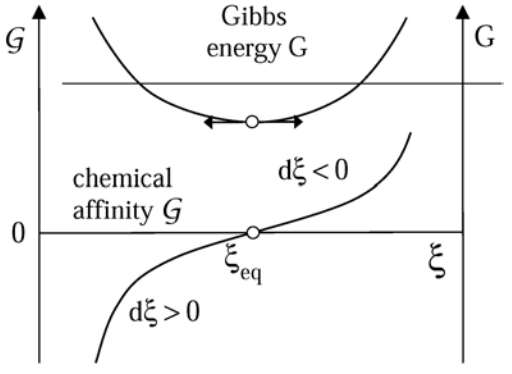

Fig. 4.8.3: Assumed thermodynamic properties of the Gibbs energy G and chemical affinity $\mathcal{G}$ in the vicinity of an equilibrium.

Moreover from (3.1.19),

$$\mathcal{G} = \frac{\partial G}{\partial \xi}_{|p,T}\,, \qquad \frac{\partial \mathcal{G}}{\partial \xi}_{|p,T} = \frac{\partial^2 G}{\partial \xi^2}_{|p,T}\,. \tag{4.8.9}$$

Requiring a stable equilibrium $\xi = \xi_{\rm eq}$ amounts to a positive second derivative $\partial^2 G/\partial \xi^2 > 0$, which, together with the inequality $-\mathcal{G}\, d\xi \geq 0$ leads, in the vicinity of an equilibrium, to the configuration sketched in Fig. 4.8.3. A particular case is considered in Section 3.1.7.1 and illustrated by Fig. 3.1.2 where $J = d\xi/dt$. For a quantified example, see Kestin [1968], p. 295, where the Gibbs energy and chemical affinity are plotted during the dissociation of water vapor $2\,H_2O \rightleftharpoons 2\,H_2{+}O_2$ at constant pressure and temperature (notice that his chemical affinity is the negative of the one used here).

4.8.5 Are growth and structuration dissipative processes?

A useful hint for the thermodynamic analysis of a mixture is the two-step application of the second principle, Krishnaswamy and Batra [1997], Klisch and Hoger [2003]. A set of state variables **A** is defined as well as a set of all variables **B** including diffusion fluxes, thermal and velocity gradients, etc. Equilibrium paths for which $\mathbf{B} \sim \mathbf{A}$ are assumed to be path-independent, or reversible: this assumption turns the second principle into an equality for equilibrium paths and allows to define the entropy, a constructed entity rather than a primitive function, as a function of **A**. This property is adopted for arbitrary processes, e.g., when diffusion occurs due to distinct velocities of the species. However arbitrary processes are a priori not reversible and they are constrained by the entropy inequality. This viewpoint is in line with Ericksen [1991] who showed that (thermal or hydraulic) diffusion can not be considered as a reversible process.

In relation with the above point, Krishnaswamy and Batra [1997] and Klisch and Hoger [2003] define materials that can not experience reversible growth and materials that can. As an example worked out by Klisch and Hoger [2003],

their section 3.3, reversible growth is possible under equilibrium paths if the growth law $\mathbf{L}^{\rm g} = \mathcal{L}(\mathbf{L}^{\rm e}, \dots)$ which provides the rate of growth in terms of the elastic velocity 'gradient' $\mathbf{L}^{\rm e}$ verifies the property,

$$\mathcal{L}(-\mathbf{L}^{\rm e}, \cdots) = -\mathcal{L}(\mathbf{L}^{\rm e}, \cdots)\,. \tag{4.8.10}$$

Now, it remains to assess what is the practical significance of the notion of (ir)reversible growth. Are the natural and engineered growths of cartilage reversible or irreversible in the above sense ?

In fact, even if metabolic reactions are nowadays commonly given the possibility to be two-way, in practice some reactions are mainly in one direction. Indeed, anabolism and catabolism, and growth and degradation, usually do not follow the same paths and require or provide energy. They are to be definitely irreversible. For example, the energetic profile of glycolysis displayed in Fig. 20.2.3 shows three steps with significant decrease of free enthalpy, namely

- hexokinase/glucokinase that controls the rate of entrance of glucose into the pathway;
- phospho-fructokinase 1 which gives the limiting rate to the glycolysis;
- pyruvate kinase that controls the production of the glycolysis.

These steps are irreversible and they are bypassed during neo-glycogenesis. The other steps of glycolysis are practically reversible and indeed they are followed in reverse direction during neo-glycogenesis. The formation of highly energetic triglycerides from fatty acids in adipocytes, and their hydrolysis, are similarly considered irreversible.

Still, there might exist growth mechanisms that can be considered to be reversible, perhaps depending on the definition of reversibility.

Another issue to be addressed arises in presence of mechanisms that contribute negatively to the dissipation. Self-healing phenomena of geological and engineering materials belong to this category, Section 23.8. In the framework of growth of tissues, mechanisms that endow the tissues with a structure, a concept that takes several forms, are potential candidates to enter the issue. The consequences on the growth rate are considered in the framework of elastic-growing mixtures in Chapter 23.

4.8.6 Onsager relations and rate potential

The entropy production of the mixture associated with growth, remodeling, structuration, deformation and dissipation $\hat{S}_{(\mathrm{i},1,4)}$ is postulated in the format of Eqn (4.8.1),

$$T\hat{S}_{(\mathrm{i},1,4)} = -\sum_{k\in\mathcal{S}^*} \mathbf{f}_k : \mathbf{L}^{\rm g}_k - \sum_{k\in\mathcal{S}^*} R_k \frac{dr^k}{dt} - \sum_{n\in\mathcal{N}} X_n \frac{d\xi_n}{dt} \geq 0\,. \tag{4.8.11}$$

This expression implies that growth and remodeling, corresponding to the first and second terms in (4.8.11), contribute independently to dissipation. The dissipation mechanism due to mechanical viscosity is accounted for by $n = 1$, and the mechanisms $n \in \mathcal{N}$, $n \neq 1$, account for other sources of structuration and dissipation. They might be of scalar, vector or tensor natures.

In order to ensure positiveness of the entropy production associated with mechanics and growth, one may use, close to equilibrium, the Onsager formalism. An alternative nonlinear form is proposed later for scalar variables.

Assuming for simplicity that couplings occur only within each of the three groups displayed in (4.8.11), the driving forces may be considered linear with respect to the rates,

$$-\mathbf{f}_k = \sum_{l\in\mathcal{S}^*} \mathbf{L}^{\rm g}_l : \boldsymbol{\mathcal{F}}_{lk}, \quad k\in\mathcal{S}^*; \qquad -R_k = \sum_{l\in\mathcal{S}^*} \frac{dr^l}{dt}\,\mathcal{R}_{lk}, \quad k\in\mathcal{S}^*; \qquad -X_n = \sum_{l\in\mathcal{N}} \frac{d\xi_l}{dt}\,\mathcal{X}_{ln}, \quad n\in\mathcal{N}\,, \tag{4.8.12}$$

where $\boldsymbol{\mathcal{F}}$, $\mathcal{R}$ and $\mathcal{X}$ are *symmetric* and *(semi-)positive definite* 'matrices' of appropriate size and nature. The symmetry is a choice, motivated by the fact that the skew-symmetric parts of these matrices are elusive in the dissipation rate. Uncoupling of the physical phenomenon k from the others is obtained by deleting all terms except the diagonal one, eg. $\mathcal{R}_{lk} = 0$, for all $l \neq k$, and, due to symmetry, $\mathcal{R}_{kl} = 0$, for all $l \neq k$.

The above matrices may be functions of the state variables, but they are a priori independent of the rates they multiply. Then the rate potential per unit reference volume $\Omega^{(\mathrm{i})}$,

$$\Omega^{(\mathrm{i})} = \sum_{k,l\in\mathcal{S}^*} \frac{1}{2}\mathbf{L}^{\rm g}_l : \boldsymbol{\mathcal{F}}_{lk} : \mathbf{L}^{\rm g}_k + \sum_{k,l\in\mathcal{S}^*} \frac{1}{2}\frac{dr^l}{dt}\,\mathcal{R}_{lk}\,\frac{dr^k}{dt} + \sum_{l,n\in\mathcal{N}} \frac{1}{2}\frac{d\xi_l}{dt}\,\mathcal{X}_{ln}\frac{d\xi_n}{dt} \geq 0\,, \tag{4.8.13}$$

is homogeneous of degree 2 with respect to the dissipation rates, so that

$$T\hat{S}_{(\mathrm{i},1,4)} = 2\,\Omega^{(\mathrm{i})} = \sum_{k\in\mathcal{S}^*} \frac{\partial\Omega^{(\mathrm{i})}}{\partial \mathbf{L}^{\mathrm{g}}_k} : \mathbf{L}^{\mathrm{g}}_k + \cdots \geq 0\,. \tag{4.8.14}$$

Under these assumptions, equilibrium, defined by the vanishing of the rates $\mathbf{L}^{\mathrm{g}}_k \cdots$, clearly corresponds to the minimum of the entropy production. That is, out-of-equilibrium excursions necessarily increase the entropy production, in agreement with the arguments of Section 4.7.4.2.

Note 4.9 on nonlinear internal entropy production.

The nonlinear dissipation law proposed in Chapter 10 aims at bounding the rates (fluxes) when the thermodynamic forces (gradients) become large.

Another type of nonlinearity may be introduced through the existence of a surface in the space of thermodynamic forces. Vanishing fluxes may imply the thermodynamic forces to vanish or simply to remain in some prescribed domain.

4.9 General constitutive principles

In an axiomatic or rational (in a Noll and Truesdell perspective) analysis, there are five basic principles that have to be satisfied by constitutive equations, whether for a single body or for mixtures, e.g., Mandel [1974], p. 79, Truesdell [1984], p. 230. They are conceived as 'rules to guide us when we come to set up constitutive relations in the first place', Wang and Truesdell [1973], p. 135. They are briefly stated below:

1. *Determinism* asserts that natural phenomena can be described and predicted. There exists a set of variables such that the knowledge of their past and present values determines the present response of the mixture.
2. *Equipresence* states that any 'quantity present as an independent variable in one constitutive relation must be assumed so present in all', Wang and Truesdell [1973], p. 141. Passman et al., p. 301 in Truesdell [1984], find the principle applicable to single bodies and homogeneous mixtures, but they replace it by the *Principle of phase separation* for inhomogeneous mixtures. The latter states that the principle of equipresence applies to individual phases in terms of their *own* set of independent variables, while interaction and exchange terms follow the general principle of equipresence in terms of *all* independent variables. An example is shown in Section 4.5.4.
3. *Local action* implies that the constitutive response of the species at a point of space depends only of the thermokinetic processes in a close neighborhood of that point. This principle is removed for non local constitutive equations of the integral type where the material response at a point depends on the thermokinetic processes in a domain of non zero measure around that point. Whether constitutive equations involving higher order gradients estimated at the point of interest follow the principle or not is a bit more debatable.
   Non local effects have been advocated to smooth out discontinuities and failure processes in engineering materials, as they regularize the mathematical partial differential equations and restore the well-posedness of boundary value problems. Typically, the thickness of intense straining in cohesionless granular materials is observed to extend over a few grains. Long range interactions are also advocated in biological tissues modeling. Murray [2003] points out the role of long sensors (the filopodia) that are attached to the cells and that extend far, further than next neighbors, in the extracellular matrix. Their role seems significant in providing information on the matrix mass density. They are also advocated to signal the presence of a neighboring cell: upon reception of this information, the cell stops, deflects, or even reverses, its motion.
4. *Material frame-indifference* requires that the constitutive equations of the species are independent of the observer.
5. *Dissipation* requires some form of the second principle to be satisfied for any thermokinetic processes.

To these five statements, Wang and Truesdell [1973], p. 135, add a sixth physical principle that allows for specialization, namely

6. *Material symmetry.* There exists a symmetry group, or group of invariance, describing the properties of the body, which leaves unchanged the constitutive equations. The simplest case is that of a mixture of one solid and several unstructured fluids: the mixture inherits the material symmetries of the solid.

When exploiting the dissipation inequality, and developing diffusion constitutive equations, it is a standard practice to use the *Onsager reciprocity relations* to express the 'fluxes' in terms of the 'forces', e.g., de Groot and Mazur [1962]. Having chosen what we call fluxes and what we call forces, the fluxes are expressed in terms of the forces via a *symmetric* (semi-)definite diffusion matrix. Once a choice has been made, one can embark in consistent modifications of the pairs that leave invariant the dissipation, Exercise 16.1.

Truesdell [1984], p. 365, criticizes at length the Onsagerist approach, that claims that the definition of fluxes and forces is dictated by the fact that the fluxes are the time derivatives of 'something' (a void statement: indeed let $f(t) = \int_0^t g(\tau)\, d\tau$, then $g(t) = df(t)/dt$). Truesdell [1984], p. 387 et seq., also smashes the so-called *Curie principle* according to which coupling between quantities of different tensorial character would be forbidden. In fact, representation theorems of isotropic functions circumvent, or solve, the issue.

The dissipation inequality is a powerful tool to develop constitutive equations and to restrict the number of arguments of the constitutive functions. The idea loosely referred to as *Coleman-Noll device*, Coleman [1964], is of pure algebraic nature. Let a and b be two independent dimensionless scalar variables and $A = A(a,b)$ and $B = B(a,b,db/dt)$ two constitutive functions that should satisfy the inequality

$$A(a,b)\, da + B(a,b,db/dt)\, db \geq 0, \quad \forall\, da,\ db\,. \tag{4.9.1}$$

Since da and db are arbitrary, let us choose first $db = 0$, $da = 1$, and next $db = 0$, $da = -1$, so that $A(a,b) \geq 0$ and $-A(a,b) \geq 0$. Then

$$A(a,b) = 0, \quad B(a,b,db/dt)\, db \geq 0, \quad \forall\, db\,. \tag{4.9.2}$$

The above equality on the left is a very strong result. The remaining inequality on the right is less clear-cut at first glance, it leaves more degrees of freedom to introduce viscous effects, but it usually provides tractable restrictions on the material coefficients, once an explicit form for $B(a,b,db/dt)$ has been chosen. Typically, $B(a,b,db/dt) = c\, db/dt$, where the material function c is independent of db/dt. Then $c \geq 0$. Examples of viscous tissues undergoing growth are considered in Section 21.6.4.

More advanced use of the inequality can be done to address a number of constitutive issues in the mechanics of materials, like irreversibilities or damage. Indeed, the idea is to postulate the existence of surfaces whose convexity is exploited. As an example, growth rate laws that comply with the dissipation inequality are worked out in Section 22.5, postulating the existence of convex homeostatic surfaces in stress space.

Appendix: Algebraic derivations for Chapter 4

• Proof of Eqn (4.5.6):

Take the barycentric derivative of $(4.3.4)_2$, namely $\rho\, \mathbf{v} = \sum_k \rho^k\, \mathbf{v}_k$, to obtain

$$\frac{D\rho}{Dt}\, \mathbf{v} + \rho\, \frac{D\mathbf{v}}{Dt} = \sum_{k\in\mathcal{K}} \rho^k\, \frac{d^k \mathbf{v}_k}{dt} + \frac{d^k \rho^k}{dt}\, \mathbf{v}_k - \boldsymbol{\nabla}(\rho^k \mathbf{v}_k)\cdot \overset{(b)}{\mathbf{v}}_k \quad \text{by (2.7.1), (4.3.5),} \tag{4.A.1}$$

and therefore, by (4.4.5), (4.4.7),

$$\begin{aligned}
\rho\, \frac{D\mathbf{v}}{Dt} &= \sum_{k\in\mathcal{K}} \rho^k\, \frac{d^k \mathbf{v}_k}{dt} + \hat{\rho}^k\, \mathbf{v}_k - \rho^k \mathbf{v}_k \,\mathrm{div}\, \mathbf{v}_k - \boldsymbol{\nabla}(\rho^k \mathbf{v}_k)\cdot \overset{(b)}{\mathbf{v}}_k - (\hat{\rho}\, \mathbf{v} - \rho\, \mathbf{v}\, \mathrm{div}\, \mathbf{v}) \\
&= \sum_{k\in\mathcal{K}} \rho^k\, \frac{d^k \mathbf{v}_k}{dt} + \hat{\rho}^k\, \overset{(b)}{\mathbf{v}}_k - \rho^k \mathbf{v}_k \,\mathrm{div}\, \overset{(b)}{\mathbf{v}}_k - \boldsymbol{\nabla}(\rho^k \mathbf{v}_k)\cdot \overset{(b)}{\mathbf{v}}_k \quad \text{by } (4.3.4)_2, (4.3.5) \\
&= \sum_{k\in\mathcal{K}} \rho^k\, \frac{d^k \mathbf{v}_k}{dt} + \hat{\rho}^k\, \overset{(b)}{\mathbf{v}}_k - \sum_{k\in\mathcal{K}} \mathrm{div}\,(\rho^k\, \mathbf{v}_k \otimes \overset{(b)}{\mathbf{v}}_k) \\
&= \sum_{k\in\mathcal{K}} \rho^k\, \frac{d^k \mathbf{v}_k}{dt} + \hat{\rho}^k\, \overset{(b)}{\mathbf{v}}_k - \sum_{k\in\mathcal{K}} \mathrm{div}\,(\rho^k\, \overset{(b)}{\mathbf{v}}_k \otimes \overset{(b)}{\mathbf{v}}_k) \quad \text{by (4.3.5)}\,.
\end{aligned} \tag{4.A.2}$$

Insertion of this relation in the sum over all species $k \in \mathcal{K}$ of the individual balances of momentum (4.5.5) yields

$$\mathrm{div}\, \boldsymbol{\sigma} + \rho\, (\mathbf{b} - \frac{D\mathbf{v}}{Dt}) + \sum_{k\in\mathcal{K}} \hat{\rho}^k\, (\tilde{\mathbf{v}}_k - \mathbf{v}) + \hat{\boldsymbol{\pi}}^k = \mathbf{0}\,. \tag{4.A.3}$$

Use of the closure relation (4.5.2) provides finally (4.5.6) □ .

• Proof of Eqn (4.6.17):

$$
\begin{aligned}
\frac{d\mathbb{C}}{dt} &= \sum_{k\in\mathcal{K}} \int_V \frac{\partial c_k}{\partial t} + \operatorname{div}(c_k\,\mathbf{v}_k)\; dV \quad \text{by } (2.7.5)_6 \\
&= \sum_{k\in\mathcal{K}} \int_V \frac{d^k c_k}{dt} + c_k \operatorname{div}\,\mathbf{v}_k\; dV \quad \text{by (2.7.1)} \\
&= \sum_{k\in\mathcal{K}} \int_V \rho^k \mathbf{v}_k \cdot \frac{d^k \mathbf{v}_k}{dt} + \frac{1}{2}\,\hat{\rho}^k \mathbf{v}_k^2\; dV \quad \text{by (4.4.5)} \\
&= \sum_{k\in\mathcal{K}} \int_V \mathbf{v}_{\mathrm{s}} \cdot \Big(\rho^k \frac{d^k \mathbf{v}_k}{dt} + \hat{\rho}_k\,\mathbf{v}_k - \hat{\rho}_k\,\frac{\mathbf{v}_{\mathrm{s}}}{2}\Big) + \mathbf{M}_k \cdot \frac{d^k \mathbf{v}_k}{dt} + \frac{\hat{\rho}^k}{2}\Big(\frac{\mathbf{M}_k}{\rho^k}\Big)^2 dV \quad \text{by (4.3.2), (4.4.3)} \\
&= \int_V \mathbf{v}_{\mathrm{s}} \cdot \operatorname{div}\,\boldsymbol{\sigma}^I + \mathbf{v}_{\mathrm{s}} \cdot (\rho\,\mathbf{b} + \hat{\mathbf{p}} - \hat{\rho}\,\frac{\mathbf{v}_{\mathrm{s}}}{2})\; dV \\
&\quad + \textstyle\sum_{k\in\mathcal{K}} \int_V \mathbf{M}_k \cdot \frac{d^k \mathbf{v}_k}{dt} + \frac{\hat{\rho}^k}{2}\Big(\frac{\mathbf{M}_k}{\rho^k}\Big)^2 dV \quad \text{by (4.5.9)} \\
&= \int_V -\boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} + \mathbf{v}_{\mathrm{s}} \cdot (\rho\,\mathbf{b} + \hat{\mathbf{p}} - \hat{\rho}\,\frac{\mathbf{v}_{\mathrm{s}}}{2})\; dV + \sum_{k\in\mathcal{K}} \int_V \mathbf{M}_k \cdot \frac{d^k \mathbf{v}_k}{dt} + \frac{\hat{\rho}^k}{2}\Big(\frac{\mathbf{M}_k}{\rho^k}\Big)^2 dV \\
&+ \sum_{k\in\mathcal{K}} \int_{\partial V} \big(\mathbf{v}_k \cdot \boldsymbol{\sigma}^k - \mathbf{M}_k \cdot \frac{\boldsymbol{\sigma}^k}{\rho^k}\big) \cdot d\mathbf{S}\;\square\,.
\end{aligned}
\tag{4.A.4}
$$

• Proof of the balance of energy (4.6.22) for the mixture by summation:
We start by deriving the local energy for the mixture $U = \sum_{k\in K} \rho^k\, u_k$.

$$
\begin{aligned}
\frac{dU}{dt} &= \sum_{k\in K} \frac{d^k \rho^k}{dt} u_k + \rho^k \frac{d^k u_k}{dt} - \boldsymbol{\nabla}(\rho^k u_k) \cdot (\mathbf{v}_k - \mathbf{v}_{\mathrm{s}}) \quad \text{by (2.7.1)} \\
&= \sum_{k\in K} -\rho^k u_k \operatorname{div}\mathbf{v}_k + \boldsymbol{\sigma}^k : \boldsymbol{\nabla}\mathbf{v}_k - \operatorname{div}\,\mathbf{Q}_k + \Theta_k - \boldsymbol{\nabla}(\rho^k u_k) \cdot (\mathbf{v}_k - \mathbf{v}_{\mathrm{s}}) \\
&\qquad + \hat{\rho}^k \big(\tilde{u}_k + \tfrac{1}{2}(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\big) + \hat{\mathcal{U}}^k \quad \text{by (4.4.5), (4.6.11)} \\
&= -U \operatorname{div}\mathbf{v}_{\mathrm{s}} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - \operatorname{div}\,\mathbf{Q}^I + \Theta^I + \sum_{k\in K} -\operatorname{div}(u_k\,\mathbf{M}_k) + \boldsymbol{\sigma}^k : \boldsymbol{\nabla}(\mathbf{v}_k - \mathbf{v}_{\mathrm{s}}) \\
&+ \sum_{k\in K} \hat{\rho}^k \big(\tilde{u}_k + \tfrac{1}{2}(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\big) + \hat{\mathcal{U}}^k \\
&= -U \operatorname{div}\mathbf{v}_{\mathrm{s}} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - \operatorname{div}\,\mathbf{Q}^I + \Theta^I + \sum_{k\in K} -\operatorname{div}(h_k\,\mathbf{M}_k) - \operatorname{div}\,\boldsymbol{\sigma}^k \cdot (\mathbf{v}_k - \mathbf{v}_{\mathrm{s}}) \\
&+ \sum_{k\in K} \hat{\rho}^k\,(\tfrac{1}{2}\mathbf{v}_k^2 - \tilde{\mathbf{v}}_k \cdot \mathbf{v}_k) - \hat{\boldsymbol{\pi}}^k \cdot \mathbf{v}_k + \hat{U} \quad \text{by (4.6.8), (4.6.9), (4.6.14)} \\
&= -U \operatorname{div}\mathbf{v}_{\mathrm{s}} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - \operatorname{div}\,\mathbf{Q}^I + \Theta^I + \sum_{k\in K} -\operatorname{div}(h_k\,\mathbf{M}_k) - \mathbf{M}_k \cdot (\frac{d^k \mathbf{v}_k}{dt} - \mathbf{b}_k) \\
&+ \sum_{k\in K} \hat{\rho}^k \big(\tfrac{1}{2}\mathbf{v}_k^2 - \tilde{\mathbf{v}}_k \cdot \mathbf{v}_k - (\mathbf{v}_k - \tilde{\mathbf{v}}_k) \cdot (\mathbf{v}_k - \mathbf{v}_{\mathrm{s}})\big) - \hat{\boldsymbol{\pi}}^k \cdot \mathbf{v}_{\mathrm{s}} + \hat{U} \quad \text{by (4.5.5)} \\
&= -U \operatorname{div}\mathbf{v}_{\mathrm{s}} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - \operatorname{div}\,\mathbf{Q}^I + \Theta^I + \sum_{k\in K} -\operatorname{div}(h_k\,\mathbf{M}_k) - \mathbf{M}_k \cdot (\frac{d^k \mathbf{v}_k}{dt} - \mathbf{b}_k) \\
&+ \sum_{k\in K} \hat{\rho}^k \big(-\tfrac{1}{2}\mathbf{v}_k^2 + \mathbf{v}_{\mathrm{s}} \cdot \mathbf{v}_k\big) - (\hat{\rho}^k\,\tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k) \cdot \mathbf{v}_{\mathrm{s}} + \hat{U} \\
&= -U \operatorname{div}\mathbf{v}_{\mathrm{s}} + \boldsymbol{\sigma}^I : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - \operatorname{div}\,\mathbf{Q}^I + \Theta^I + \sum_{k\in K} -\operatorname{div}(h_k\,\mathbf{M}_k) - \mathbf{M}_k \cdot (\frac{d^k \mathbf{v}_k}{dt} - \mathbf{b}_k) \\
&+ \sum_{k\in K} -\frac{\hat{\rho}^k}{2}\Big(\frac{\mathbf{M}_k}{\rho^k}\Big)^2 + \hat{\rho}\,\frac{\mathbf{v}_{\mathrm{s}}^2}{2} - \hat{\mathbf{p}} \cdot \mathbf{v}_{\mathrm{s}} + \hat{U} \quad \text{by (4.5.2)}\;\square\,.
\end{aligned}
\tag{4.A.5}
$$

Chapter 5

Anisotropic and conewise elasticity

Given that many biological tissues are reinforced by a collagen network, it is appropriate to emphasize their mechanical anisotropy. Since the collagen fiber response differs much according to the compressive or tensile nature of the load, this aspect, coined conewise mechanical response, is worth to be scrutinized. The first section serves to illustrate the different types of elasticity that are used to reproduce aspects of the mechanical response of solids.

5.1 Hypoelasticity, elasticity and hyperelasticity

Based on experimental data or theoretical conceptions, a number of elastic models with stress or strain dependent moduli have been proposed. Attention is focused here on the consequences of this dependency on the recoverability of strain and work done in a closed stress path. Necessary and sufficient conditions for an elastic material to be hyperelastic are given. The purpose is illustrated by examples and requires only the simplest setting, namely isotropic materials and infinitesimal strains. The exposition follows closely Loret [1985].

It is instrumental to decompose the strain $\boldsymbol{\epsilon}$ and stress $\boldsymbol{\sigma}$ into their isotropic and deviatoric parts, namely

$$\boldsymbol{\epsilon} = \epsilon_v \, \frac{\mathbf{I}}{3} + \mathbf{e}, \quad \text{with} \quad \epsilon_v = \operatorname{tr} \boldsymbol{\epsilon} \,, \tag{5.1.1}$$

and

$$\boldsymbol{\sigma} = p \, \mathbf{I} + \mathbf{s}, \quad \text{with} \quad p = \frac{1}{3} \operatorname{tr} \boldsymbol{\sigma} \,. \tag{5.1.2}$$

Besides the first order scalar invariants, namely the volume change ϵ_v and the mean stress p, the second order invariants, referred to as shear stress q and shear strain ϵ_q, namely

$$q = (\tfrac{3}{2} \, \mathbf{s} : \mathbf{s})^{1/2}, \quad \epsilon_q = (\tfrac{2}{3} \, \mathbf{e} : \mathbf{e})^{1/2} \,, \tag{5.1.3}$$

will be needed. The increments of strain energy $\mathcal{W}$ and complementary energy $\mathcal{W}_c$ can then be decomposed as follows,

$$\begin{aligned} \delta \mathcal{W} &= \boldsymbol{\sigma} : \delta \boldsymbol{\epsilon} = p \, \delta \epsilon_v + \mathbf{s} : \delta \mathbf{e}, \\ \delta \mathcal{W}_c &= \boldsymbol{\epsilon} : \delta \boldsymbol{\sigma} = \epsilon_v \, \delta p + \mathbf{e} : \delta \mathbf{s} \,. \end{aligned} \tag{5.1.4}$$

Consider now the incremental stress-strain relationship,

$$d\boldsymbol{\epsilon} = \frac{dp}{3 \, K_t} \, \mathbf{I} + \frac{d\mathbf{s}}{2 \, G_t} \,, \tag{5.1.5}$$

where K_t and G_t are referred to as *tangent* moduli. This relationship embodies three types of constitutive response defined by Table 5.1.1, Fung [1965], Mandel [1974].

The whole issue centers around the fact that the tangent elastic moduli may depend on the stress and strain invariants. To simplify the exposition, the elastic moduli will be assumed to depend on the stress invariants only (and not on the strain invariants).

Now let us consider a particular class of isotropic elastic materials that satisfy

Table 5.1.1: Definitions of hypoelasticity, elasticity and hyperelasticity.

Hypoelasticity	The relationship (5.1.5) is not integrable
Elasticity	The relationship (5.1.5) is integrable and there exists a one to one relation $\boldsymbol{\epsilon} = \boldsymbol{\epsilon}(\boldsymbol{\sigma})$
Hyperelasticity	The relationship (5.1.5) is integrable and there exists a potential $V_c(\boldsymbol{\sigma})$ such that $\boldsymbol{\epsilon} = \partial V_c/\partial \boldsymbol{\sigma}$

Assumption 5.1: the stress-strain relationship of these materials is defined by the *secant* moduli $K_s(p,q)$ and $G_s(p,q)$ and the reference stress $p_a\,\mathbf{I}$ corresponds to an undeformed hydrostatic state:

$$\boldsymbol{\epsilon} = \frac{p - p_a}{3\,K_s}\,\mathbf{I} + \frac{\mathbf{s}}{2\,G_s}. \tag{5.1.6}$$

For this class, the incremental energy and complementary energy can be expressed in terms of the pairs of scalar invariants $(\epsilon_v,\, p)$ and $(\epsilon_q,\, q)$, which appear as work-conjugate pairs,

$$\begin{aligned} \delta\mathcal{W} &= p\,\delta\epsilon_v + q\,\delta\epsilon_q, \\ \delta\mathcal{W}_c &= \epsilon_v\,\delta p + \epsilon_q\,\delta q. \end{aligned} \tag{5.1.7}$$

Denoting by $\delta\mathcal{W}_{\text{ext}}$ the incremental external work, dU the increment of internal energy, dC the increment of kinetic energy, dS the increment of entropy, all measured per unit volume, and by T the temperature, the first and second laws of thermodynamics may be expressed in the form,

$$\begin{aligned} \delta\mathcal{W}_{\text{ext}} + \delta Q &= dU + dC, \\ \delta Q &= T\,dS - \delta f, \end{aligned} \tag{5.1.8}$$

where δf is the dissipated work. Note that a distinction is made between the differential operators d and δ. For an arbitrary function $A(\mathbf{B})$ depending on a vector or tensor field $\mathbf{B}$, this notation aims at stressing the fact $dA(\mathbf{B})$ depends only on the end points $\mathbf{B}$ and $\mathbf{B} + d\mathbf{B}$, while $\delta A(\mathbf{B})$ may depend on the actual path followed to join the end points $\mathbf{B}$ and $\mathbf{B} + d\mathbf{B}$.

Using the balance of momentum, the incremental work of deformation (strain energy) $\delta\mathcal{W}$ can be shown to be equal to the incremental external work $\delta\mathcal{W}_{\text{ext}}$ minus the incremental kinetic energy dC, namely $\delta\mathcal{W} = \delta\mathcal{W}_{\text{ext}} - dC$. For the purpose of this section, the inertia contribution can be neglected. Moreover the examples examined below satisfy one of the following assumptions:

Assumption 5.2: the thermomechanical process is adiabatic:

$$\delta\mathcal{W} = \delta\mathcal{W}_{\text{ext}} = dU\,. \tag{5.1.9}$$

Assumption 5.3: the thermomechanical process is isothermal and no dissipation takes place:

$$\delta\mathcal{W} = \delta\mathcal{W}_{\text{ext}} = d(U - T\,S), \quad \delta f = 0\,. \tag{5.1.10}$$

In order to characterize the mechanical responses, the residual strain and residual energy are calculated after a stress cycle $\mathcal{C}$, i.e., a closed stress path, in the plane $(p,\, q)$. Three typical responses result as defined by Tables 5.1.1 and 5.1.2, and illustrated below. The cycles considered in these tables are assumed to have some 'thickness', i.e., to encircle a non vanishing area.

If the stress cycle is followed *exactly* in inverse direction, then, for all three responses, the initial strain is retrieved. Similarly, the energy input is entirely recovered, as long as no additional thermomechanical mechanism gives rise to dissipation. This observation justifies the terminology of stored and recoverable energy associated with the stress cycle.

5.1.1 A hypoelastic material

Consider the mechanical response defined by the following scalar incremental relations where both the tangent moduli depend on the mean stress, Coon and Evans [1971], Hueckel and Drescher [1975],

$$d\epsilon_v = \frac{dp}{K_t(p)}, \quad d\epsilon_q = \frac{dq}{3\,G_t(p)}\,. \tag{5.1.11}$$

For a closed path C_σ in the stress plane (p, q), e.g., a rectangular path with sides parallel to the axes,

- the strain path C_ϵ in the plane $(\epsilon_v,\, \epsilon_q)$ is in general not closed, that is a residual strain appears;
- the integral $\int_{C_\sigma} \delta\mathcal{W}$ does not vanish. Therefore, as indicated by Eqn $(5.1.8)_1$, energy may have been extracted from or stored into the material, depending on the clockwise or anticlockwise direction of the path.

Table 5.1.2: Residual strain $\Delta\boldsymbol{\epsilon}$ and residual energy $\Delta\mathcal{W}$ after a stress cycle.

Type of Response	Residual Strain $\Delta\boldsymbol{\epsilon}$	Residual Energy $\Delta\mathcal{W}$
Hypoelasticity	$\neq 0$	$\neq 0$
Elasticity	$= 0$	$\neq 0$
Hyperelasticity	$= 0$	$= 0$

5.1.2 An elastic material

The mechanical response defined by the following scalar incremental relations has relevance to granular materials, Nova and Wood [1978],

$$d\epsilon_v = \kappa\, d\mathrm{Ln}\,|\frac{p}{p_a}|, \quad d\epsilon_q = \Gamma\, d\Big(\frac{q}{p}\Big)\,, \tag{5.1.12}$$

with κ and Γ two material constants. These relations define an elastic material according to Table 5.1.1. The stress-strain relation can be integrated, and the secant moduli result as

$$K_s = \frac{p - p_a}{\kappa\,\mathrm{Ln}\,|\dfrac{p}{p_a}|}, \quad G_s = \frac{p}{3\,\Gamma}\,. \tag{5.1.13}$$

On the other hand, like for hypoelastic materials, a residual energy appears after a closed stress cycle.

5.1.3 A particular hyperelastic material

The elastic potential $V_c(\boldsymbol{\sigma})$ can be identified with the complementary energy $\mathcal{W}_c$. To a closed stress path C_σ corresponds a closed strain path, like for elastic materials. But in addition, the residual complementary energy and the residual energy vanish,

$$\int_{C_\sigma} d\mathcal{W}_c = 0, \quad \int_{C_\sigma} d\mathcal{W} = \int_{C_\sigma} d\,(\boldsymbol{\sigma} : \boldsymbol{\epsilon} - \mathcal{W}_c) = 0\,. \tag{5.1.14}$$

Since the materials are isotropic, the complementary energy depends on the stress $\boldsymbol{\sigma}$ only through the three scalar invariants p, q, and J_3. To simplify the exposition, the complementary energy is first assumed to depend only on p and q. Then the expressions (5.1.7) and (5.1.14) imply,

$$\epsilon_v = \frac{\partial \mathcal{W}_c}{\partial p}, \quad \epsilon_q = \frac{\partial \mathcal{W}_c}{\partial q}\,. \tag{5.1.15}$$

A necessary and sufficient condition for the elastic potential $\mathcal{W}_c(p,\, q)$ to exist is that the cross-derivatives are equal,

$$\frac{\partial \epsilon_v}{\partial q} = \frac{\partial \epsilon_q}{\partial p}, \quad \frac{\partial \epsilon_v}{\partial J_3} = 0, \quad \frac{\partial \epsilon_q}{\partial J_3} = 0\,. \tag{5.1.16}$$

Thus the elastic materials defined by (5.1.6) are hyperelastic iff

$$\frac{\partial}{\partial q}(\frac{p}{K_s}) = \frac{\partial}{\partial p}(\frac{q}{3\,G_s}), \quad \frac{\partial K_s}{\partial J_3} = 0, \quad \frac{\partial G_s}{\partial J_3} = 0\,. \tag{5.1.17}$$

Exercise 5.3 extends the analysis to nonlinear isotropic elastic materials and gives the conditions for these materials to be hyperelastic.

An interesting particular case consists in assuming the Poisson's ratio ν to be constant, or equivalently the ratio $K_s/3G_s$ to be constant, say equal to $K_s^0/3G_s^0$. Then

$$\begin{bmatrix} -\dfrac{K_s^0}{3G_s^0}\,q & p \\ dp & dq \end{bmatrix} \begin{bmatrix} \partial K_s/\partial p \\ \partial K_s/\partial q \end{bmatrix} = \begin{bmatrix} 0 \\ dK_s \end{bmatrix}. \tag{5.1.18}$$

Along the method of characteristics, the determinant of the above matrix,

$$\frac{K_s^0}{3G_s^0}\,q\,dq + p\,dp\,, \tag{5.1.19}$$

is zeroed. Hence the secant moduli K_s and G_s are functions of

$$\Big(\frac{p}{p_a}\Big)^2 + \frac{K_s^0}{3G_s^0}\Big(\frac{q}{p_a}\Big)^2\,. \tag{5.1.20}$$

A power expression defined by an exponent $n<1$ is often adopted, Vermeer [1978],

$$K_s = K_s^0\,p_a\Big[\Big(\frac{p}{p_a}\Big)^2 + \frac{K_s^0}{3G_s^0}\Big(\frac{q}{p_a}\Big)^2\Big]^{(1-n)/2}\,. \tag{5.1.21}$$

Exercise 5.19 develops a nonlinear anisotropic hyperelastic model, extending the idea built into (5.1.18).

An alternative particular case assumes the secant shear modulus to depend on p only, namely $G_s = G_s(p)$. Then (5.1.17) implies that K_s is defined up to an arbitrary function $A(p)$,

$$\frac{1}{K_s} = \frac{q^2}{2\,p}\frac{\partial}{\partial p}\,\frac{1}{3\,G_s} + A(p)\,. \tag{5.1.22}$$

As a third particular case, the following equivalence holds

$$K_s = K_s(p) \quad\Leftrightarrow\quad G_s = G_s(q)\,. \tag{5.1.23}$$

Incidentally, this equivalence confirms that the material defined by the secant moduli (5.1.13) is merely elastic, and not hyperelastic.

5.2 Anisotropic linear elasticity

5.2.1 Matrix representation

The linear elastic stress-strain relation is phrased in terms of the elastic *stiffness* $\mathbb{E}$, also referred to as elastic *tensor moduli*. It may be expressed in arbitrary cartesian axes,

$$\boldsymbol{\sigma} = \mathbb{E} : \boldsymbol{\epsilon}, \quad \sigma_{ij} = E_{ijkl}\,\epsilon_{kl}\,. \tag{5.2.1}$$

It may also be cast in matrix form $[\boldsymbol{\sigma}] = [\mathbb{E}]\,[\boldsymbol{\epsilon}]$, via the elastic stiffness matrix $[\mathbb{E}]$,

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} = \begin{bmatrix} E_{1111} & E_{1122} & E_{1133} & \sqrt{2}E_{1123} & \sqrt{2}E_{1113} & \sqrt{2}E_{1112} \\ E_{2211} & E_{2222} & E_{2233} & \sqrt{2}E_{2223} & \sqrt{2}E_{2213} & \sqrt{2}E_{2212} \\ E_{3311} & E_{3322} & E_{3333} & \sqrt{2}E_{3323} & \sqrt{2}E_{3313} & \sqrt{2}E_{3312} \\ \sqrt{2}E_{2311} & \sqrt{2}E_{2322} & \sqrt{2}E_{2333} & 2E_{2323} & 2E_{2313} & 2E_{2312} \\ \sqrt{2}E_{1311} & \sqrt{2}E_{1322} & \sqrt{2}E_{1333} & 2E_{1323} & 2E_{1313} & 2E_{1312} \\ \sqrt{2}E_{1211} & \sqrt{2}E_{1222} & \sqrt{2}E_{1233} & 2E_{1223} & 2E_{1213} & 2E_{1212} \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix}. \tag{5.2.2}$$

This matrix form is referred to as isometric representation. It follows tensor rules under changes of the coordinate axes, Walpole [1984], Mehrabadi and Cowin [1990]. It conserves energy, namely $\boldsymbol{\sigma} : \boldsymbol{\epsilon} = [\boldsymbol{\sigma}]^{\mathrm{T}}\,[\boldsymbol{\epsilon}]$ as well as euclidean norms, e.g., for the stress tensor $\boldsymbol{\sigma} : \boldsymbol{\sigma} = [\boldsymbol{\sigma}]^{\mathrm{T}}\,[\boldsymbol{\sigma}]$.

If the elastic stiffness $\mathbb{E}$ is symmetric, it is invertible iff it is positive definite (PD). The conditions for positive definiteness will be explored for different kinds of anisotropy in the sequel. Whether symmetric or not, if the elastic stiffness $\mathbb{E}$ is invertible, the inverse relation involves the elastic compliance $\mathbb{S}$,

$$\boldsymbol{\epsilon} = \mathbb{S} : \boldsymbol{\sigma}, \quad \epsilon_{ij} = S_{ijkl}\,\sigma_{kl}\,. \tag{5.2.3}$$

The matrix form $[\boldsymbol{\epsilon}] = [\mathbb{S}] : [\boldsymbol{\sigma}]$ introduces the compliance matrix $[\mathbb{S}]$,

$$\begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix} = \begin{bmatrix} S_{1111} & S_{1122} & S_{1133} & \sqrt{2}S_{1123} & \sqrt{2}S_{1113} & \sqrt{2}S_{1112} \\ S_{2211} & S_{2222} & S_{2233} & \sqrt{2}S_{2223} & \sqrt{2}S_{2213} & \sqrt{2}S_{2212} \\ S_{3311} & S_{3322} & S_{3333} & \sqrt{2}S_{3323} & \sqrt{2}S_{3313} & \sqrt{2}S_{3312} \\ \sqrt{2}S_{2311} & \sqrt{2}S_{2322} & \sqrt{2}S_{2333} & 2S_{2323} & 2S_{2313} & 2S_{2312} \\ \sqrt{2}S_{1311} & \sqrt{2}S_{1322} & \sqrt{2}S_{1333} & 2S_{1323} & 2S_{1313} & 2S_{1312} \\ \sqrt{2}S_{1211} & \sqrt{2}S_{1222} & \sqrt{2}S_{1233} & 2S_{1223} & 2S_{1213} & 2S_{1212} \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} . \tag{5.2.4}$$

The compliance tensor and matrix enjoy the same symmetry properties as their respective inverses. The isometric representation is at variance with the so-called Voigt representation, where the out-of diagonal terms are multiplied by 2 in the strain pseudo-vector $[\boldsymbol{\epsilon}]$, and by 1 in the stress pseudo-vector $[\boldsymbol{\sigma}]$. The Voigt representation does not follow tensor rules under changes of the coordinate axes but it conserves energy. The two representations are contrasted in Exercise 5.4.

Warning: The matrix form (5.2.2) assumes that the components of the vectors and matrix gather components of entities which are written on a single cartesian basis. Later, it will appear advantageous to use the axes linked to the material symmetry, referred to as orthotropy axes. Let $\mathbf{e}_i$, $\mathbf{e}_i^\epsilon$ and $\mathbf{e}_i^\sigma$, $i \in [1,3]$, be the cartesian axes associated with the orthotropy axes, with the principal axes of strain and with the principal axes of stress respectively,

$$\begin{aligned} \boldsymbol{\epsilon} &= \epsilon_{ii}^* \, \mathbf{e}_i^\epsilon \otimes \mathbf{e}_i^\epsilon = \epsilon_{ij} \, \mathbf{e}_i \otimes \mathbf{e}_j , \\ \boldsymbol{\sigma} &= \sigma_{ii}^* \, \mathbf{e}_i^\sigma \otimes \mathbf{e}_i^\sigma = \sigma_{ij} \, \mathbf{e}_i \otimes \mathbf{e}_j , \\ \mathbb{E} &= E_{ijkl} \, \mathbf{e}_i \otimes \mathbf{e}_j \otimes \mathbf{e}_k \otimes \mathbf{e}_l \, . \end{aligned} \tag{5.2.5}$$

For general anisotropy, the principal axes of strain and stress do not coincide, see Exercise 5.15.

5.2.2 Minor and major symmetries

The elastic moduli enjoy *minor* symmetries,

$$\text{minor symmetries} \begin{cases} \text{1. by necessity :} \quad E_{ijkl} = E_{jikl}, \quad i,j,k,l \in [1,3]; \\ \text{2. by choice :} \; E_{ijkl} = E_{ijlk}, \quad i,j,k,l \in [1,3] \, . \end{cases} \tag{5.2.6}$$

Under the two first indices, the symmetry is a *necessity*, due to the symmetry of the Cauchy stress. Under the two last indices, it is a *choice* dictated by simplicity. That it is a choice and not a requirement is commented in Exercise 5.2.

The major symmetry of the elastic tensor moduli, or equivalently compliance, amounts to the symmetry of the elastic matrix, or equivalently compliance matrix,

$$\text{major symmetries} \quad E_{ijkl} = E_{klij}, \quad i,j,k,l \in [1,3] \, . \tag{5.2.7}$$

The major symmetry property amounts to the existence of an elastic potential, also called strain energy function when it depends on the strain.

5.2.3 Microstructure and symmetry groups

5.2.3.1 The group of symmetry or invariance

The mathematical structure which is appropriate to define the anisotropic mechanical and transport properties of materials is the *group*. A group $\mathcal{G}$ is a set of elements endowed with an internal composition rule denoted here by the symbol $\cdot$, namely if $\mathbf{A}$ and $\mathbf{B}$ belong to $\mathcal{G}$, so does $\mathbf{A} \cdot \mathbf{B}$. Elements of the group obey the following three axioms:

1. *associativity*: for any $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C} \in \mathcal{G}$, then
$$(\mathbf{A}\cdot\mathbf{B})\cdot\mathbf{C} = \mathbf{A}\cdot(\mathbf{B}\cdot\mathbf{C});$$
2. *neutral element*: there exists an element $\mathbf{E} \in \mathcal{G}$ such that,
$$\text{for any } \mathbf{A} \in \mathcal{G},\ \mathbf{A}\cdot\mathbf{E} = \mathbf{E}\cdot\mathbf{A} = \mathbf{A};$$
3. *inverse element*: for any $\mathbf{A} \in \mathcal{G}$, there exists an element noted $\mathbf{A}^{-1}$ in $\mathcal{G}$ such that
$$\mathbf{A}\cdot\mathbf{A}^{-1} = \mathbf{A}^{-1}\cdot\mathbf{A} = \mathbf{E}.$$

The group is said *abelian*[5.1] or commutative if in addition
$$\text{for any } \mathbf{A},\ \mathbf{B} \in \mathcal{G},\ \text{then } \mathbf{A}\cdot\mathbf{B} = \mathbf{B}\cdot\mathbf{A}.$$

A set $\mathcal{G}'$ is a *subgroup* of $\mathcal{G}$, and one notes $\mathcal{G}' \subset \mathcal{G}$, if, for any $\mathbf{A}$, $\mathbf{B} \in \mathcal{G}'$, then $\mathbf{A}\cdot\mathbf{B}^{-1}$ belongs to $\mathcal{G}'$. This condition implies in particular that the neutral element belongs to $\mathcal{G}'$.

For the issue at hand, the elements of the groups are second order tensors and the internal composition rule is the inner product. The neutral element is the identity tensor and the groups are abelian.

The *symmetry group*, or *invariance group*, is the group of changes of axes that leaves invariant the stress-strain relation, that is
$$\underbrace{\boldsymbol{\sigma} = \boldsymbol{\mathcal{L}}(\boldsymbol{\epsilon})}_{\text{reference axes}} \iff \underbrace{\boldsymbol{\sigma}* = \boldsymbol{\mathcal{L}}(\boldsymbol{\epsilon}*)}_{\text{axes } *}, \tag{5.2.8}$$
or equivalently, $\boldsymbol{\mathcal{L}} = \boldsymbol{\mathcal{L}}*$. Consequently, the invariance properties for a linear elastic material are those of the elastic stiffness, or compliance.

The invariance groups contain only *isometries*: for any element $\mathbf{R}$, its norm subordinate to a vector norm, namely $\| \mathbf{R} \| = \sup_{\mathbf{x}} \| \mathbf{R}\cdot\mathbf{x} \| / \| \mathbf{x} \|$, is equal to one. In fact, all elements of the *complete orthogonal group* $\mathcal{O}(3)$ satisfy the orthogonality property,
$$\mathbf{R}\cdot\mathbf{R}^{\mathrm{T}} = \mathbf{R}^{\mathrm{T}}\cdot\mathbf{R} = \mathbf{I}, \tag{5.2.9}$$
and they are

1. either *rotations* (or *proper orthogonal tensors*) such that $\det\mathbf{R} = +1$;
2. or *symmetries* which enjoy the property $\mathbf{R} = \mathbf{R}^{\mathrm{T}}$, so that $\mathbf{R}^2 = \mathbf{I}$. One distinguishes symmetries (or reflections) with respect to a plane of unit normal $\mathbf{n}$, namely $\mathbf{I} - 2\,\mathbf{n}\otimes\mathbf{n}$, such that $\det\mathbf{R} = -1$, and symmetries with respect to a point, such that $\det\mathbf{R} = -1$ in $\mathbb{R}^3$.

The *proper orthogonal group* $\mathcal{SO}(3)$ involves only rotations as defined in Section 2.5.5. The larger the symmetry group, the more the material displays symmetries, and the smaller is the number of independent coefficients required to define the elastic stiffness. If $\mathcal{G}$ is the complete orthogonal group $\mathcal{O}(3)$, then the material response is said to be *isotropic*. If $\mathcal{G}$ is the *proper orthogonal group* $\mathcal{SO}(3)$, then the material response is said to be *hemitropic*.

If the elastic stiffness enjoys the major symmetry property, that is, if the material is in fact hyperelastic, then the most general anisotropy requires $6\times(6+1)/2 = 21$ elastic coefficients, as can be checked on the matrix representation (5.2.2). This number boils down to 2 for isotropy.

Remark: For a finite strain analysis, the symmetry group depends on the reference configuration, Section 2.11.3. This point should be highlighted for example for a material prestressed by an (an)isotropic initial stress.

5.2.3.2 Structural and fabric anisotropies

A mechanical response is said to be *isotropic* if the response to a load does not depend on the direction of this load. Otherwise, the mechanical response is said to be *anisotropic*.

Elastic anisotropy may be due to different phenomena:

- it may be *inherent* or induced by a loading process, which is accompanied by large strains, damage associated with cracks, nucleation, etc.;
- in biological tissues like in many engineered materials, the anisotropy corresponds to a sought directional property. For example, collagen fibers are expected to exist in a significant density and to be aligned with the traction direction in a tissue whose physiological role is to undergo tension, e.g., ligaments, muscles, arteries, etc. Similar directional compressive or tensile reinforcement is sought in honeycombs and fiber reinforced composites;
- sometimes anisotropy arises simply as a result of the formation process. Such is the case of sedimentary rocks which are deposited under gravity. Clays become progressively anisotropic as the vertical or horizontal tectonic loads increase;

[5.1] Abelian groups are named after the Norwegian mathematician N.H. Abel (1802-1829).

- a material, whether biological, geological or engineered, may be looked at several scales. Let us consider a material formed by a set of elements. One should distinguish the anisotropy due to the *morphology* and the *anisotropy of organization*. In reference to granular materials, the former property concerns the fact that the elements may be spherical, elliptical or else polyhedral. The latter property describes the direction and intensity of contact between elements. A random directional distribution of anisotropic elements results in an isotropic material. Conversely, a directionally oriented distribution of isotropic elements results in an anisotropic material.

In Section 7.4.3, we consider a method of determination of the coefficients of orthotropic and transversely isotropic poroelastic materials: the issue there is to define experiments that are deemed *independent*. A basic tenet of the analysis is that the symmetry group and the axes of material symmetry are known. In fact, the determination of the macroscopic symmetry axes for heterogeneous tissues, possibly reinforced by fibers or other curvilinear objects with a random orientation, is a difficult issue, especially when no spatial scale in the microstructure is prevalent. Moreover, measurements based on stereological methods, Kanatani [1985], may show dispersion or may leave uncertainties. A potential model to tackle these aspects might consider, instead of a tissue reinforced by one or two families of fibers, a smoothed orientation distribution function, Section 12.3.

An approach to define the symmetry group and the axes of symmetry of an elastic material consists

(a) in obtaining in arbitrary cartesian axes the stiffness tensor $\mathbb{E}^{\rm exp}$ via an experimental program aimed at delivering the 21 elastic constants;

(b) in detecting to which of the nine elastic symmetry groups/classes [5.2] the group of the measured elastic stiffness is closest;

(c) in defining the elastic stiffness $\mathbb{E}^*$ belonging to the chosen symmetry group the measured stiffness is closest.

Point (a) uses mechanical or acoustical tests. Since the symmetry directions are unknown, mechanical tests may easily involve off-axis loadings which are prone to induce a heterogeneous stress and strain state. Ultrasonic measurements along the direction give rise to a quasi-longitudinal wave and two quasi-transversal waves, yielding three wave-speeds. Determining the 21 elastic constants thus requires a priori to probe along at least 7 directions. However, probing along different directions generally provides redundant rather than independent information so that, even for an orthotropic material, it is necessary to probe along more than three directions. Redundant data might be used to estimate errors of measurements.

Points (b) and (c) require the definitions of distances over the set of fourth order elasticity tensors via norms, e.g., the Euclidean norm. Directional averaging provides an element $\mathbb{E}^*$ of the symmetry group $\mathcal{S}_*$ which can be seen as a Voigt bound (associated with uniform strain). Proceeding similarly with the compliance $\mathbb{S}^{\rm exp}$ yields a Reuss bound $\mathbb{S}^*$ (associated with uniform stress). In fact, the Euclidean norm is not invariant under inversion: it will not deliver the same outcome to the minimization problem depending whether the stiffness or compliance are targeted. Other norms like the log-Euclidean norm will yield a unique result, see, e.g., Norris [2006] for references.

For point (b), François et al. [1998] have proposed to plot the pole figure of the experimental stiffness $\mathbb{E}^{\rm exp}$. In this crystallographic construction, the normals to the material symmetry planes reveal as dark spots or bands (no spot for triclinic, 1 spot for monoclinic, 3 spots at 120° for trigonal, etc.). The closest symmetry group $\mathcal{S}_*$ is decided by comparing *de visu* the pole figure of the experimental stiffness with the pole figures of the nine symmetry groups. In practice, the quality of the image depends on the accuracy of the measurements.

Fedorov [1968] has addressed point (c) with the particular view that the chosen symmetry group is the isotropic group. Minimizing the distances between the slowness surfaces of the measured and isotropic materials, he found the bulk and shear moduli as $K* = E^{\rm exp}_{iijj}/9$ and $\mu* = E^{\rm exp}_{ijij}/10 - E^{\rm exp}_{iijj}/30$. This result is also obtained by minimizing the distance between the stiffness tensors. In fact, point (c) may be seen as projecting the measured stiffness onto the set of stiffness tensors belonging to the chosen symmetry group. Norris [2006] generalized the approach of Fedorov by targeting symmetry groups other than isotropy: he found that the slowness surface approach and the projection of the stiffness using the Euclidean norm yield the same result.

As a further issue, tissue engineering is concerned with finding the optimal orientation of an anisotropic elastic material, by minimizing the strain energy over rotation of the material axes under a fixed load, e.g., Rovati and Taliercio [2003].

[5.2] The terminology in crystallography is different from the one used in Section 5.2.4.1: the nine groups of elastic symmetry are named triclinic (21), monoclinic (13), trigonal (6 and 7), tetragonal (6 and 7), hexagonal (5), cubic (3) and isotropic (2), the numbers in parentheses indicating the number of independent elastic coefficients, Lekhnitskii [1963], p. 26. In fact, there are thirty two classes of *geometric* symmetry in crystals, but only nine groups of *elastic* symmetry.

5.2.4 From anisotropic to isotropic linear hyperelasticity

Under a rotation of the coordinate axes $\mathbf{e}_i$ to $\mathbf{e}_i^* = R_{ij}\,\mathbf{e}_j$, $i \in [1,3]$, the components of the stress $\boldsymbol{\sigma}$ change to $\boldsymbol{\sigma}^* = \mathbf{R}\cdot\boldsymbol{\sigma}\cdot\mathbf{R}^{\mathrm{T}}$, Exercise 2.1. The relation (5.2.8) becomes

$$\mathbf{R}\cdot(\mathbb{E}:\boldsymbol{\epsilon})\cdot\mathbf{R}^{\mathrm{T}} = \mathbb{E}:(\mathbf{R}\cdot\boldsymbol{\epsilon}\cdot\mathbf{R}^{\mathrm{T}}),\ \forall\boldsymbol{\epsilon},\ \forall\mathbf{R}\in\mathcal{G} \quad\Leftrightarrow\quad E_{ijkl} = R_{mi}\,R_{nj}\,R_{pk}\,R_{ql}\,E_{mnpq}\,. \tag{5.2.10}$$

5.2.4.1 Fourth order tensors with minor and major symmetries

A number of coordinate transformations are now concatenated:

1. Symmetry with respect to the coordinate plane $x_3 = 0$, referred to as monoclinic symmetry in crystallography.
   Let us consider a material whose elastic properties mirror with respect to the plane $x_3 = 0$. Thus

$$\mathbf{R}_3 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix} \in \mathcal{G}\,, \tag{5.2.11}$$

belongs to its symmetry group $\mathcal{G}$. Satisfaction of the relation (5.2.10) implies the components E_{ijkl} of the elastic tensor that contains an odd number of indices 3 to vanish, Exercise 5.5. The 13 remaining coefficients are arbitrary, Eqn (5.2.12),

$$\underbrace{\begin{bmatrix} \bullet & \bullet & \bullet & 0 & 0 & \bullet \\ \bullet & \bullet & \bullet & 0 & 0 & \bullet \\ \bullet & \bullet & \bullet & 0 & 0 & \bullet \\ 0 & 0 & 0 & \bullet & \bullet & 0 \\ 0 & 0 & 0 & \bullet & \bullet & 0 \\ \bullet & \bullet & \bullet & 0 & 0 & \bullet \end{bmatrix}}_{\begin{array}{c}\text{symmetry // } x_3 = 0\\ \text{13 independent coefficients}\end{array}} ; \quad \underbrace{\begin{bmatrix} \bullet & \bullet & \bullet & 0 & 0 & 0 \\ \bullet & \bullet & \bullet & 0 & 0 & 0 \\ \bullet & \bullet & \bullet & 0 & 0 & 0 \\ 0 & 0 & 0 & \bullet & 0 & 0 \\ 0 & 0 & 0 & 0 & \bullet & 0 \\ 0 & 0 & 0 & 0 & 0 & \bullet \end{bmatrix}}_{\begin{array}{c}\text{orthotropy}\\ \text{9 independent coefficients}\end{array}} . \tag{5.2.12}$$

2. *Orthotropy*: symmetry with respect to the coordinate planes $x_1 = 0$ and $x_3 = 0$.
   The transformation

$$\mathbf{R}_1 = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{5.2.13}$$

and $\mathbf{R}_3$ belong to the group $\mathcal{G}$, then $\mathbf{R}_1\cdot\mathbf{R}_3 = -\mathbf{R}_2$ belongs to $\mathcal{G}$. The changes in components of $\boldsymbol{\sigma}$ and $\boldsymbol{\epsilon}$ under $-\mathbf{R}_2$ and $\mathbf{R}_2$ are identical, so that $\mathbf{R}_2$ belongs to $\mathcal{G}$. In words, symmetry with respect to two coordinate planes implies symmetry with respect to the three coordinate planes, a property called *orthotropy*, or orthorhombic symmetry in crystallography. Satisfaction of the relation (5.2.10) implies that only nine components remain arbitrary as illustrated on Eqn $(5.2.12)_2$.

3. *Quadratic symmetry*: orthotropy + equivalence of two planes of coordinate axes $x_1 = 0$ and $x_2 = 0$.
   Then the transformation

$$\mathbf{R}_{12} = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{5.2.14}$$

belongs to the invariance group. Satisfaction of the relation (5.2.10) yields the three restrictions,

$$E_{1111} = E_{2222}, \quad E_{1133} = E_{2233}, \quad E_{2323} = E_{3131}\,, \tag{5.2.15}$$

so that the number of independent coefficients of the elastic stiffness reduces to $9 - 3 = 6$,

$$\underbrace{\begin{bmatrix} \square & \circ & \odot & 0 & 0 & 0 \\ \circ & \square & \odot & 0 & 0 & 0 \\ \odot & \odot & \diamond & 0 & 0 & 0 \\ 0 & 0 & 0 & \triangle & 0 & 0 \\ 0 & 0 & 0 & 0 & \triangle & 0 \\ 0 & 0 & 0 & 0 & 0 & \sqcup \end{bmatrix}}_{\begin{array}{c}\text{quadratic symmetry} \\ \text{6 independent coefficients}\end{array}} . \tag{5.2.16}$$

The quadratic symmetry property is referred to as tetragonal symmetry in crystallography. The homogenization process of a brick devoid of a central cylinder as a unit cell yields such a quadratic symmetry. The mechanical properties mirror the geometrical lack of radial/cylindrical symmetry.

4. *Cubic symmetry*: orthotropy + equivalence of the three coordinate axes.
   Equivalence of the axes 1 and 3 implies the transformation

$$\mathbf{R}_{13} = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix} , \tag{5.2.17}$$

to belong to the symmetry group. The resulting further three constraints,

$$E_{1111} = E_{2222} = E_{3333}, \quad E_{1122} = E_{1133} = E_{2233}, \quad E_{2323} = E_{3131} = E_{1212} , \tag{5.2.18}$$

imply the number of independent elastic coefficients to be $6 - 3 = 3$,

$$\underbrace{\begin{bmatrix} \square & \odot & \odot & 0 & 0 & 0 \\ \odot & \square & \odot & 0 & 0 & 0 \\ \odot & \odot & \square & 0 & 0 & 0 \\ 0 & 0 & 0 & \triangle & 0 & 0 \\ 0 & 0 & 0 & 0 & \triangle & 0 \\ 0 & 0 & 0 & 0 & 0 & \triangle \end{bmatrix}}_{\begin{array}{c}\text{cubic symmetry} \\ \text{3 independent coefficients}\end{array}} . \tag{5.2.19}$$

5. *Transverse isotropy*: rotational invariance about a coordinate axis, e.g., $x_3 = 0$.
   Then

$$\mathbf{R}_\alpha = \begin{bmatrix} \cos\alpha & \sin\alpha & 0 \\ -\sin\alpha & \cos\alpha & 0 \\ 0 & 0 & 1 \end{bmatrix} \in \mathcal{G}, \quad \forall \alpha \in [0,\, 2\,\pi[. \tag{5.2.20}$$

Quadratic symmetry in the plane 1-2 can be shown to be verified. Moreover, Eqn (5.2.10) implies in particular,

$$\begin{aligned} E_{1212} &= R_{1p}\, R_{2q}\, [-\sin\alpha\, \cos\alpha\, E_{11pq} + (\cos^2\alpha - \sin^2\alpha)\, E_{12pq} + \sin\alpha\, \cos\alpha\, E_{22pq}] \\ &= (\cos^2\alpha\, \sin^2\alpha)\, (E_{1111} + E_{2222} - 2\, E_{1122}) + (\cos^2\alpha - \sin^2\alpha)^2\, E_{1212} . \end{aligned} \tag{5.2.21}$$

Therefore

$$E_{1212} = \frac{1}{2}\,(E_{1111} - E_{1122})\,. \tag{5.2.22}$$

The number of independent coefficients is thus $6 - 1 = 5$,

$$\underbrace{\begin{bmatrix} \square & \circ & \odot & 0 & 0 & 0 \\ \circ & \square & \odot & 0 & 0 & 0 \\ \odot & \odot & \diamond & 0 & 0 & 0 \\ 0 & 0 & 0 & \triangle & 0 & 0 \\ 0 & 0 & 0 & 0 & \triangle & 0 \\ 0 & 0 & 0 & 0 & 0 & \square - \circ \end{bmatrix}}_{\begin{array}{c}\text{transverse isotropy}\\ \text{5 independent coefficients}\end{array}}. \tag{5.2.23}$$

Transverse isotropy is referred to as hexagonal symmetry in crystallography.

6. *Isotropy*: $\mathcal{G} = \mathcal{O}(3)$ complete orthogonal group

Concatenating the restrictions associated with cubic symmetry and transverse isotropy, only two independent coefficients remain arbitrary, say λ and μ, and $E_{1111} = \lambda + 2\,\mu$, $E_{1122} = \lambda$ and $E_{2323} = \mu$,

$$\underbrace{\begin{bmatrix} \square & \circ & \circ & 0 & 0 & 0 \\ \circ & \square & \circ & 0 & 0 & 0 \\ \circ & \circ & \square & 0 & 0 & 0 \\ 0 & 0 & 0 & \square - \circ & 0 & 0 \\ 0 & 0 & 0 & 0 & \square - \circ & 0 \\ 0 & 0 & 0 & 0 & 0 & \square - \circ \end{bmatrix}}_{\begin{array}{c}\text{isotropy}\\ \text{2 independent coefficients}\end{array}}. \tag{5.2.24}$$

5.2.4.2 Isotropic tensors of various orders

Isotropic tensors are invariant under the complete orthogonal group $\mathcal{O}(3)$. An isotropic tensor with an odd number of indices necessarily vanishes: apply the symmetry with respect to a plane, as done for fourth order tensors in Exercise 5.5. Moreover, the components are invariant under cyclic permutation of their indices, which corresponds to changes of the coordinate axes. Consequently, isotropic second order tensors are parallel to the identity tensor $\mathbf{I}$.

A careful proof also shows that isotropic fourth order tensors are defined by three coefficients,

$$E_{ijkl} = \lambda\, I_{ij}\, I_{kl} + \mu_1\, I_{ik}\, I_{jl} + \mu_2\, I_{il}\, I_{jk}\,. \tag{5.2.25}$$

The rewriting shown in Table 5.2.1 highlights the symmetry, or lack of symmetry, under the two first and last indices. Indeed, $\sigma_{ij} = E_{ijkl}\,\epsilon_{kl}$ is equal to $\lambda\,(I_{kl}\epsilon_{kl})\,I_{ij} + \mu\,(\epsilon_{ij} + \epsilon_{ji}) + \mu'\,(\epsilon_{ij} - \epsilon_{ji})$, with $\mu = \frac{1}{2}\,(\mu_1 + \mu_2)$ and $\mu' = \frac{1}{2}\,(\mu_1 - \mu_2)$. If the strain $\boldsymbol{\epsilon}$ is symmetric, the coefficient μ' is elusive.

A compact proof is shown in Jeffreys and Jeffreys [1980], p. 88. A slightly different method is used by Fung [1977], p. 192. Here is a brief summary. To prove that the components of a tensor $\mathbf{A}$ in the coordinate system $\mathbf{x}$ and in the rotated coordinates $\mathbf{x}^* = \mathbf{R}\cdot\mathbf{x}$, $x_i^* = R_{ij}\,x_j$, $i \in [1,3]$, are equal, say $A_{ijk\cdots} = A^*_{ijk\cdots}$, one may consider the infinitesimal rotation of angle θ (counted positive in the trigonometric sense) about the axis $\mathbf{n}$ that rotates the coordinates $\mathbf{x}$ to $\mathbf{x}^* = \mathbf{x} + \theta\,\mathbf{n}\wedge\mathbf{x}$, namely componentwise, $x_i^* = R_{ij}\,x_j$, with $R_{ij} = I_{ij} + \theta\,n_z\,e_{zji}$, from which $A^*_{ijk\cdots} = R_{ip}\,R_{jq}\,R_{kr}\,\cdots\,A_{pqr\cdots}$. The procedure yields, to first order,

$$\begin{aligned} A^*_{ij} &= A_{ij} + \theta\,n_z\,(e_{zqj}\,A_{iq} + e_{zpi}\,A_{pj}); \\ A^*_{ijk} &= A_{ijk} + \theta\,n_z\,(e_{zqj}\,A_{iqk} + e_{zpi}\,A_{pjk} + e_{zrk}\,A_{ijr}); \\ A^*_{ijkl} &= A_{ijkl} + \theta\,n_z\,(e_{zqj}\,A_{iqks} + e_{zpi}\,A_{pjks} + e_{zrk}\,A_{ijrl} + e_{zsl}\,A_{ijks})\,. \end{aligned} \tag{5.2.26}$$

Table 5.2.1: Non trivial isotropic tensors from order 0 to four, Fung [1977].

Order		Isotropic Tensors
0	Scalars	All
1	Vectors	None
2	Tensors	$\alpha\, I_{ij},\ \forall \alpha \in \mathbb{R}$
3	Tensors	Permutation symbol under $\mathcal{SO}(3)$
4	Tensors	$\lambda\, I_{ij}\, I_{kl} + \mu\,(I_{ik}\, I_{jl} + I_{il}\, I_{jk}) + \mu'\,(I_{ik}\, I_{jl} - I_{il}\, I_{jk}),\ \forall \lambda, \mu, \mu' \in \mathbb{R}$

That the elements listed in Table 5.2.1 are invariant under these infinitesimal rotations can be checked via the formulas (2.1.10). The proof that only the elements in this table satisfy the invariance under infinitesimal rotations is more tedious. To finish the proof, it remains to check that the elements of Table 5.2.1 are invariant under reflections and arbitrary rotations.

The permutation symbol is isotropic with respect to rotations only, not under reflections: therefore, it is not isotropic under the complete orthogonal group, and it should therefore be referred to as hemitropic. As an extension, the tensor $\mathbf{e} \otimes \mathbf{I} = (e_{ijk}\, I_{lm}$ is a fifth order hemitropic tensor.

5.2.5 Linear isotropic elastic materials

For linear isotropic elastic materials, the strain energy $\mathcal{W}(\boldsymbol{\epsilon})$, stress and stiffness $\mathbb{E}$,

$$\left\{\begin{array}{rcl} \mathcal{W}(\boldsymbol{\epsilon}) & = & \dfrac{\lambda}{2}\,(\mathbf{I}:\boldsymbol{\epsilon})^2 + \mu\,\mathbf{I}:\boldsymbol{\epsilon}^2\,, \\ \boldsymbol{\sigma} & = & \lambda\,(\mathbf{I}:\boldsymbol{\epsilon})\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon}\,, \\ \mathbb{E} & = & \lambda\,\mathbf{I}\otimes\mathbf{I} + 2\,\mu\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}\,, \end{array}\right. \tag{5.2.27}$$

are defined by the Lamé moduli λ and μ. The inverse relations for the complementary energy, strain and compliance tensor are best expressed in terms of the Young's modulus E and Poisson's ratio ν,

$$\left\{\begin{array}{rcl} \mathcal{W}_c(\boldsymbol{\sigma}) & = & -\dfrac{\nu}{2\,E}\,(\mathbf{I}:\boldsymbol{\sigma})^2 + \dfrac{1+\nu}{2\,E}\,\mathbf{I}:\boldsymbol{\sigma}^2\,, \\ \boldsymbol{\epsilon} & = & -\dfrac{\nu}{E}\,(\mathbf{I}:\boldsymbol{\sigma})\,\mathbf{I} + \dfrac{1+\nu}{E}\,\boldsymbol{\sigma}\,, \\ \mathbb{E}^{-1} & = & -\dfrac{\nu}{E}\,\mathbf{I}\otimes\mathbf{I} + \dfrac{1+\nu}{E}\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}\,. \end{array}\right. \tag{5.2.28}$$

For the record, let us note the following generic relations (Malvern [1969], p. 293, provides a number of additional useful relations of this type),

$$\begin{array}{l} \dfrac{1}{E} = \dfrac{\lambda+\mu}{\mu\,(3\,\lambda+2\,\mu)}\,, \quad \dfrac{\nu}{E} = \dfrac{\lambda}{2\,\mu\,(3\,\lambda+2\,\mu)}\,, \quad K = \dfrac{E}{3(1-2\,\nu)} = \lambda + \dfrac{2}{3}\,\mu\,, \\ E = \dfrac{9\,K\,\mu}{3\,K+\mu}\,, \quad \nu = \dfrac{3\,K-2\,\mu}{2\,(3\,K+\mu)}\,, \quad \lambda = K - \dfrac{2}{3}\,\mu\,, \\ \lambda = \dfrac{E\,\nu}{(1+\nu)\,(1-2\,\nu)}\,, \quad \mu = \dfrac{E}{2\,(1+\nu)}\,, \\ \lambda + 2\,\mu = \dfrac{E\,(1-\nu)}{(1+\nu)\,(1-2\,\nu)} = 2\,\mu\,\dfrac{1-\nu}{1-2\,\nu} = 3\,K\,\dfrac{1-\nu}{1+\nu}\,. \end{array} \tag{5.2.29}$$

The conditions of positive definiteness (or of invertibility of the stiffness), and of strong ellipticity (or of existence of two real strictly positive body wave-speeds), read[5.3],

$$\begin{array}{l} \mathbb{E} \text{ Positive Definite (PD)} \ \Leftrightarrow\ 3\,\lambda + 2\,\mu > 0 \text{ and } \mu > 0 \Leftrightarrow\ E > 0 \text{ and } \nu \in]-1,\, \tfrac{1}{2}[\,. \\ \mathbb{E} \text{ Strongly Elliptic (SE)} \ \Leftrightarrow\ \lambda + 2\,\mu > 0 \text{ and } \mu > 0 \Leftrightarrow\ E > 0 \text{ and } \nu \in]-1,\, \tfrac{1}{2}[\cup]1,\, \infty[\,. \end{array} \tag{5.2.30}$$

[5.3] Note that $E > 0$ and $\nu \in]1, \infty[$ implies $\lambda + 2\,\mu > 0 > \lambda + (2/3)\,\mu$, while $E > 0$ and $\nu \in]-1, 1/2[$ implies $\lambda + 2\,\mu > \lambda + (2/3)\,\mu > 0$.

In cartesian axes, the tensorial product $\overline{\underline{\otimes}}$ is defined componentwise as in (2.1.24),

$$(\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B})_{ijkl} = \frac{1}{2}\,(A_{ik}\,B_{jl} + A_{il}\,B_{jk}), \quad (\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B})[\mathbf{X}] = \frac{1}{2}\,(\mathbf{A}\cdot\mathbf{X}\cdot\mathbf{B}^{\mathrm{T}} + \mathbf{A}\cdot\mathbf{X}^{\mathrm{T}}\cdot\mathbf{B}^{\mathrm{T}})\,, \tag{5.2.31}$$

which, for $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{X}$ symmetric second order tensors, simplifies, to

$$(\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B})[X] = \mathbf{A}\cdot\mathbf{X}\cdot\mathbf{B}. \tag{5.2.32}$$

It is useful to record the component forms in arbitrary cartesian axes of the basic generators for isotropic materials,

$$[\mathbf{I}\otimes\mathbf{I}] = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \quad [\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}] = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}. \tag{5.2.33}$$

Note that $\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}$ is the identity tensor of order four over symmetric second order tensors,

$$\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} = \mathbf{I}_4\,. \tag{5.2.34}$$

The matrix form of the isotropic elastic stress-strain relation can thus be cast, in arbitrary cartesian axes, in the form,

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} = \begin{bmatrix} \lambda+2\,\mu & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda+2\,\mu & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda+2\,\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\,\mu & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\,\mu & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\,\mu \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix}. \tag{5.2.35}$$

5.2.6 Linear orthotropic elastic materials

Let $\mathbf{e}_a$, $a\in[1,3]$, be three orthonormal vectors indicating the directions of orthotropy of the elastic material. For infinitesimal strains, no distinction is made between the reference and current values of these entities, respectively $\underline{\mathbf{e}}_a$ and $\mathbf{e}_a$, $a\in[1,3]$. The second order tensors $\mathbf{A}_a = \mathbf{e}_a\otimes\mathbf{e}_a$, $a\in[1,3]$, are called *structure tensors*. They satisfy the identity,

$$\mathbf{A}_1 + \mathbf{A}_2 + \mathbf{A}_3 = \mathbf{I}\,, \tag{5.2.36}$$

with $\mathbf{I}$ the 2nd order identity tensor.

Convention: In this section, the convention of summation over the mute indices a and b applies. A subscript bar prevents this summation.

When the strain is the independent variable, the elastic potential $\mathcal{W}$, stress $\boldsymbol{\sigma} = \partial\mathcal{W}/\partial\boldsymbol{\epsilon} = \mathbb{E}:\boldsymbol{\epsilon}$ and elastic tensor moduli $\mathbb{E} = \partial^2\mathcal{W}/\partial\boldsymbol{\epsilon}\partial\boldsymbol{\epsilon}$ can be cast in the following format in terms of the generalized Lamé moduli $\lambda_{\mathrm{ab}} = \lambda_{\mathrm{ba}}$, μ_{a}, $a,b\in[1,3]$, Curnier et al. [1994],

$$\left\{\begin{array}{rcl} \mathcal{W}(\boldsymbol{\epsilon}) & = & \dfrac{\lambda_{\mathrm{ab}}}{2}\,(\mathbf{A}_a:\boldsymbol{\epsilon})\,(\mathbf{A}_b:\boldsymbol{\epsilon}) + \mu_{\mathrm{a}}\,\mathbf{A}_a:\boldsymbol{\epsilon}^2\,, \\ \boldsymbol{\sigma} & = & \dfrac{\lambda_{\mathrm{ab}}}{2}\,\Big((\mathbf{A}_a:\boldsymbol{\epsilon})\,\mathbf{A}_b + (\mathbf{A}_b:\boldsymbol{\epsilon})\,\mathbf{A}_a\Big) + \mu_{\mathrm{a}}\,(\mathbf{A}_a\cdot\boldsymbol{\epsilon} + \boldsymbol{\epsilon}\cdot\mathbf{A}_a)\,, \\ \mathbb{E} & = & \dfrac{\lambda_{\mathrm{ab}}}{2}\,(\mathbf{A}_a\otimes\mathbf{A}_b + \mathbf{A}_b\otimes\mathbf{A}_a) + \mu_{\mathrm{a}}\,(\mathbf{A}_a\,\overline{\underline{\otimes}}\,\mathbf{I} + \mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{A}_a)\,. \end{array}\right. \tag{5.2.37}$$

Elements of proof are deferred to Exercises 5.8, 5.11, and 6.5.

The number of independent coefficients depends on the material symmetries:

$$\begin{array}{lllll} \text{orthotropy} & 3\,\lambda_{\underline{aa}}, & 3\,\lambda_{\rm ab}(=\lambda_{\rm ba}),\ a<b, & 3\,\mu_{\rm a}, & 9 \text{ independent coefficients} \\ \text{transverse isotropy} & 2\,\lambda_{\underline{aa}}, & 1\,\lambda_{\rm ab}(=\lambda_{\rm ba}),\ a<b, & 2\,\mu_{\rm a}, & 5 \text{ independent coefficients} \\ \text{isotropy} & 1\,\lambda_{\underline{aa}}=\lambda, & & 1\,\mu_{\rm a}=\mu, & 2 \text{ independent coefficients} \end{array} \tag{5.2.38}$$

The components of the tensor moduli can be made explicit,

$$\begin{aligned} \mathbb{E} &= \sum_{a,b}\frac{\lambda_{\rm ab}}{2}\left(\mathbf{A}_a\otimes\mathbf{A}_b+\mathbf{A}_b\otimes\mathbf{A}_a\right)+\sum_a \mu_{\rm a}\left(\mathbf{A}_a\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_a\right), \\ E_{ijkl} &= \sum_{a,b}\frac{\lambda_{\rm ab}}{2}\left(A_{aij}\,A_{bkl}+A_{bij}\,A_{akl}\right)+\sum_a\frac{\mu_{\rm a}}{2}(A_{aik}\,I_{jl}+A_{ail}\,I_{jk}+A_{ajl}\,I_{ik}+A_{ajk}\,I_{il}), \\ E_{\underline{iiii}} &= \sum_{a,b}\lambda_{\rm ab}\,A_{a\underline{ii}}\,A_{b\underline{ii}}+\sum_a 2\,\mu_{\rm a}\,A_{a\underline{ii}} \quad \text{for i = j = k = l}, \\ E_{\underline{iikk}} &= \sum_{a,b}\frac{\lambda_{\rm ab}}{2}\left(A_{a\underline{ii}}\,A_{b\underline{kk}}+A_{a\underline{kk}}\,A_{b\underline{ii}}\right) \quad \text{for i = j} \neq \text{k = l}, \\ E_{\underline{ijij}} &= \sum_a\frac{\mu_{\rm a}}{2}\left(A_{a\underline{ii}}+A_{a\underline{jj}}\right) \qquad\qquad \text{for i = k} \neq \text{j = l}. \end{aligned} \tag{5.2.39}$$

In the axes of orthotropy, the elastic relation $(5.2.37)_2$ takes the following form,

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} = \begin{bmatrix} \lambda_{11}+2\,\mu_1 & \lambda_{12} & \lambda_{13} & 0 & 0 & 0 \\ \lambda_{12} & \lambda_{22}+2\,\mu_2 & \lambda_{23} & 0 & 0 & 0 \\ \lambda_{13} & \lambda_{23} & \lambda_{33}+2\,\mu_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu_2+\mu_3 & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu_1+\mu_3 & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu_1+\mu_2 \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix}. \tag{5.2.40}$$

For the sake of reference, the coefficients of the stiffness matrix in the orthotropy axes will be denoted through the components $c_{ij}=c_{ji}$, $i,j\in[1,3]$, and $c_{\underline{ii}}$, $i=4,5,6$,

$$[\mathbb{E}] = \begin{bmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{22} & c_{23} & 0 & 0 & 0 \\ c_{13} & c_{23} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\,c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\,c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\,c_{66} \end{bmatrix}. \tag{5.2.41}$$

Alternatively, and equivalently, when the stress is the independent variable, the complementary energy $\mathcal{W}_c$, the strain $\boldsymbol{\epsilon}=\partial\mathcal{W}_c/\partial\boldsymbol{\sigma}=\mathbb{E}^{-1}:\boldsymbol{\sigma}$ and the elastic compliance tensor $\mathbb{E}^{-1}$ can be expressed in terms of the Young's moduli E's and generalized Poisson's ratios ν's, linked by the symmetry relations[5.4]

$$\frac{\nu_{\rm ba}}{E_{\rm b}}=\frac{\nu_{\rm ab}}{E_{\rm a}},\quad a\neq b\in[1,3]\,. \tag{5.2.42}$$

[5.4] As a consequence of these three constraints, we have the relation $\nu_{12}\,\nu_{23}\,\nu_{31}=\nu_{21}\,\nu_{13}\,\nu_{32}$.

Indeed, Curnier et al. [1994],

$$\left\{\begin{array}{rcl} \mathcal{W}_c(\boldsymbol{\sigma}) &=& -\dfrac{\nu_{\rm ab}}{2\,E_{\rm a}}\,(\mathbf{A}_a\!:\!\boldsymbol{\sigma})\,(\mathbf{A}_b\!:\!\boldsymbol{\sigma}) + \dfrac{1+\nu_{\underline{\rm aa}}}{2\,E_{\rm a}}\,\mathbf{A}_a\!:\!\boldsymbol{\sigma}^2\,, \\ \boldsymbol{\epsilon} &=& -\dfrac{\nu_{\rm ab}}{2\,E_{\rm a}}\Big((\mathbf{A}_a\!:\!\boldsymbol{\sigma})\,\mathbf{A}_b + (\mathbf{A}_b\!:\!\boldsymbol{\sigma})\,\mathbf{A}_a\Big) + \dfrac{1+\nu_{\underline{\rm aa}}}{2\,E_{\rm a}}\,(\mathbf{A}_a\cdot\boldsymbol{\sigma}+\boldsymbol{\sigma}\cdot\mathbf{A}_a)\,, \\ \mathbb{E}^{-1} &=& -\dfrac{\nu_{\rm ab}}{2\,E_{\rm a}}\,(\mathbf{A}_a\otimes\mathbf{A}_b+\mathbf{A}_b\otimes\mathbf{A}_a) + \dfrac{1+\nu_{\underline{\rm aa}}}{2\,E_{\rm a}}\,(\mathbf{A}_a\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_a)\,. \end{array}\right. \tag{5.2.43}$$

Recall that the convention of summation over repeated indices does not apply to underlined indices.

As in (5.2.38), the number of independent coefficients depends on the material symmetries:

orthotropy	$3\,\nu_{\rm ab},\ a<b,$	$3\,\mu_{\rm ab},\ a<b,$	$3\,E_{\rm a},$	9 independent coefficients
transverse isotropy	$2\,\nu_{\rm ab},\ a<b,$	$1\,\mu_{\rm ab},\ a<b,$	$2\,E_{\rm a},$	5 independent coefficients
isotropy	$1\,\nu_{\rm ab}=\nu,$		$1\,E_{\rm a}=E,$	2 independent coefficients

(5.2.44)

Like for any material symmetry, the Young's modulus $E_{\rm a}$ associated with the direction $\mathbf{e}_a$ is defined from the compliance tensor,

$$\frac{1}{E_{\rm a}} = (\mathbf{e}_a\otimes\mathbf{e}_a)\,:\,\mathbb{E}^{-1}\,:\,(\mathbf{e}_a\otimes\mathbf{e}_a)\,. \tag{5.2.45}$$

The elastic relation $(5.2.43)_2$ can be cast in the following matrix form in the orthotropy axes,

$$\begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix} = \begin{bmatrix} \dfrac{1}{E_1} & -\dfrac{\nu_{21}}{E_2} & -\dfrac{\nu_{31}}{E_3} & 0 & 0 & 0 \\ -\dfrac{\nu_{12}}{E_1} & \dfrac{1}{E_2} & -\dfrac{\nu_{32}}{E_3} & 0 & 0 & 0 \\ -\dfrac{\nu_{13}}{E_1} & -\dfrac{\nu_{23}}{E_2} & \dfrac{1}{E_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \dfrac{1}{2\,\mu_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \dfrac{1}{2\,\mu_{13}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \dfrac{1}{2\,\mu_{12}} \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix}, \tag{5.2.46}$$

where

$$\frac{1}{\mu_{\rm ab}} = \frac{1}{\mu_{\rm ba}} = \frac{1+\nu_{\underline{\rm aa}}}{E_{\rm a}} + \frac{1+\nu_{\underline{\rm bb}}}{E_{\rm b}}, \quad a\neq b\in[1,3]\,. \tag{5.2.47}$$

The above forms (5.2.43), (5.2.46) and (5.2.47) introduce the (additional) generalized Poisson's ratios $\nu_{\rm ab}, a\geq b$, $a,b\in[1,3]$. Let us insist that the latter are not independent coefficients. They are obtained from the three generalized Young's moduli $E_{\rm a}$, $a\in[1,3]$ and three Poisson's ratios $\nu_{\rm ab}, a<b$, $a,b\in[1,3]$, via the symmetry relations (5.2.42).

The Young's moduli and Poisson's ratios can be calculated in terms of the generalized Lamé moduli, and conversely. The necessary algebras are left as an exercise, Exercise 5.9.

Convexity of the elastic potential of a linear elastic material can be shown to be equivalent to the positive definiteness of the elastic tensor moduli. The explicit conditions are explored in Exercise 5.10.

5.2.7 Prestress/prestrain in linear hyperelastic materials

The elastic potentials in the above section are homogeneous of degree two with respect to the strain or stress, so that stress and strain vanish simultaneously. The existence of an initial stress $\boldsymbol{\sigma}_0$ or initial strain $\boldsymbol{\epsilon}_0 = -\mathbb{E}^{-1}:\boldsymbol{\sigma}_0$

emanates from a linear term, namely

$$\left\{\begin{array}{rcl} \mathcal{W}(\boldsymbol{\epsilon}) &=& \dfrac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} + \boldsymbol{\sigma}_0 : \boldsymbol{\epsilon} \Leftrightarrow \boldsymbol{\sigma} = \mathbb{E} : \boldsymbol{\epsilon} + \boldsymbol{\sigma}_0, \\ \mathcal{W}_c(\boldsymbol{\sigma}) &=& \dfrac{1}{2}\,\boldsymbol{\sigma} : \mathbb{E}^{-1} : \boldsymbol{\sigma} + \boldsymbol{\epsilon}_0 : \boldsymbol{\sigma} \Leftrightarrow \boldsymbol{\epsilon} = \mathbb{E}^{-1} : \boldsymbol{\sigma} + \boldsymbol{\epsilon}_0\,. \end{array}\right. \tag{5.2.48}$$

The next version has another flavor, towards nonlinear elasticity and/or conewise response, but it is strictly equivalent to (5.2.48) for linear elasticity,

$$\left\{\begin{array}{rcl} \mathcal{W}(\boldsymbol{\epsilon}) &=& \dfrac{1}{2}\,(\boldsymbol{\epsilon} - \boldsymbol{\epsilon}_0) : \mathbb{E} : (\boldsymbol{\epsilon} - \boldsymbol{\epsilon}_0) \Leftrightarrow \boldsymbol{\sigma} = \mathbb{E} : (\boldsymbol{\epsilon} - \boldsymbol{\epsilon}_0), \\ \mathcal{W}_c(\boldsymbol{\sigma}) &=& \dfrac{1}{2}\,(\boldsymbol{\sigma} - \boldsymbol{\sigma}_0) : \mathbb{E}^{-1} : (\boldsymbol{\sigma} - \boldsymbol{\sigma}_0) \Leftrightarrow \boldsymbol{\epsilon} = \mathbb{E}^{-1} : (\boldsymbol{\sigma} - \boldsymbol{\sigma}_0) \end{array}\right. \tag{5.2.49}$$

5.2.8 Linear transversely isotropic elastic materials

For transversely isotropic materials, with the axis 3 as symmetry axis, the elastic characteristics specialize as indicated below. Details are provided in Exercise 5.11.

The stiffness expresses in terms of five independent generalized Lamé moduli λ_{T}, λ_{L}, λ_{LT}, μ_{T} and μ_{L}, namely in the orthotropy axes,

$$[\mathbb{E}] = \begin{bmatrix} \lambda_{\mathrm{T}} + 2\,\mu_{\mathrm{T}} & \lambda_{\mathrm{T}} & \lambda_{\mathrm{LT}} & 0 & 0 & 0 \\ \lambda_{\mathrm{T}} & \lambda_{\mathrm{T}} + 2\,\mu_{\mathrm{T}} & \lambda_{\mathrm{LT}} & 0 & 0 & 0 \\ \lambda_{\mathrm{LT}} & \lambda_{\mathrm{LT}} & \lambda_{\mathrm{L}} + 2\,\mu_{\mathrm{L}} & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\,\mu_{\mathrm{L}} & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\,\mu_{\mathrm{L}} & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\,\mu_{\mathrm{T}} \end{bmatrix}. \tag{5.2.50}$$

Similarly to the orthotropic case, the stiffness matrix in the orthotropy axes is recorded through the components of the associated 6×6 pseudo-matrix,

$$[\mathbb{E}] = \begin{bmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{13} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\,c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\,c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{11} - c_{12} \end{bmatrix}. \tag{5.2.51}$$

Conversely, the compliance matrix expresses in terms of two generalized Young's moduli, a shear modulus and two Poisson's ratios,

- E_{L} longitudinal, or axial, elastic modulus;
- E_{T} transverse, or cross-axial, elastic modulus;
- μ_{L} longitudinal, or zonal, shear modulus;
- ν_{T} transverse Poisson's ratio;
- ν_{L} longitudinal Poisson's ratio,

namely,

$$[\mathbb{E}]^{-1} = \begin{bmatrix} \dfrac{1}{E_{\rm T}} & -\dfrac{\nu_{\rm T}}{E_{\rm T}} & -\dfrac{\nu_{\rm L}}{E_{\rm L}} & 0 & 0 & 0 \\ -\dfrac{\nu_{\rm T}}{E_{\rm T}} & \dfrac{1}{E_{\rm T}} & -\dfrac{\nu_{\rm L}}{E_{\rm L}} & 0 & 0 & 0 \\ -\dfrac{\nu_{\rm L}}{E_{\rm L}} & -\dfrac{\nu_{\rm L}}{E_{\rm L}} & \dfrac{1}{E_{\rm L}} & 0 & 0 & 0 \\ 0 & 0 & 0 & \dfrac{1}{2\,\mu_{\rm L}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \dfrac{1}{2\,\mu_{\rm L}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \dfrac{1}{2\,\mu_{\rm T}} \end{bmatrix}, \tag{5.2.52}$$

where the transverse shear modulus expresses in terms of $E_{\rm T}$ and $\nu_{\rm T}$,

$$\frac{1}{\mu_{\rm T}} = \frac{2\,(1+\nu_{\rm T})}{E_{\rm T}}\,. \tag{5.2.53}$$

The following identifications have been used (the indices 1 and 2 may be exchanged):

$$E_1 = E_{\rm T}, \quad E_3 = E_{\rm L}, \quad \nu_{12} = \nu_{\rm T}, \quad \nu_{31} = \nu_{\rm L}, \quad \frac{\nu_{13}}{E_{\rm T}} = \frac{\nu_{\rm L}}{E_{\rm L}}, \quad \mu_L = \mu_{13}\,. \tag{5.2.54}$$

The generalized Lamé moduli of the elastic stiffness may be calculated in terms of the coefficients of the elastic compliance matrix, and conversely, Exercise 5.12.

Positive definiteness of the stiffness matrix expresses as, Exercise 5.13,

$$\mu_{\rm T} > \max(-\lambda_{\rm T}/2, 0), \quad (\lambda_{\rm T}+\mu_{\rm T})\,(\lambda_{\rm L}+2\,\mu_{\rm L}) > \lambda_{\rm LT}^2, \quad \mu_{\rm L} > 0\,, \tag{5.2.55}$$

while positive definiteness of the compliance matrix can be cast in the format,

$$E_{\rm L} > 0, \quad E_{\rm T} > 0, \quad -1 < \nu_{\rm T} < 1, \quad \frac{1-\nu_{\rm T}}{2}\frac{E_{\rm L}}{E_{\rm T}} - (\nu_{\rm L})^2 > 0, \quad \mu_{\rm L} > 0\,. \tag{5.2.56}$$

These two sets of conditions can be checked to be equivalent using the relations between the coefficients of the stiffness and compliance matrices established in Exercise 5.12.

The strong ellipticity condition is defined by Eqn (11.E.7) with the notation of (5.E.30). It bounds the generalized Lamé moduli,

$$\mu_{\rm T} > \max(-\lambda_{\rm T}/2, 0), \quad \mu_{\rm L} > \max(-\lambda_{\rm L}/2, 0), \quad \mu_{\rm L} + \sqrt{(\lambda_{\rm L}+2\,\mu_{\rm L})\,(\lambda_{\rm T}+2\,\mu_{\rm T})} > |\lambda_{\rm T}+\mu_{\rm T}|\,. \tag{5.2.57}$$

Once again, using the relations between the coefficients of the stiffness and compliance matrices established in Exercise 5.12, the strong ellipticity conditions can be expressed in terms of the generalized Young's moduli and Poisson's ratios.

A particular case will serve to illustrate the restrictions implied by positive definiteness and strong ellipticity, and their differences, Loret and Rizzi [1997]. Starting from the general expression (5.E.27), transverse isotropy is defined by a single parameter deviation from the underlying isotropic backbone, namely $a_1 = \lambda$, $a_2 = 2\,\mu$, $a_3 = 0$, $a_4 \neq 0$, $a_5 = 0$, so that $c_{11} = \lambda + 2\,\mu$, $c_{12} = c_{13} = \lambda$, $c_{44} = \mu$, but $c_{33} = \lambda + 2\,\mu + a_4$.

Assuming the stiffness of the underlying isotropic backbone to be positive definite, the positive definiteness of the transversely isotropic material yields, in addition to $(5.2.30)_1$,

$$\lambda + \frac{2}{3}\,\mu > 0, \quad \mu > 0, \quad a_4 > a_4^{\rm LPD} \equiv -\mu\,\frac{3\,\lambda + 2\,\mu}{\lambda + \mu} = -E\,. \tag{5.2.58}$$

On the other hand, the strong ellipticity of the transversely isotropic material implies, in addition to $(5.2.30)_2$,

$$\lambda + 2\,\mu > 0, \quad \mu > 0, \quad a_4 > a_4^{\rm LSE} \equiv \begin{cases} -4\,\mu\,\dfrac{\lambda+\mu}{\lambda+2\,\mu} & \text{if } \lambda \geq 0, \\ -(\lambda+2\,\mu) & \text{if } \lambda \leq 0\,. \end{cases} \tag{5.2.59}$$

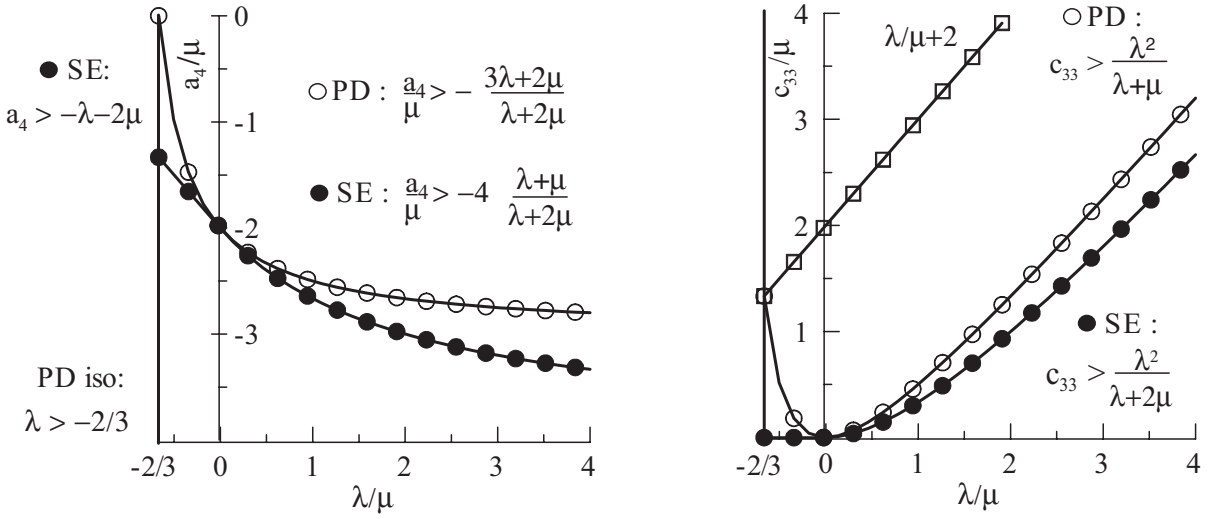

Fig. 5.2.1: Limit values of the parameter a_4 measuring a transversely isotropic perturbation from isotropy, according to (5.2.58), (5.2.59), (5.2.60). Reprinted with permission from Loret and Rizzi [1997].

Interestingly, these conditions relax the lower bound of the coefficient c_{33},

$$c_{33} > c_{33}^{\text{LPD}} \equiv \frac{\lambda^2}{\lambda+\mu}, \quad c_{33} > c_{33}^{\text{LSE}} \equiv \begin{cases} \dfrac{\lambda^2}{\lambda+2\,\mu} & \text{if } \lambda \geq 0, \\ 0 & \text{if } \lambda \leq 0\,. \end{cases} \tag{5.2.60}$$

The limit curves are plotted in Fig. 5.2.1. Note that the condition for positive definiteness is always strictly stronger than the condition for strong ellipticity, except at $\lambda = 0$, where the losses of positive definiteness and of strong ellipticity coincide.

5.2.9 Linear cubic elasticity

A cubic material is defined by three independent coefficients λ, λ' and μ,

$$\begin{cases} \mathcal{W}(\boldsymbol{\epsilon}) &= \dfrac{\lambda'}{2}\,(\mathbf{I}:\boldsymbol{\epsilon})^2 + \mu\,\mathbf{I}:\boldsymbol{\epsilon}^2 + \dfrac{1}{2}\,(\lambda-\lambda')\sum_a (\mathbf{A}_a:\boldsymbol{\epsilon})^2\,, \\ \boldsymbol{\sigma} &= \lambda'\,(\mathbf{I}:\boldsymbol{\epsilon})\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon} + (\lambda-\lambda')\sum_a (\mathbf{A}_a:\boldsymbol{\epsilon})\,\mathbf{A}_a\,, \\ \mathbb{E} &= \lambda'\,\mathbf{I}\otimes\mathbf{I} + 2\,\mu\,\mathbf{I}\,\underline{\otimes}\,\mathbf{I} + (\lambda-\lambda')\sum_a \mathbf{A}_a\otimes\mathbf{A}_a\,. \end{cases} \tag{5.2.61}$$

The stiffness may also be expressed componentwise in the symmetry axes as

$$E_{ijkl} = \lambda'\,I_{ij}\,I_{kl} + \mu\,(I_{ik}\,I_{jl} + I_{il}\,I_{jk}) + (\lambda-\lambda')\,I'_{ijkl}\,, \tag{5.2.62}$$

where all the components if $\mathbf{I}'$ vanish but $I'_{1111} = I'_{2222} = I'_{3333} = 1$. In the axes of material symmetry, the matrix form of the stress-strain relation reads

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} = \begin{bmatrix} \lambda+2\,\mu & \lambda' & \lambda' & 0 & 0 & 0 \\ \lambda' & \lambda+2\,\mu & \lambda' & 0 & 0 & 0 \\ \lambda' & \lambda' & \lambda+2\,\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\,\mu & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\,\mu & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\,\mu \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix}. \tag{5.2.63}$$

The compliance matrix expresses in terms of the three coefficients E, ν' and μ,

$$\begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix} = \begin{bmatrix} \frac{1}{E} & -\frac{\nu'}{E} & -\frac{\nu'}{E} & 0 & 0 & 0 \\ -\frac{\nu'}{E} & \frac{1}{E} & -\frac{\nu'}{E} & 0 & 0 & 0 \\ -\frac{\nu'}{E} & -\frac{\nu'}{E} & \frac{1}{E} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{2\,\mu} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{2\,\mu} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{2\,\mu} \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix}, \tag{5.2.64}$$

with

$$E = \lambda + 2\,\mu - \frac{2\,(\lambda')^2}{\lambda + 2\,\mu + \lambda'}\,, \quad \nu' = \frac{\lambda'}{\lambda + 2\,\mu + \lambda'}\,. \tag{5.2.65}$$

The conditions of positive definiteness of the elastic stiffness or compliance matrices boil down to

$$\{\lambda + 2\,\mu > \lambda' > -\frac{1}{2}(\lambda + 2\,\mu)\,, \quad \mu > 0\} \Leftrightarrow \{E > 0, \quad -1 < \nu' < \frac{1}{2}\,, \quad \mu > 0\}\,. \tag{5.2.66}$$

See Exercise 5.14 for a direct proof.

5.2.10 Saint-Venant's relations for linear elasticity

In absence of data on the elastic coefficients, algebraic assumptions are sometimes requested. Saint-Venant's relations[5.5] should be understood as such, Saint-Venant [1863], Lekhnitskii [1963]. They provide non trivial information for orthotropic and transversely isotropic materials, and should boil down to the standard isotropic relations as the material tends to an isotropic material.

For orthotropic materials, the Saint-Venant's relations read,

$$f_{\rm SV}(\mathbb{E}) = \frac{1}{\mu_{\rm ab}} - \frac{1+\nu_{\rm ab}}{E_{\rm a}} - \frac{1+\nu_{\rm ba}}{E_{\rm b}} = 0, \quad a \neq b \in [1,3]\,. \tag{5.2.67}$$

Other equivalent forms can be derived via the symmetry relations (5.2.42).

For transversely isotropic materials, with help of (5.2.54), the Saint-Venant's relation in the longitudinal direction ($a = 1, 2$; $b = 3$) specializes to,

$$f_{\rm SV}(\mathbb{E}) = \frac{1}{\mu_{\rm L}} - \frac{1}{E_{\rm T}} - \frac{1}{E_{\rm L}} - 2\,\frac{\nu_{\rm L}}{E_{\rm L}} = 0\,, \tag{5.2.68}$$

while it is an identity in the plane ($a = 2$; $b = 1$), namely $1/\mu_{\rm T} = 2\,(1+\nu_{\rm T})/E_{\rm T}$.

5.2.11 A particular elastic material with fabric anisotropy

There are several ways to introduce fabric into the elastic properties. One way is, along Cowin [1985], to assume that the elastic potential $\mathcal{W} = \mathcal{W}(\boldsymbol{\epsilon}, \mathbf{G})$ depends on both the infinitesimal strain tensor $\boldsymbol{\epsilon}$ and of the traceless second order fabric tensor $\mathbf{G}$ introduced in Section 12.5. The second step consists in applying representation theorems for scalar-valued isotropic functions, Section 2.11.3. For linear elasticity, the elastic potential involves 9 coefficients c_i, $i \in [1,9]$, which depend on the isotropic scalar invariants of $\mathbf{G}$, namely:

$$\begin{aligned} \mathcal{W} \;&=\; \frac{a_1}{2}(\mathrm{tr}\,\boldsymbol{\epsilon})^2 + \frac{a_2}{2}\mathrm{tr}\,\boldsymbol{\epsilon}^2 + \frac{a_3}{2}(\mathrm{tr}\,\boldsymbol{\epsilon}\cdot\mathbf{G})^2 + a_4\,\mathrm{tr}\,\boldsymbol{\epsilon}^2\cdot\mathbf{G} + \frac{a_5}{2}(\mathrm{tr}\,\boldsymbol{\epsilon}\cdot\mathbf{G}^2)^2 + \frac{a_6}{2}\mathrm{tr}\,(\boldsymbol{\epsilon}\cdot\mathbf{G})^2 + \\ &+\; a_7\,\mathrm{tr}\,\boldsymbol{\epsilon}\;\mathrm{tr}\,\boldsymbol{\epsilon}\cdot\mathbf{G} + a_8\,\mathrm{tr}\,\boldsymbol{\epsilon}\cdot\mathbf{G}\;\mathrm{tr}\,\boldsymbol{\epsilon}\cdot\mathbf{G}^2 + a_9\,\mathrm{tr}\,\boldsymbol{\epsilon}\;\mathrm{tr}\,\boldsymbol{\epsilon}\cdot\mathbf{G}^2\,. \end{aligned} \tag{5.2.69}$$

[5.5] Named after the French engineer, physicist and mathematician Adhémar Jean Claude Barré de Saint-Venant (1797-1886).

The resulting fourth order elastic tensor $\mathbb{E} = \partial^2\mathcal{W}/\partial\boldsymbol{\epsilon}\,\partial\boldsymbol{\epsilon}$, endowed with minor and major symmetries, takes the form:

$$\begin{aligned}\mathbb{E} &= a_1\,\mathbf{I}\otimes\mathbf{I} + a_2\,\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I} + a_3\,\mathbf{G}\otimes\mathbf{G} + a_4\,(\mathbf{G}\,\overline{\underline{\otimes}}\,\mathbf{I} + \mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{G}) + a_5\,\mathbf{G}^2\otimes\mathbf{G}^2 + a_6\,\mathbf{G}\,\overline{\underline{\otimes}}\,\mathbf{G} + \\ &+ a_7\,(\mathbf{I}\otimes\mathbf{G} + \mathbf{G}\otimes\mathbf{I}) + a_8\,(\mathbf{G}\otimes\mathbf{G}^2 + \mathbf{G}^2\otimes\mathbf{G}) + a_9\,(\mathbf{I}\otimes\mathbf{G}^2 + \mathbf{G}^2\otimes\mathbf{I})\,.\end{aligned} \tag{5.2.70}$$

The fact that $\mathbf{G}$ is traceless affects the formal representation (5.2.69) only through the functional dependence of the scalar functions c_i upon the invariants of $\mathbf{G}$.

An alternative, particular and more compact, form of anisotropic elasticity based on a second order fabric tensor has been proposed by Valanis [1990] and Zysset and Curnier [1995] for the analysis of damage in metals and biomaterials. Its particularly appealing format makes possible the existence of a correspondence principle in the analysis of instability in geomaterials, Bigoni and Loret [1999], Loret et al. [2001].

The derivation is essentially heuristic, as follows. Let us first record the elastic isotropic tensor $\mathbb{E}_{\rm iso}$ which will be viewed as a reference:

$$\mathbb{E}_{\rm iso} = \lambda\,\mathbf{I}\otimes\mathbf{I} + 2\,\mu\,\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}\,, \tag{5.2.71}$$

where λ and μ are the standard Lamé moduli. Given a symmetric second order tensor $\mathbf{B}$, the homogeneous *de visu* modification of $\mathbb{E}_{\rm iso}$[5.6],

$$\mathbb{E} = \lambda\,\mathbf{B}\otimes\mathbf{B} + 2\,\mu\,\mathbf{B}\,\overline{\underline{\otimes}}\,\mathbf{B}\,, \tag{5.2.72}$$

associates with a strain $\boldsymbol{\epsilon}$ the effective stress $\boldsymbol{\sigma}$ (recall the notation $(\mathbf{B}\,\overline{\underline{\otimes}}\,\mathbf{B})_{ijkl} = (B_{ik}\,B_{jl} + B_{il}\,B_{jk})/2$),

$$\boldsymbol{\sigma} = \mathbb{E} : \boldsymbol{\epsilon} \equiv \lambda\,(\mathbf{B} : \boldsymbol{\epsilon})\,\mathbf{B} + 2\,\mu\,\mathbf{B}\cdot\boldsymbol{\epsilon}\cdot\mathbf{B}\,. \tag{5.2.73}$$

Clearly, for this transformation to be meaningful, $\mathbf{B}$ should satisfy some restrictions. For the elasticity tensor $\mathbb{E}$ to be positive definite, $\mathbf{B}$ should be definite and, without loss of generality, we shall assume $\mathbf{B}$ to be positive definite. Consequently, $\mathbf{B}$ can not be traceless. There is no loss of generality either in scaling $\mathbf{B}$ to facilitate comparison with respect to the isotropic reference $\mathbb{E}_{\rm iso}$. Summarizing, $\mathbf{B}$ is built from a traceless fabric tensor $\mathbf{G}$ and satisfies the following conditions:

$$\mathbf{B} = g\,\mathbf{I} + \mathbf{G} \qquad \text{Positive Definite}\,, \qquad \operatorname{tr}\mathbf{B}^2 = 3\,. \tag{5.2.74}$$

Note that the eigendirections of $\mathbf{B}$ are the axes of orthotropy of the material elasticity. An alternative format could use an angle α and a unit traceless second order tensor $\hat{\mathbf{G}}$,

$$\mathbf{B} = \cos\,\alpha\,\mathbf{I} + \sqrt{3}\,\sin\alpha\,\hat{\mathbf{G}}\,. \tag{5.2.75}$$

As a second consequence of the positive definiteness and scaling of $\mathbf{B}$, g belongs to the interval $]0,1]$. As a third consequence, the necessary and sufficient conditions for positive definiteness and strong ellipticity of $\mathbb{E}$ turn out to be the same as for the isotropic reference $\mathbb{E}_{\rm iso}$:

$$\mathbb{E} \text{ Positive Definite } \Leftrightarrow\ 3\,\lambda + 2\,\mu > 0 \text{ and } \mu > 0\,, \tag{5.2.76}$$

$$\mathbb{E} \text{ Strongly Elliptic } \Leftrightarrow\ \lambda + 2\,\mu > 0 \text{ and } \mu > 0\,. \tag{5.2.77}$$

Positive definiteness results from the relation,

$$\begin{aligned}&\mathbf{X} : \mathbb{E} : \mathbf{X} = \tilde{\mathbf{X}} : \mathbb{E}_{\rm iso} : \tilde{\mathbf{X}},\\ &\text{for } \mathbf{X} = \mathbf{X}^{\rm T}, \quad \tilde{\mathbf{X}} = \mathbf{B}^{1/2}\cdot\mathbf{X}\cdot\mathbf{B}^{1/2}\,,\end{aligned} \tag{5.2.78}$$

that holds for any symmetric second order tensor $\mathbf{X}$. Similarly, the strong ellipticity property results from Eqn (11.2.30) that will be shown later.

Moreover, the elastic compliance tensor has also the same format as its isotropic counterpart,

$$\mathbb{E}^{-1} = -\frac{\nu}{E}\,\mathbf{B}^{-1}\otimes\mathbf{B}^{-1} + \frac{1+\nu}{E}\,\mathbf{B}^{-1}\,\overline{\underline{\otimes}}\,\mathbf{B}^{-1}\,, \tag{5.2.79}$$

[5.6] Note also that a material endowed with linear isotropic elasticity in a reference configuration turns anisotropic in the current configuration and its elastic tensor moduli undergo a transformation associated with the left Cauchy-Green tensor of the very form (5.2.72). See Eqn (2.9.8) and Section 2.9 for a detailed derivation.

so that

$$\boldsymbol{\epsilon} = \mathbb{E}^{-1} : \boldsymbol{\sigma} = -\frac{\nu}{E} (\mathbf{B}^{-1} : \boldsymbol{\sigma}) \mathbf{B}^{-1} + \frac{1+\nu}{E} \mathbf{B}^{-1} \cdot \boldsymbol{\sigma} \cdot \mathbf{B}^{-1}, \tag{5.2.80}$$

where the Young's modulus E and Poisson's ratio ν are linked to the Lamé moduli in the usual way, Eqn (5.2.29).

Let $\mathbf{B} = \sum_a b_a \mathbf{B}_a$ be the spectral decomposition of the fabric tensor $\mathbf{B}$. If the latter is considered independent of strain, then the material is in fact hyperelastic and

$$\left\{ \begin{array}{rcl} \mathcal{W}(\boldsymbol{\epsilon}) & = & \frac{\lambda}{2} (\mathbf{B} : \boldsymbol{\epsilon})^2 + \mu (\mathbf{B} \cdot \boldsymbol{\epsilon}) : (\boldsymbol{\epsilon} \cdot \mathbf{B}), \\ \boldsymbol{\sigma} & = & \frac{\lambda}{2} b_a b_b \Big((\mathbf{B}_a : \boldsymbol{\epsilon}) \mathbf{B}_b + (\mathbf{B}_b : \boldsymbol{\epsilon}) \mathbf{B}_a \Big) + \mu\, b_a b_b (\mathbf{B}_a \cdot \boldsymbol{\epsilon} \cdot \mathbf{B}_b + \mathbf{B}_b \cdot \boldsymbol{\epsilon} \cdot \mathbf{B}_a), \\ \mathbb{E} & = & \frac{\lambda}{2} b_a b_b (\mathbf{B}_a \otimes \mathbf{B}_b + \mathbf{B}_b \otimes \mathbf{B}_a) + \mu\, b_a b_b (\mathbf{B}_a \underline{\otimes} \mathbf{B}_b + \mathbf{B}_b \underline{\otimes} \mathbf{B}_a). \end{array} \right. \tag{5.2.81}$$

In the orthotropy axes, the stiffness and compliance matrices can be cast in the respective forms,

$$[\mathbb{E}] = \begin{bmatrix} (\lambda + 2\mu) b_1^2 & \lambda b_1 b_2 & \lambda b_1 b_3 & 0 & 0 & 0 \\ \lambda b_1 b_2 & (\lambda + 2\mu) b_2^2 & \lambda b_2 b_3 & 0 & 0 & 0 \\ \lambda b_1 b_3 & \lambda b_2 b_3 & (\lambda + 2\mu) b_3^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\mu b_2 b_3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\mu b_1 b_3 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\mu b_1 b_2 \end{bmatrix}, \tag{5.2.82}$$

and

$$[\mathbb{E}]^{-1} = \begin{bmatrix} \frac{1}{E}\frac{1}{b_1^2} & -\frac{\nu}{E}\frac{1}{b_1 b_2} & -\frac{\nu}{E}\frac{1}{b_1 b_3} & 0 & 0 & 0 \\ -\frac{\nu}{E}\frac{1}{b_1 b_2} & \frac{1}{E}\frac{1}{b_2^2} & -\frac{\nu}{E}\frac{1}{b_2 b_3} & 0 & 0 & 0 \\ -\frac{\nu}{E}\frac{1}{b_1 b_3} & -\frac{\nu}{E}\frac{1}{b_2 b_3} & \frac{1}{E}\frac{1}{b_3^2} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{2\mu}\frac{1}{b_2 b_3} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{2\mu}\frac{1}{b_1 b_3} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{2\mu}\frac{1}{b_1 b_2} \end{bmatrix}. \tag{5.2.83}$$

When the eigenvalues $b_i > 0$, $i \in [1,3]$, of $\mathbf{B}$ are distinct, the above elastic anisotropy involves four scalar parameters, namely λ, μ, and two of the three eigenvalues of $\mathbf{B}$, in addition to the eigenvectors $\mathbf{b}_i$, $i \in [1,3]$, of $\mathbf{B}$ which play the role of orthotropy directions. Now, two questions may arise:

1. Is this anisotropy a particular case of the nine parameter family defined earlier, Eqn (5.2.69)?
2. Is this anisotropy a particular case of structural anisotropy?

Zysset and Curnier [1995] have given an affirmative answer to the first of the above questions and identified the coefficients a_i, $i \in [1,9]$, in relation (5.2.69):

$$a_1 = \lambda g^2,\ a_2 = 2\mu g^2,\ a_3 = \lambda,\ a_4 = 2\mu g,\ a_6 = 2\mu,\ a_7 = \lambda g,\ a_5 = a_8 = a_9 = 0. \tag{5.2.84}$$

The answer to the second question is affirmative as well: a proof is sketched in Exercise 5.17.

When two of the eigenvalues of $\mathbf{B}$ are equal, the material response is defined by three independent scalar parameters, and it is transversely isotropic. The proof is deferred to Exercise 5.18.

Otherwise, due to the scaling Eqn (5.2.74), $\mathbf{B} = \mathbf{I}$ and the material response is isotropic as expected.

Remark: the fabric elasticity above does not satisfy the Saint-Venant's relations .

On comparing (5.2.46) and (5.2.83), the Young's moduli and Poisson's ratios are identifed to

$$E_{\rm a} = E\, b_a^2, \quad \nu_{\rm ab} = \nu\, \frac{b_a}{b_b}, \quad a \neq b \in [1,3]\,. \tag{5.2.85}$$

The Saint-Venant's relation can be recast in the format,

$$\frac{1}{\mu} = \frac{b_a^2 + b_b^2}{b_a\, b_b}\, \frac{1}{E} + 2\, \frac{\nu}{E}, \quad a \neq b \in [1,3]\,. \tag{5.2.86}$$

Since $1/\mu = 2/E + 2\,\nu/E$, it is not satisfied, unless $b_a = b_b$, which indeed, as already observed, takes place for a transversely isotropic material in the symmetry plane.

5.3 Spectral analysis of the elastic matrix

The spectral analysis of the elasticity tensor has been addressed, among the firsts, by Mehrabadi and Cowin [1990] and Luehr and Rubin [1990].

The point is to search for the eigenvalues and eigenmodes of the elasticity stiffness or compliance tensors. The isometric representation makes it possible to perform this spectral analysis on the matrix representation itself, namely

$$\boldsymbol{\sigma} = \mathbb{E} : \boldsymbol{\epsilon} = \Lambda\, \boldsymbol{\epsilon} \quad \Leftrightarrow \quad [\boldsymbol{\sigma}] = [\mathbb{E}][\boldsymbol{\epsilon}] = \Lambda\, [\boldsymbol{\epsilon}]\,. \tag{5.3.1}$$

The maximum number of eigenvalues and eigenmodes is thus six. Since the stiffness matrix is symmetric, the eigenvalues and eigenmodes are real. Let $\Lambda^{(k)}$ and $\boldsymbol{\epsilon}^{(k)}$ ($[\boldsymbol{\epsilon}^{(k)}]$ in vector form) be the k-th eigenvalue and unit eigenmode, respectively, $\boldsymbol{\epsilon}^{(\underline{k})} : \boldsymbol{\epsilon}^{(\underline{k})} = 1$. Then, if the eigenvalues are distinct, the stiffness can be decomposed as the sum

$$\mathbb{E} = \sum_{k=1}^{6} \Lambda^{(k)}\, \mathbb{P}^{(k)}\,, \tag{5.3.2}$$

where the fourth order *projection operators* on the associated subspaces,

$$\mathbb{P}^{(k)} = \boldsymbol{\epsilon}^{(\underline{k})} \otimes \boldsymbol{\epsilon}^{(\underline{k})}, \quad k \in [1,6], \tag{5.3.3}$$

are orthonormal,

$$\mathbb{P}^{(k)} : \mathbb{P}^{(l)} = \mathbb{P}^{(\underline{k})}\, I_{\underline{k}l}, \quad k,l \in [1,6], \tag{5.3.4}$$

and sum to the fourth order identity tensor,

$$\sum_{k=1}^{6} \mathbb{P}^{(k)} = \mathbf{I}_4\,. \tag{5.3.5}$$

5.3.1 Spectral analysis: linear elastic isotropic materials

In the particular case of an isotropic material, $2\,\mu$ is the shear eigenvalue of multiplicity 5 with eigenmodes defined by the expresssions,

$$[\boldsymbol{\epsilon}^{(1)}] = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \quad [\boldsymbol{\epsilon}^{(2)}] = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad [\boldsymbol{\epsilon}^{(3)}] = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}; \tag{5.3.6}$$

$$[\boldsymbol{\epsilon}^{(4)}] = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad [\boldsymbol{\epsilon}^{(5)}] = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \tag{5.3.7}$$

while the bulk eigenvalue $K = \lambda + (2/3)\,\mu$ is associated with the eigenmode $\boldsymbol{\epsilon}^{(6)} = \mathbf{I}/\sqrt{3}$. We thus have a spectral decomposition of the elastic tensor,

$$\mathbb{E} \;=\; \overbrace{2\,\mu \sum_{k\in[1,5]} \mathbb{P}^{(k)}}^{\text{isochoric part}} \;+\; \overbrace{K\,\mathbb{P}^{(6)}}^{\substack{\text{dilatational}\\ \text{part}}}\,. \tag{5.3.8}$$

Table 5.3.1: Spectral decomposition of the isotropic elastic tensor.

Eigenvalue	Multiplicity	Eigenmode	Property
$\Lambda^{(1\to5)}=2\,\mu$	5	$\boldsymbol{\epsilon}^{(1\to5)}$, Eqns (5.3.6)-(5.3.7)	Isochoric
$\Lambda^{(6)}=K$	1	$\boldsymbol{\epsilon}^{(6)}=\mathbf{I}/\sqrt{3}$	Dilatational

5.3.2 Spectral analysis: linear elastic transversely isotropic materials

5.3.2.1 Transverse isotropy: PD and SE domains

Let us start from the transversely isotropic elastic matrix (5.2.51). When four eigenvalues of $\mathbb{E}$ are distinct, two of them are double, $\Lambda^{(1,2)}$ and $\Lambda^{(3,4)}$, and the other two are single, $\Lambda^{(5)}$ and $\Lambda^{(6)}$,

$$\Lambda^{(5,6)}=\frac{1}{2}\left(c_{11}+c_{12}+c_{33}\pm\sqrt{(c_{11}+c_{12}-c_{33})^2+8\,c_{13}^2}\right), \tag{5.3.9}$$

associated with the eigenmodes

$$\boldsymbol{\epsilon}^{(5,6)}=\mathbf{diag}\left[c_{12}(\Lambda^{(5,6)}-c_{33})+c_{13}^2,\ c_{12}(\Lambda^{(5,6)}-c_{33})+c_{13}^2,\ c_{13}(\Lambda^{(5,6)}-c_{11}+c_{12})\right]. \tag{5.3.10}$$

The spectral decomposition of the elastic tensor takes the form,

$$\mathbb{E}\ =\ \overbrace{2\,c_{44}\sum_{k=1,2}\mathbb{P}^{(k)}+(c_{11}-c_{12})\sum_{k=3,4}\mathbb{P}^{(k)}}^{\text{isochoric part}}\ +\ \overbrace{\Lambda^5\,\mathbb{P}^5\ +\ \Lambda^6\,\mathbb{P}^6}^{\text{dilatational part}}. \tag{5.3.11}$$

The eigenvalues and associated eigenmodes are listed in Table 5.3.2.

Table 5.3.2: Spectral decomposition of the transversely isotropic elastic tensor.

Eigenvalue	Multiplicity	Eigenmode	Property
$\Lambda^{(1,2)}=2\,c_{44}$	2	$\boldsymbol{\epsilon}^{(1,2)}$, Eqn (5.3.6)	Isochoric
$\Lambda^{(3,4)}=c_{11}-c_{12}$	2	$\boldsymbol{\epsilon}^{(3,4)}$, Eqn (5.3.7)	Isochoric
$\Lambda^{(5,6)}$, Eqn (5.3.9)	1	$\boldsymbol{\epsilon}^{(5,6)}$, Eqn (5.3.10)	Dilatational

5.3.2.2 Transverse isotropy: limit of the PD domain

A special case of transverse isotropy defined by a one-parameter deviation with respect to isotropy is considered in section Section 5.2.8. The spectral analysis of the elastic stiffness at loss of positive definiteness for $a_4=a_4^{\rm LPD}$ specializes as follows when $\lambda/\mu\neq0$:

$$\begin{aligned}
&-\ \text{eigenvalues } \Lambda^{(1,2,3,4)}=2\,\mu \text{ of multiplicity 4;}\\
&\quad \Lambda^{(5)}=\frac{3\,\lambda^2+4\,\lambda\,\mu+2\,\mu^2}{\lambda+\mu}>0;\qquad \Lambda^{(6)}=0 \text{ of multiplicity 1;}\\
&-\ \text{eigenmodes } \boldsymbol{\epsilon}^{(1,2,3,4)} \text{ given by Eqns (5.3.6) – (5.3.7) ;}\\
&\quad [\boldsymbol{\epsilon}^{(5)}]=\sqrt{\tilde\epsilon}\begin{bmatrix}1&0&0\\0&1&0\\0&0&\tilde\lambda\end{bmatrix};\quad [\boldsymbol{\epsilon}^{(6)}]=\frac{\sqrt{\tilde\epsilon}}{\sqrt{2}}\begin{bmatrix}-\tilde\lambda&0&0\\0&-\tilde\lambda&0\\0&0&2\end{bmatrix},
\end{aligned} \tag{5.3.12}$$

with $\tilde\epsilon=(\lambda+\mu)/\Lambda^{(5)}$ and $\tilde\lambda=\lambda/(\lambda+\mu)$. Therefore, the spectral decomposition of the elastic stiffness remains formally as indicated by (5.3.11).

5.3.2.3 Transverse isotropy: limit of the PD and SE domains

The case where $\lambda = 0$ is peculiar because it is the only value for which losses of strong ellipticity and positive definiteness take place simultaneously, Section 5.2.8.

According to Section 2.2.4, the null space of $\mathbb{E}$, namely the eigenmodes of $\mathbb{E}$ associated with its zero eigenvalue, contains a symmetrized dyadic form $\boldsymbol{\epsilon}^{\otimes}$ only for this value. Indeed, then the spectral analysis of $\boldsymbol{\epsilon}$ is modified as follows:

– eigenvalues $\Lambda^{(1,2,3,4,5)} = 2\,\mu$ of algebraic multiplicity 5; $\quad \Lambda^{(6)} = 0$ of multiplicity 1;

– eigenmodes $\boldsymbol{\epsilon}^{(1)}, \boldsymbol{\epsilon}^{(2)}, \boldsymbol{\epsilon}^{(3)}$ given by Eqns (5.3.6) – (5.3.7) and

$$[\boldsymbol{\epsilon}^{(4)}] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad [\boldsymbol{\epsilon}^{(5)}] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}; \quad [\boldsymbol{\epsilon}^{(6)}] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{5.3.13}$$

As alluded for earlier, the eigenmode $\boldsymbol{\epsilon}^{(6)}$ has indeed a dyadic form, namely $\boldsymbol{\epsilon}^{(6)} = \mathbf{e}_3 \otimes \mathbf{e}_3$, while its counterpart in the case $\lambda \neq 0$ does not have such a form (even at loss of positive definiteness). Thus, for $\lambda = 0$, the spectral decomposition of $\mathbb{E}$ reads:

$$\mathbb{E} = \overbrace{2\,\mu \sum_{k\in[1,3]} \mathbb{P}^{(k)}}^{\substack{\text{isochoric} \\ \text{contribution}}} + \overbrace{2\,\mu \sum_{k=4,5} \mathbb{P}^{(k)}}^{\substack{\text{dilatational} \\ \text{contribution}}} + \overbrace{[\,\Lambda^6\,\mathbb{P}^{(6)}\,]}^{\substack{\text{dilatational} \\ \text{contribution}}} . \tag{5.3.14}$$

5.3.3 Spectral analysis: linear elastic orthotropic materials

The spectral analysis is performed on the matrix form (5.2.41). The three real positive eigenvalues $\Lambda = 2\,c_{\underline{ii}}$, $i = 4, 5$ and 6, are associated with the deviatoric eigenmodes $\boldsymbol{\epsilon}^{(1)}$, $\boldsymbol{\epsilon}^{(2)}$ and $\boldsymbol{\epsilon}^{(3)}$ of Eqn (5.3.6) in that respective order. The three eigenvalues Λ stemming from the 3×3 principal minor $[\mathbf{c}]$, which are solutions of the secular eqution,

$$-\Lambda^3 + I_1([\mathbf{c}])\,\Lambda^2 - I_2([\mathbf{c}])\,\Lambda + I_3([\mathbf{c}]) = 0\,, \tag{5.3.15}$$

are real positive as well since the symmetric stiffness is assumed to be positive definite.

A particular eigenvalue Λ is associated with an isochoric eigenmode if it satisfies simultaneously the relation,

$$\Lambda^2 - \big(c_{11} + c_{22} - c_{13} - c_{23}\big)\,\Lambda + (c_{11} - c_{13})\,(c_{22} - c_{23}) - (c_{12} - c_{13})\,(c_{12} - c_{23}) = 0\,. \tag{5.3.16}$$

This equation results from the following manipulations. The eigenvalue problem is expressed in the format $([\mathbf{c}] - \Lambda\,[\mathbf{I}])\,[\boldsymbol{\epsilon}] = \mathbf{0}$, with $[\boldsymbol{\epsilon}] = [\epsilon_{11}\ \epsilon_{22}\ \epsilon_{33}]^{\mathrm{T}}$. Insertion of $\epsilon_{33} = -\epsilon_{11} - \epsilon_{22}$ in the two first of these equations yields a system for ϵ_{11} and ϵ_{22} with zero rhs. For the solution to be non trivial, the determinant of this system should vanish, resulting in (5.3.16). Two equivalent relations can be obtained by permutation of the indices. Summing the three relations delivers a quadratic relation for Λ with symmetric coefficients.

5.4 Fiber-reinforced materials: extension-contraction response

Fibers are sustaining tensile loads. They buckle under compressive loads. One may also be tempted to consider that the fibers are active in extension, not in contraction. Actually, these two points of view, the stress and the strain points of view, are not equivalent in a general three-dimensional analysis, nor even in a one-dimensional context.

The sets of strains which correspond to extension and contraction will be defined through the notion of *cone*, which is defined in the footnote on p. 70. This section first summarizes the basic relations that any conewise mechanical response has to satisfy. Several forms of anisotropy are examined. A second part reviews the experimental data available to date in the literature for a particular material, which is reinforced by fibers, namely articular cartilage.

Alternative approaches to deal with fiber uncrimping and fiber reinforcement are exposed in Chapters 12 and 19.

5.4.1 Basic remarks on the mechanical response of fiber-reinforced tissues

Articular cartilage is a porous medium saturated by an electrolyte. Compressive loads are sustained by negatively charged macromolecules, the proteoglycans. An interconnected network of collagen fibers allows cartilage to resist tensile and shear loads. Therefore, the apparent mechanical properties of cartilage are bound to be anisotropic *and* distinct in extension and contraction.

The mechanical response of articular cartilage is the result of electro-chemomechanical couplings. In fact, the definition of a purely mechanical response is not unambiguous. Actually, the most reliable sources of information are those who present rough data, free of interpretation, showing applied or measured stress and strain components: such data will reveal the *apparent*, or coupled, or macroscopic, material response of cartilage.

The picture is actually still more complex because chemomechanical couplings are accompanied with diffusion, a phenomenon that per se introduces spatial heterogeneity. It is possible to free the data of this heterogeneity by collecting only measurements at steady states, at which diffusion has come to an end. However, there are several characteristic times in the electro-chemomechanical response of cartilage due to its compartmental structure. Indeed, deformation may become steady before diffusion stops, so that, in practice, data that are reported to correspond to steady states may be biased by a slowly ongoing diffusion. The latter may marginally affect deformation but might, in the long range or when the loading conditions change, lead to difficulties of interpretation.

Another source of difficulty is due to the fact that articular cartilage has a heterogeneous composition in depth. Thus, measurements will depend on the location, and they may also be biased by the size (thickness) of the specimens tested.

5.4.2 Conewise constitutive response: generalities

5.4.2.1 Extension-contraction and tension-compression dependent responses

A distinction should be made between two types of conewise responses, Fig. 5.4.1:

- the mechanical response of the tissue may be *strain driven*. In particular, the moduli along the orthotropy directions may assume different values depending on the sign of the strains along these directions, so that the tensor moduli are said to be **extension-contraction** dependent.
- alternatively, the response may be *stress driven*, so that the moduli depend on the sign of some stress component along the orthotropy axes, and the tensor moduli are said to be **tension-compression** dependent.

This second possibility is not pursued below, and emphasis is placed on the extension-contraction conewise response. Still, a strain based criterion has to face the crucial choice of the reference configuration (where the strain vanishes). For articular cartilages, the hypertonic state is the natural candidate.

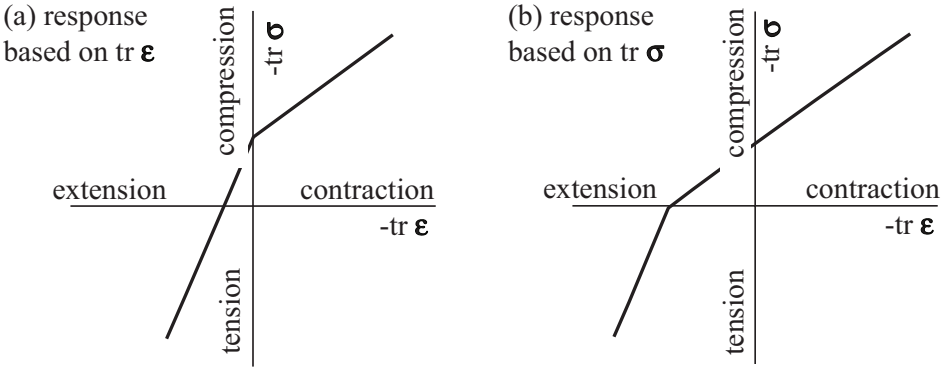

Fig. 5.4.1: For an isotropic elastic material, the sole bulk modulus may take distinct values whether (a) in an extension-contraction strain based conewise response, or (b) in a tension-compression stress based conewise response.

With this terminology in place, the sign conventions for strains and stresses can be defined. An extension gives rise to a positive strain and tension is associated with a positive stress.

5.4.2.2 Analysis of an extension-contraction dependent response

Let us note $g(\boldsymbol{\epsilon}) = 0$ the interface in strain-space on both sides of which the tensor moduli differ. For definiteness, the side $g(\boldsymbol{\epsilon}) > 0$ will be denoted by the superscript '+' and the side $g(\boldsymbol{\epsilon}) < 0$ by the superscript '−'. Two basic properties are required:

- the stress $\boldsymbol{\sigma}$ is continuous across the interface $g(\boldsymbol{\epsilon}) = 0$;
- the stress is differentiable on each side of the interface, in fact $d\boldsymbol{\sigma}/d\boldsymbol{\epsilon}$ is equal to the tensor moduli $\mathbb{E}$ on each side of the interface.

Then by an extension of the Hadamard's compatibility conditions exposed in Section 11.1.3, the difference $\mathbb{E}^+ - \mathbb{E}^-$ should be dyadic as encapsulated by

Proposition 5.1 The tensor moduli on each side of the interface $g(\boldsymbol{\epsilon}) = 0$ differ by a symmetric dyadic product,

$$\mathbb{E}^+ = \mathbb{E}^- + s\,\frac{dg}{d\boldsymbol{\epsilon}} \otimes \frac{dg}{d\boldsymbol{\epsilon}}\,, \tag{5.4.1}$$

where $s = s(g(\boldsymbol{\epsilon}))$ denotes the amplitude of the jump across the interface, equivalently

$$\begin{cases} \boldsymbol{\sigma} &= \mathbb{E}^- : \boldsymbol{\epsilon} & \text{on } g(\boldsymbol{\epsilon}) \le 0, \\ \boldsymbol{\sigma} &= \mathbb{E}^+ : \boldsymbol{\epsilon} = (\mathbb{E}^- + s\,\dfrac{dg}{d\boldsymbol{\epsilon}} \otimes \dfrac{dg}{d\boldsymbol{\epsilon}}) : \boldsymbol{\epsilon} & \text{on } g(\boldsymbol{\epsilon}) \ge 0\,. \end{cases} \tag{5.4.2}$$

Note 5.1 on rank one modifications.

There are other instances in continuum mechanics where the traces of two fourth order tensors are required to coincide along some interface, e.g., the elastic and elastoplastic tensor moduli. As another example, one may cite the drained and undrained elastic tensors in fluid-saturated porous media, e.g., Loret et al. [2001] and Section 7.4.

Note 5.2 on piecewise and global hyperelasticity.

A constitutive law which is piecewise hyperelastic and satisfies the above condition (5.4.1) is (globally) hyperelastic, Curnier et al. [1994].

Note 5.3 on convex domains.

One may wish to have both sides of the interface convex in order to apply the classical results of functional analysis. Then the interface should be a hyperplane, i.e., $dg/d\boldsymbol{\epsilon}$ constant.

Note 5.4 on conewise symmetry groups.

The material symmetry groups on each side of the interface might be distinct, e.g., isotropy on one side and orthotropy on the other side.

5.4.3 Application to materials with one family of fibers

Let $\mathbf{m} = \mathbf{e}_1$ be the unit vector that indicates the direction of the fibers in a reference configuration, and

$$\mathbf{A}_1 = \mathbf{M} = \mathbf{m} \otimes \mathbf{m}\,. \tag{5.4.3}$$

The fibers are assumed to be mechanically active only if they undergo extension, namely

$$g(\boldsymbol{\epsilon}) \equiv \boldsymbol{\epsilon} : \mathbf{M} \ge 0\,. \tag{5.4.4}$$

Thus the moduli corresponding to extended fibers and contracted fibers differ only by the dyadic product,

$$\mathbb{E} = \mathbb{E}^- + s\,\mathcal{H}(\mathbf{M} : \boldsymbol{\epsilon})\,\mathbf{M} \otimes \mathbf{M}\,, \tag{5.4.5}$$

where $s = s(\boldsymbol{\epsilon} : \mathbf{M})$ is the magnitude of the jump, and $\mathcal{H}$ is the Heaviside step function.

The matrix form of this relation in the cartesian axes $(\mathbf{e}_1 = \mathbf{m}, \mathbf{e}_2, \mathbf{e}_3)$ shows that the two elastic stiffnesses differ by a single diagonal term,

$$[\mathbb{E}] = [\mathbb{E}^-] + s\,\mathcal{H}(\mathbf{M} : \boldsymbol{\epsilon}) \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}. \tag{5.4.6}$$

5.4.4 Application to materials with two families of fibers

Let $\mathbf{m}_1$ and $\mathbf{m}_2$ be the unit vectors (non necessarily orthogonal) that indicate the directions of the fibers in a reference configuration. The fibers are assumed to be mechanically active only if they undergo extension, namely

$$g_i(\boldsymbol{\epsilon}) \equiv \boldsymbol{\epsilon} : \mathbf{M}_i \geq 0, \quad i = 1, 2\,. \tag{5.4.7}$$

Thus the moduli corresponding to extended fibers and contracted fibers differ only by the dyadic products,

$$\mathbb{E} = \mathbb{E}^- + s_1\, \mathcal{H}(\mathbf{M}_1 : \boldsymbol{\epsilon})\, \mathbf{M}_1 \otimes \mathbf{M}_1 + s_2\, \mathcal{H}(\mathbf{M}_2 : \boldsymbol{\epsilon})\, \mathbf{M}_2 \otimes \mathbf{M}_2\,, \tag{5.4.8}$$

where $s = s_i(\boldsymbol{\epsilon} : \mathbf{M}_i)$, $i = 1, 2$, are the magnitudes of the jumps.

The two families of fibers are said *mechanically equivalent*, if their mechanical properties are identical and if their densities are identical. Then the mechanical response becomes *locally* orthotropic: the orthogonal axes on which the fiber axes mirror are the orthotropy axes.

5.4.5 Application to linear orthotropic materials: octantwise response

5.4.5.1 The number of independent coefficients

The above relations are now applied to an orthotropic material whose response is extension-contraction dependent. There are three interfaces $g(\boldsymbol{\epsilon}) = \mathbf{A}_a : \boldsymbol{\epsilon} = 0$, $a \in [1, 3]$, defined by the structure tensors $\mathbf{A}$, so that there are a priori $2^3 = 8$ possible stiffnesses, as indicated by Table 5.4.1 and illustrated by Fig. 5.4.5.1.

Table 5.4.1: Algebraic definition of the octants.

Octant nb.	$\mathbf{A}_1 : \boldsymbol{\epsilon}$	$\mathbf{A}_2 : \boldsymbol{\epsilon}$	$\mathbf{A}_3 : \boldsymbol{\epsilon}$
1	+	+	+
2	-	+	+
3	+	+	-
4	-	+	-
5	+	-	+
6	-	-	+
7	+	-	-
8	-	-	-

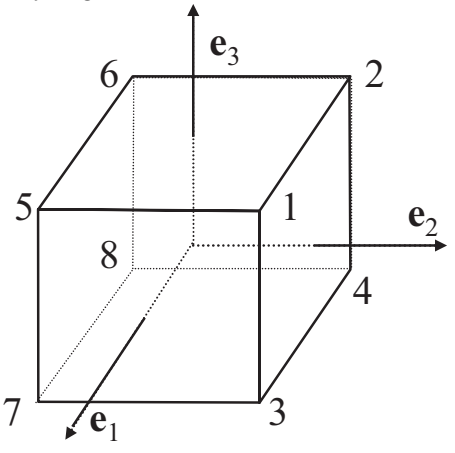

Fig. 5.4.2: Visual definition of the octants.

Let us show that there are only three possible discontinuities. This point is formalized in

Proposition 5.2 The eight tensor moduli defining the response in the eight octants differ at most by **three** scalars.

There are several ways to show this proposition. It is clear, from Proposition 5.1, that the sole discontinuities are represented by symmetric dyadic terms. Looking at the expression of the tensor moduli (5.2.37), we thus see that there are only three such terms, namely $\lambda_{\underline{aa}}\, \mathbf{A}_a \otimes \mathbf{A}_a$, $a \in [1, 3]$. This observation is formalized by

Proposition 5.3 on the discontinuity pattern, Chaboche et al. [1995], Curnier et al. [1994].

The sole possible discontinuities between two arbitrary octants are defined by the jumps $[\![\lambda_{\underline{aa}}]\!]$, $a \in [1, 3]$, of the three coefficients $\lambda_{\underline{aa}}$, $a \in [1, 3]$,

$$[\mathbb{E}^+] = [\mathbb{E}^-] + [\![\lambda_{11}]\!]\, \mathbf{A}_1 \otimes \mathbf{A}_1 + [\![\lambda_{22}]\!]\, \mathbf{A}_2 \otimes \mathbf{A}_2 + [\![\lambda_{33}]\!]\, \mathbf{A}_3 \otimes \mathbf{A}_3\,, \tag{5.4.9}$$

and, in the orthotropy axes,

$$[\mathbb{E}^+] = [\mathbb{E}^-] + \begin{bmatrix} [\![\lambda_{11}]\!] & 0 & 0 & 0 & 0 & 0 \\ 0 & [\![\lambda_{22}]\!] & 0 & 0 & 0 & 0 \\ 0 & 0 & [\![\lambda_{33}]\!] & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}. \tag{5.4.10}$$

The six other coefficients λ_{ab}, $a < b \in [1, 3]$, and μ_{a}, $a \in [1, 3]$, cannot undergo jumps. Therefore the complete octantwise extension-contraction dependent response is defined by 9+3=12 independent coefficients.

5.4.5.2 Consequences for the Young's moduli and Poisson's ratios

At this point, a warning should be issued.

According to Proposition 5.3, had we considered a tension-compression dependent response, we would have observed, from the elastic compliance (5.2.46), that the sole three coefficients that undergo jumps are the three Young's moduli $E_{\rm a}$, $a \in [1,3]$, *while the six other coefficients* $\nu_{\rm ab}$, $a < b \in [1,3]$, *and* $\nu_{\underline{\rm aa}}$, $a \in [1,3]$, *cannot undergo jumps.*

Thus, the tension-compression dependent response and the extension-contraction dependent response are not correlated. As indicated by (5.E.17)–(5.E.24), the modifications of the generalized Young's moduli and Poisson's ratios *deduced* from the modifications of the generalized Lamé moduli will *not* satisfy in general the tension-compression relations above.

Now, let us return to the extension-contraction response and let us consider the determination of the coefficients.

If the generalized Lamé moduli are measured, then there is no problem of methodology and the subsequent discussion is of no concern. On the other hand, if the components of the compliance matrix are measured in some octants, a problem of methodology arises.

Indeed, according to (5.E.18)–(5.E.19), the three Young's moduli $E_{\rm a}$, $a \in [1,3]$, and the three Poisson's ratios $\nu_{\rm ab}$, $a < b \in [1,3]$, undergo jumps, since they depend on the $\lambda_{\underline{\rm aa}}$, $a \in [1,3]$. On the other hand, according to (5.E.21), the coefficients $(1+\nu_{\underline{\rm aa}})/E_{\underline{a}}$, $a \in [1,3]$, are continuous, so that the three Poisson's ratios $\nu_{\underline{\rm aa}}$, $a \in [1,3]$, undergo jumps as well. The situation is summarized in

Proposition 5.4 number of independent coefficients.

For an extension-contraction response, *all nine coefficients*, namely the Young's moduli $E_{\rm a}$, $a \in [1,3]$, and the six Poisson's ratios $\nu_{\rm ab}$, $a \leq b \in [1,3]$, *undergo jumps across octants*, since they depend on the $\lambda_{\underline{\rm aa}}$'s, $a \in [1,3]$. The compliance matrices of the eight octants are in general different. Clearly these jumps are not arbitrary, they are dictated by the three jumps $\lambda_{\underline{\rm aa}}$, $a \in [1,3]$. Between the $8 \times 9 = 72$ coefficients defining the eight octants, there exist relations so that the total number of independent coefficients defining the complete octantwise response is equal to twelve. As an example of such relations, Eqn (5.E.21) indicates, since the $\mu_{\rm a}$, $a \in [1,3]$, do not undergo jumps, that the coefficients

$$\frac{1+\nu_{\underline{\rm aa}}}{E_{\underline{a}}}, \quad a \in [1,3]\,, \tag{5.4.11}$$

are the same in all eight octants. Other relations are obtained by imposing that the three coefficients $\lambda_{\rm ab}$, $a < b \in [1,3]$, deduced from the $\nu_{\rm ab}$, $a \leq b \in [1,3]$, and $E_{\rm a}$, $a \in [1,3]$, should be identical in all octants. Thus, from (5.E.24), each of the three terms

$$\left\{ \begin{array}{l} \Delta_{\rm U}\,\big(\dfrac{\nu_{13}}{E_1}\,\dfrac{\nu_{23}}{E_2} + \dfrac{\nu_{12}}{E_1}\,\dfrac{1}{E_3}\big), \\ \Delta_{\rm U}\,\big(\dfrac{\nu_{12}}{E_1}\,\dfrac{\nu_{23}}{E_2} + \dfrac{\nu_{13}}{E_1}\,\dfrac{1}{E_2}\big), \\ \Delta_{\rm U}\,\big(\dfrac{\nu_{12}}{E_1}\,\dfrac{\nu_{13}}{E_1} + \dfrac{\nu_{23}}{E_2}\,\dfrac{1}{E_1}\big), \end{array} \right. \tag{5.4.12}$$

is the same over all eight octants, $\Delta_{\rm U} = \det \mathbb{E}^{\rm U}_{3\times 3}$ being the determinant of the upper 3×3 principal minor $\mathbb{E}^{\rm U}_{3\times 3}$ of the tensor moduli (5.2.40). On the other hand, we have from (5.E.23), that each of the three terms

$$\left\{ \begin{array}{l} \Delta_{\rm U}\,\big(\dfrac{1}{E_2}\,\dfrac{1}{E_3} - (\dfrac{\nu_{23}}{E_2})^2\big), \\ \Delta_{\rm U}\,\big(\dfrac{1}{E_1}\,\dfrac{1}{E_3} - (\dfrac{\nu_{13}}{E_1})^2\big), \\ \Delta_{\rm U}\,\big(\dfrac{1}{E_1}\,\dfrac{1}{E_2} - (\dfrac{\nu_{12}}{E_1})^2\big), \end{array} \right. \tag{5.4.13}$$

can take only two values over the eight octants.

Let us reiterate that only twelve independent measurements [5.7] of the Poisson's and Young's moduli need be performed to define the complete octantwise response. For example, one might measure the nine coefficients in a certain octant and any three other coefficients in the other octants.

[5.7] Independent in the sense that they are not equivalent to (5.4.11) and (5.4.12).

5.4.6 Application to transversely isotropic materials

For transversely isotropic materials, defined in terms of 5 elastic coefficients, as indicated in Exercise 5.11,

$$\begin{aligned} \boldsymbol{\sigma} &= a_1\,(\mathrm{tr}\,\boldsymbol{\epsilon})\,\mathbf{I} + a_2\,\boldsymbol{\epsilon} + a_3\,\big((\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon})\,\mathbf{I} + (\mathrm{tr}\,\boldsymbol{\epsilon})\,\mathbf{M}\big) + \\ &+ a_4\,(\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon})\,\mathbf{M} + a_5\,(\mathbf{M}\cdot\boldsymbol{\epsilon} + \boldsymbol{\epsilon}\cdot\mathbf{M})\,; \\ \mathbb{E} &= a_1\,\mathbf{I}\otimes\mathbf{I} + a_2\,\mathbf{I}\underline{\overline{\otimes}}\,\mathbf{I} + a_3\,\big(\mathbf{M}\otimes\mathbf{I} + \mathbf{I}\otimes\mathbf{M}\big) + \\ &+ a_4\,\mathbf{M}\otimes\mathbf{M} + a_5\,(\mathbf{M}\underline{\overline{\otimes}}\,\mathbf{I} + \mathbf{I}\underline{\overline{\otimes}}\,\mathbf{M})\,, \end{aligned} \tag{5.4.14}$$

there exist two interfaces, delineating the sign of the volume change, namely $\mathbf{I}:\boldsymbol{\epsilon}=0$, across which only a_1 can undergo a jump, and the sign of the strain along the symmetry axis $\mathbf{M}:\boldsymbol{\epsilon}=0$, across which only a_4 can undergo a jump. The elastic coefficients may therefore differ by the two dyadic products,

$$\mathbb{E}^+ - \mathbb{E}^- = [\![a_1]\!]\,\mathbf{I}\otimes\mathbf{I} + [\![a_4]\!]\,\mathbf{M}\otimes\mathbf{M}\,. \tag{5.4.15}$$

5.4.7 Application to isotropic materials

Since for isotropic materials the stiffness has the form,

$$\mathbb{E} = \lambda\,\mathbf{I}\otimes\mathbf{I} + 2\,\mu\,\mathbf{I}\underline{\overline{\otimes}}\,\mathbf{I}, \tag{5.4.16}$$

there exists a single interface, delineating the sign of the volume change, namely $\mathbf{I}:\boldsymbol{\epsilon}=0$, across which only λ can undergo a jump, while μ is continuous. Thus both E and ν undergo jumps but in such a way that $\mu = E/2\,(1+\nu)$ is continuous across the interface.

Note that, for linear isotropic materials, the *extension-contraction* and *tension-compression* dependent responses are identical because the interfaces $\mathbf{I}:\boldsymbol{\epsilon}=0$ and $\mathbf{I}:\boldsymbol{\sigma}=0$, are clearly linked, indeed $\mathbf{I}:\boldsymbol{\epsilon} = \mathbf{I}:\boldsymbol{\sigma}/K$, with $K = E/3(1-2\,\nu) = \lambda + \frac{2}{3}\,\mu > 0$ the bulk modulus.

The situation is different in presence of an initial stress, say $\boldsymbol{\sigma} - \boldsymbol{\sigma}_0 = \mathbb{E}:\boldsymbol{\epsilon}$, or of an initial strain, say $\boldsymbol{\sigma} = \mathbb{E}:(\boldsymbol{\epsilon} - \boldsymbol{\epsilon}_0)$, as displayed by Figs. 5.4.1-(a) and (b), respectively, and of both initial stress and initial strain, $\boldsymbol{\sigma} - \boldsymbol{\sigma}_0 = \mathbb{E}:(\boldsymbol{\epsilon} - \boldsymbol{\epsilon}_0)$.

5.4.8 Cartilage as a tissue with cubic symmetry

In order to interpret an experimental study of articular cartilage, Soltz and Ateshian [2000] view the tissue as a cubic material as described in Section 5.2.9. The confined compression modulus along direction 1 (for which $\epsilon_{22} = \epsilon_{33} = 0$) is equal to $\lambda + 2\,\mu$ while the unconfined compression modulus (for which $\sigma_{22} = \sigma_{33} = 0$) is equal to $E = \sigma_{11}/\epsilon_{11}$. The confined compression modulus $\lambda + 2\,\mu$ is discontinuous along the interface $\mathrm{tr}\,\boldsymbol{\epsilon} = 0$ while the Lamé modulus λ' and the Poisson's ratio ν' should be continuous.

Extension-contraction response, Soltz and Ateshian [2000]

Measurements provide the Lamé modulus λ'=480 kPa and the shear modulus μ=170 kPa. From the data extracted from confined and unconfined compression tests shown in Table 5.4.2, the apparent Poisson's ratio ν'^- appears to be large. Still, the measured values satisfy the conditions (5.2.66) of positive definiteness of the elastic stiffness (and compliance).

Table 5.4.2: Confined and unconfined compression and torsion tests on humeral head articular cartilage plugs of 6-month-old calves, Soltz and Ateshian [2000].

Unconfined compression	$\lambda^+ + 2\,\mu = 13200$ kPa	$E^+ = 13166$ kPa	$\nu'^+ = 0.035$
Confined compression	$\lambda^- + 2\,\mu = 640$ kPa	$E^- = 229$ kPa	$\nu'^- = 0.429$

5.4.9 Cartilage as an orthotropic tissue

Orthotropy axes in articular cartilage are defined by the directions of the split-lines obtained by puncturing the joint with a needle, Fig. 5.4.3.

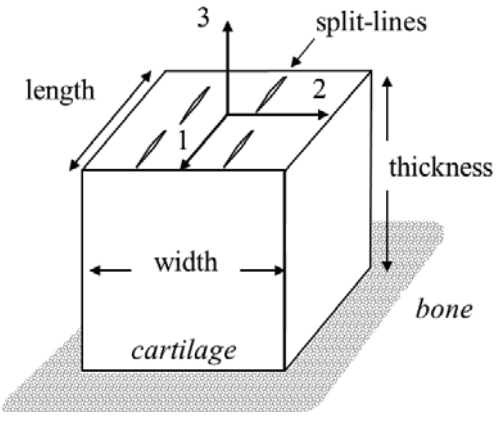

Fig. 5.4.3: In the articular cartilage layer, the orthotropy axes are defined via the split-lines appearing on the upper zone.

5.4.9.1 Unconfined compression tests along the orthotropy axes

C.C.B. Wang et al. [2003] perform unconfined compression tests over parallelepiped specimens of size 0.91 mm × 0.89 mm × 0.82 mm (length × width × thickness). Although the point is not mentioned explicitly, the tests have probably been performed at physiological salinities.

For unconfined compression along the axis x, $\sigma_{xx}<0$, $\epsilon_{xx}<0$, while $\sigma_{yy}=\sigma_{zz}=0$, $\epsilon_{yy}>0$, $\epsilon_{zz}>0$. The elastic constitutive equations (5.2.40) can be cast in the format,

$$\begin{bmatrix} \sigma_{xx}<0 \\ \sigma_{yy}=0 \\ \sigma_{zz}=0 \\ \sqrt{2}\,\sigma_{yz}=0 \\ \sqrt{2}\,\sigma_{xz}=0 \\ \sqrt{2}\,\sigma_{xy}=0 \end{bmatrix} = \begin{bmatrix} H_x^- & \lambda_{xy} & \lambda_{xz} & 0 & 0 & 0 \\ \lambda_{xy} & H_y^+ & \lambda_{yz} & 0 & 0 & 0 \\ \lambda_{xz} & \lambda_{yz} & H_z^+ & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu_y+\mu_z & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu_x+\mu_z & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu_x+\mu_y \end{bmatrix} \begin{bmatrix} \epsilon_{xx}<0 \\ \epsilon_{yy}>0 \\ \epsilon_{zz}>0 \\ \sqrt{2}\,\epsilon_{yz}(\Rightarrow=0) \\ \sqrt{2}\,\epsilon_{xz}(\Rightarrow=0) \\ \sqrt{2}\,\epsilon_{xy}(\Rightarrow=0) \end{bmatrix}, \tag{5.4.17}$$

with the notation of the Columbia group $H\equiv\lambda+2\,\mu$. The non trivial inverse relations provide the strain components along the orthotropy axes,

$$\begin{bmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \epsilon_{zz} \end{bmatrix} = \frac{\sigma_{xx}}{E_x^-} \begin{bmatrix} 1 \\ -\nu_{xy}^+ \\ -\nu_{xz}^+ \end{bmatrix}, \tag{5.4.18}$$

where, according to (5.E.18)–(5.E.19),

$$E_x^- = \frac{H_x^-\,H_y^+\,H_z^+ - H_x^-\,\lambda_{yz}^2 - H_y^+\,\lambda_{xz}^2 - H_z^+\,\lambda_{xy}^2 + 2\,\lambda_{yz}\,\lambda_{xz}\,\lambda_{xy}}{H_y^+\,H_z^+ - \lambda_{yz}^2}\,,$$
$$\nu_{xy}^+ = \frac{\lambda_{xy}\,H_z^+ - \lambda_{xz}\,\lambda_{yz}}{H_y^+\,H_z^+ - \lambda_{yz}^2}, \quad \nu_{xz}^+ = \frac{\lambda_{xz}\,H_y^+ - \lambda_{xy}\,\lambda_{yz}}{H_y^+\,H_z^+ - \lambda_{yz}^2}\,. \tag{5.4.19}$$

These relations are applied for $x=1$, $y=2$, $z=3$, for $x=2$, $y=3$, $z=1$, and for $x=3$, $y=1$, $z=2$.

Data for shoulder joints of young calves, C.C.B. Wang et al. [2003]

C.C.B. Wang et al. [2003] provide data for shoulder joints of young calves. For compression normal to the cartilage surface, strains in the depth are not homogeneous, so that the results are split in two sets, one for the top layer and one for the bottom layer of each specimen, Table 5.4.3. The vertical modulus is larger at the bottom due to the collagen network and other microstructural features close to the bone.

Table 5.4.3: *Apparent* elastic properties measured during unconfined compression tests along the three directions of material symmetry at 5-10% axial contraction, C.C.B. Wang et al. [2003].

Top Layer			Bottom Layer	
ν_{21}^{+}=0.045	ν_{13}^{+}=0.293	ν_{23}^{+}=0.307		
ν_{12}^{+}=0.053	ν_{31}^{+}=0.048	ν_{32}^{+}=0.043	ν_{31}^{+}=0.361	ν_{32}^{+}=0.363
E_1^{-}=385 kPa	E_2^{-}=377 kPa	E_3^{-}=229 kPa		E_3^{-}=1509

One, quite deceptive, key ouput of the analysis is that the compliance matrix (5.2.46) is not symmetric. The lack of symmetry is in contradiction with the hyperelastic response, and many relations derived above. Actually, exploiting the measurements of the three unconfined compression tests is not an easy task. Indeed, each test provides one Young's modulus and two Poisson's ratios corresponding to a specific octant. Moreover, the octantwise orthotropic response requires twelve independent coefficients while only nine values are measured. To proceed, C.C.B. Wang et al. [2003] make a number of simplifications in such a way that they are left with a free modulus. A parameter analysis is performed on this modulus, by varying its values between the bounds that ensure positive definiteness of the stiffness matrix[5.8].

5.4.9.2 Data from uniaxial traction

Let us consider uniaxial traction, along the axis 1, so $\sigma_{11} > 0$, $\epsilon_{11} > 0$, while $\sigma_{22} = \sigma_{33}{=}0$, $\epsilon_{22} < 0$, $\epsilon_{33} < 0$. The elastic relation (5.2.40) specializes to, with $H \equiv \lambda + 2\,\mu$,

$$\begin{bmatrix} \sigma_{11} > 0 \\ \sigma_{22} = 0 \\ \sigma_{33} = 0 \\ \sqrt{2}\,\sigma_{23} = 0 \\ \sqrt{2}\,\sigma_{13} = 0 \\ \sqrt{2}\,\sigma_{12} = 0 \end{bmatrix} = \begin{bmatrix} H_1^{+} & \lambda_{12} & \lambda_{13} & 0 & 0 & 0 \\ \lambda_{12} & H_2^{-} & \lambda_{23} & 0 & 0 & 0 \\ \lambda_{13} & \lambda_{23} & H_3^{-} & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu_2+\mu_3 & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu_1+\mu_3 & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu_1+\mu_2 \end{bmatrix} \begin{bmatrix} \epsilon_{11} > 0 \\ \epsilon_{22} < 0 \\ \epsilon_{33} < 0 \\ \sqrt{2}\,\epsilon_{23}(\Rightarrow = 0) \\ \sqrt{2}\,\epsilon_{13}(\Rightarrow = 0) \\ \sqrt{2}\,\epsilon_{12}(\Rightarrow = 0) \end{bmatrix} . \tag{5.4.20}$$

The non trivial inverse relations write

$$\begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \end{bmatrix} = \frac{\sigma_{11}}{E_1^{+}} \begin{bmatrix} 1 \\ -\nu_{12}^{-} \\ -\nu_{13}^{-} \end{bmatrix} , \tag{5.4.21}$$

where, according to (5.E.18)–(5.E.19),

$$\begin{cases} E_1^{+} = \dfrac{H_1^{+}\,H_2^{-}\,H_3^{-} - H_1^{+}\,\lambda_{23}^2 - H_2^{-}\,\lambda_{13}^2 - H_3^{-}\,\lambda_{12}^2 + 2\,\lambda_{23}\,\lambda_{13}\,\lambda_{12}}{H_2^{-}\,H_3^{-} - \lambda_{23}^2} \\ \nu_{12}^{-} = \dfrac{\lambda_{12}\,H_3^{-} - \lambda_{13}\,\lambda_{23}}{H_2^{-}\,H_3^{-} - \lambda_{23}^2}, \quad \nu_{13}^{-} = \dfrac{\lambda_{13}\,H_2^{-} - \lambda_{12}\,\lambda_{23}}{H_2^{-}\,H_3^{-} - \lambda_{23}^2} . \end{cases} \tag{5.4.22}$$

Data from Chang et al. [1999] on aged human patellar cartilage, Table 5.4.4

Cartilage strips parallel to the strip-line directions have been subjected to tensile loading, and the strains along the split-line, perpendicular and depth directions have been recorded. The measurements display a significant volumetric contraction. The data are probably affected by the fibrillated nature of the aged cartilages. The tests are expected to have been performed at physiological salinities.

[5.8] An analysis of the same flavor that aims at estimating the elastic properties of a transversely isotropic fluid-saturated porous solid in presence of an incomplete data set is reported in Section 7.4.5.1.

Table 5.4.4: Tensile tests on aged human patellar cartilage using surface strips, Chang et al. [1999]. The split-line, perpendicular and depth directions are denoted by the indices 1, 2 and 3, respectively.

Surface to mid zone	E_1^+=2800 kPa	ν_{12}^-=0.9	ν_{13}^-=1.8
Bottom	E_1^+=2900 kPa	ν_{12}^-=0.5	ν_{13}^-=0.7

Data from Huang et al. [1999] on human glenohumeral cartilage, Table 5.4.5

The cartilage was harvested from shoulders of cadavers (average age 59 years). The cartilage layers were cut into thin slices parallel to the surface (0.25 mm thick for tension slices). Slices in the surface and in the middle zone were subjected to tensile loading parallel and perpendicular to the split-line direction.

Table 5.4.5: Tensile tests on the humerus surface zone, Huang et al. [1999]. The split-line and perpendicular directions are denoted by the indices 1 and 2, respectively.

E_1^+=7840 kPa (toe region)	E_1^+=42800 kPa (higher strain)	ν_{12}^-=1.31
E_2^+=5930 kPa (toe region)	E_2^+=26300 kPa (higher strain)	ν_{21}^-=1.33

Data from Elliott et al. [2002] on aged human patellas, Table 5.4.6

Along a similar testing protocol as in the above references, cartilage strips harvested from the surface and mid zones were loaded along the split-line direction. The effects of age were scrutinized and the surface moduli were found to decrease strongly with age.

Table 5.4.6: Tensile tests parallel to the split-line direction for subjects younger than 70 years old, Elliott et al. [2002].

Surface	E_1^+=5810 kPa (toe region)	E_1^+=23920 kPa (higher strain)	ν_{12}^-=2.38
Mid zone	E_1^+=1920 kPa (toe region)	E_1^+=3180 kPa (higher strain)	ν_{12}^-=0.70

Since the stress that is involved in the constitutive equations has been assumed to be the total stress, the material properties that have been deduced are *apparent*. The measured Poisson's ratios are found very large. An anisotropic conewise response might not be incompatible with these values. However, the positive definiteness of the stiffnesses and/or compliances has not been checked in any octant. Still, actual constitutive equations should be phrased in terms of an *effective* stress and of an *effective* strain. Accounting for these crucial elements allows to simulate the tissue response to mechanical loadings with an elastic stiffness endowed with moduli and Poisson's ratios that remain within the bounds of positive definiteness, e.g., Loret and Simões [2005]a.

Exercises on Chapter 5

Exercise 5.1 Decomposition of the nonlinear isotropic elastic relationship

The general isotropic stress-strain relationship has the form

$$\boldsymbol{\epsilon} = a_1\,\mathbf{I} + a_2\,\boldsymbol{\sigma} + a_3\,\boldsymbol{\sigma}^2, \tag{5.E.1}$$

where the scalar coefficients a_i, $i \in [1,3]$, depend on the three scalar invariants $p = \operatorname{tr}\boldsymbol{\sigma}/3$, $q = ((3/2)\,\mathbf{s}:\mathbf{s})^{1/2}$ and $J_3 = \operatorname{tr}\boldsymbol{\sigma}^3$, where $\mathbf{s} = \boldsymbol{\sigma} - p\,\mathbf{I}$ is the stress deviator. Define an additive decomposition of the strain in a purely volumetric contribution and a purely deviatoric contribution.

Answer:

$$\boldsymbol{\epsilon} = \underbrace{b_1\,\mathbf{I}}_{\substack{\text{volumetric}\\ \text{contribution}}} + \underbrace{b_2\,(\overbrace{\boldsymbol{\sigma} - p\,\mathbf{I}}^{\mathbf{s}}) + b_3\,(\boldsymbol{\sigma}^2 - \operatorname{tr}\boldsymbol{\sigma}^2\,\frac{\mathbf{I}}{3})}_{\text{deviatoric contribution}}, \tag{5.E.2}$$

with $b_1 = a_1 + a_2\,p + a_3\operatorname{tr}\boldsymbol{\sigma}^2/3$, $b_2 = a_2$, $b_3 = a_3$. Note the relation

$$\boldsymbol{\sigma}^2 - \operatorname{tr}\boldsymbol{\sigma}^2\,\frac{\mathbf{I}}{3} = \mathbf{s}^2 - \operatorname{tr}\mathbf{s}^2\,\frac{\mathbf{I}}{3} + 2\,p\,\mathbf{s}. \tag{5.E.3}$$

Exercise 5.2 Minor symmetry of the linear elastic tensor

The minor symmetry of the fourth order elasticity tensor with respect to its two last indices is a choice. Indeed, it stems from the fact that the scalar product of an arbitrary second tensor $\mathbf{A}$ by a symmetric second order tensor $\mathbf{B}$ is independent of the skew-symmetric part of the former, namely

$$\mathbf{A}:\mathbf{B} = \frac{1}{2}\,(\mathbf{A} + \mathbf{A}^{\mathrm{T}}):\mathbf{B}\,. \tag{5.E.4}$$

In fact, it can be shown that the most general fourth order isotropic elastic tensor $\mathbb{E}'$ depends on three arbitrary coefficients λ, μ and μ', Malvern [1969], p. 277,

$$E_{ijkl} = \lambda\,I_{ij}\,I_{kl} + \mu\,(I_{ik}\,I_{jl} + I_{il}\,I_{jk}), \quad E'_{ijkl} = E_{ijkl} + \mu'\,(I_{ik}\,I_{jl} - I_{il}\,I_{jk}). \tag{5.E.5}$$

The infinitesimal strain $\boldsymbol{\epsilon}$ being symmetric, then $\mathbb{E}:\boldsymbol{\epsilon} = \mathbb{E}':\boldsymbol{\epsilon}$, and the skew-symmetric part of $\mathbb{E}'$ is elusive in evaluating the stress.

Exercise 5.3 Conditions of hyperelasticity

The general isotropic stress-strain relationship has the form (5.E.1). Find the conditions that ensure this elastic material to be hyperelastic.

Answer:

The complementary energy then can be cast in the format,

$$d\mathcal{W}_c = \boldsymbol{\epsilon}:d\boldsymbol{\sigma} = 3\,(a_1 + a_2\,p)\,dp + \frac{2}{3}\,a_2\,dq + \frac{a_3}{3}\,dJ_3\,. \tag{5.E.6}$$

Necessary and sufficient conditions for the elastic material (5.E.1) to be hyperelastic are

$$\begin{aligned} \frac{\partial}{\partial q}\Big(3\,(a_1 + a_2\,p)\Big) &= \frac{\partial}{\partial p}\Big(\frac{2}{3}\,a_2\Big);\\ \frac{\partial}{\partial J_3}\Big(3\,(a_1 + a_2\,p)\Big) &= \frac{\partial}{\partial p}\Big(\frac{1}{3}\,a_3\Big);\\ \frac{\partial}{\partial J_3}\Big(\frac{2}{3}\,a_2\Big) &= \frac{\partial}{\partial q}\Big(\frac{1}{3}\,a_3\Big)\,. \end{aligned} \tag{5.E.7}$$

Exercise 5.4 The Voigt representation

In the Voigt representation of the elasticity relations, the out-of diagonal terms are multiplied by 2 in the strain vector $[\boldsymbol{\epsilon}]$, and by 1 in the stress vector $[\boldsymbol{\sigma}]$. In fact, then neither $[\boldsymbol{\sigma}]$ nor $[\boldsymbol{\epsilon}]$ are vectors, and $[\mathbb{E}]$ is not a matrix. To stress this point, they are referred to as *pseudo*-vectors and *pseudo*-matrix. Indeed, under a change of cartesian axes, these entities do not change as if they were vectors and matrix in an euclidian vector space of dimension 6. To obtain the transformed representation, the components of the stress $\boldsymbol{\sigma}$, strain $\boldsymbol{\epsilon}$ and elastic moduli $\mathbb{E}$ have to be calculated, viewing these entities as second and fourth order tensors respectively. The resulting components can then be inserted in the pseudo-vectors and pseudo-matrix.

Obtain the matrix form of the elasticity relation $[\boldsymbol{\sigma}] = [\mathbb{E}]\,[\boldsymbol{\epsilon}]$ and its inverse $[\boldsymbol{\epsilon}] = [\mathbb{S}]\,[\boldsymbol{\sigma}]$ with the Voigt representation. Contrast these two matrix forms with their counterparts in the isometric representation. Show that both the Voigt and isometric representations conserve energy, namely $\boldsymbol{\sigma} : \boldsymbol{\epsilon} = [\boldsymbol{\sigma}]^{\mathrm{T}}\,[\boldsymbol{\epsilon}]$.

Answer:

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{bmatrix} = \begin{bmatrix} E_{1111} & E_{1122} & E_{1133} & E_{1123} & E_{1113} & E_{1112} \\ E_{2211} & E_{2222} & E_{2233} & E_{2223} & E_{2213} & E_{2212} \\ E_{3311} & E_{3322} & E_{3333} & E_{3323} & E_{3313} & E_{3312} \\ E_{2311} & E_{2322} & E_{2333} & E_{2323} & E_{2313} & E_{2312} \\ E_{1311} & E_{1322} & E_{1333} & E_{1323} & E_{1313} & E_{1312} \\ E_{1211} & E_{1222} & E_{1233} & E_{1223} & E_{1213} & E_{1212} \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ 2\,\epsilon_{23} \\ 2\,\epsilon_{13} \\ 2\,\epsilon_{12} \end{bmatrix}. \tag{5.E.8}$$

$$\begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ 2\,\epsilon_{23} \\ 2\,\epsilon_{13} \\ 2\,\epsilon_{12} \end{bmatrix} = \begin{bmatrix} S_{1111} & S_{1122} & S_{1133} & 2\,S_{1123} & 2\,S_{1113} & 2\,S_{1112} \\ S_{2211} & S_{2222} & S_{2233} & 2\,S_{2223} & 2\,S_{2213} & 2\,S_{2212} \\ S_{3311} & S_{3322} & S_{3333} & 2\,S_{3323} & 2\,S_{3313} & 2\,S_{3312} \\ 2\,S_{2311} & 2\,S_{2322} & 2\,S_{2333} & 4\,S_{2323} & 4\,S_{2313} & 4\,S_{2312} \\ 2\,S_{1311} & 2\,S_{1322} & 2\,S_{1333} & 4\,S_{1323} & 4\,S_{1313} & 4\,S_{1312} \\ 2\,S_{1211} & 2\,S_{1222} & 2\,S_{1233} & 4\,S_{1223} & 4\,S_{1213} & 4\,S_{1212} \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{bmatrix}. \tag{5.E.9}$$

Exercise 5.5 Symmetry with respect to the plane $x_3 = 0$

Consider an anisotropic linear elastic material. Assume its orthotropy directions to be known. The plane $x_3 = 0$ is a symmetry plane for the elastic properties. Analyze the consequences on some of the elastic coefficients.

Answer: The reflection matrix $\mathbf{R}_3$

$$\mathbf{R}_3 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \tag{5.E.10}$$

belongs to the symmetry group of the material. Let $\boldsymbol{\sigma}*$ be the transformed components of the stress $\boldsymbol{\sigma}$ in the mirror axes:

$$\boldsymbol{\sigma}* = \mathbf{R}\cdot\boldsymbol{\sigma}\cdot\mathbf{R}^{\mathrm{T}} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix} \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{12} & \sigma_{22} & \sigma_{23} \\ \sigma_{13} & \sigma_{23} & \sigma_{33} \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix} = \begin{bmatrix} \sigma_{11} & \sigma_{12} & -\sigma_{13} \\ \sigma_{12} & \sigma_{22} & -\sigma_{23} \\ -\sigma_{13} & -\sigma_{23} & \sigma_{33} \end{bmatrix}. \tag{5.E.11}$$

The stress-strain relations linking the pairs $([\boldsymbol{\epsilon}], [\boldsymbol{\sigma}])$ and $([\boldsymbol{\epsilon}*], [\boldsymbol{\sigma}*])$ should be identical. Consequently, the elastic relation

writes also $[\boldsymbol{\sigma}*] = [\mathbb{E}][\boldsymbol{\epsilon}*]$, namely

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ -\sqrt{2}\,\sigma_{23} \\ -\sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} = \begin{bmatrix} E_{1111} & E_{1122} & E_{1133} & \sqrt{2}E_{1123} & \sqrt{2}E_{1113} & \sqrt{2}E_{1112} \\ E_{2211} & E_{2222} & E_{2233} & \sqrt{2}E_{2223} & \sqrt{2}E_{2213} & \sqrt{2}E_{2212} \\ E_{3311} & E_{3322} & E_{3333} & \sqrt{2}E_{3323} & \sqrt{2}E_{3313} & \sqrt{2}E_{3312} \\ \sqrt{2}E_{2311} & \sqrt{2}E_{2322} & \sqrt{2}E_{2333} & 2E_{2323} & 2E_{2313} & 2E_{2312} \\ \sqrt{2}E_{1311} & \sqrt{2}E_{1322} & \sqrt{2}E_{1333} & 2E_{1323} & 2E_{1313} & 2E_{1312} \\ \sqrt{2}E_{1211} & \sqrt{2}E_{1222} & \sqrt{2}E_{1233} & 2E_{1223} & 2E_{1213} & 2E_{1212} \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ -\sqrt{2}\,\epsilon_{23} \\ -\sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix}, \tag{5.E.12}$$

which can be rearranged to

$$\begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sqrt{2}\,\sigma_{23} \\ \sqrt{2}\,\sigma_{13} \\ \sqrt{2}\,\sigma_{12} \end{bmatrix} = \begin{bmatrix} E_{1111} & E_{1122} & E_{1133} & -\sqrt{2}E_{1123} & -\sqrt{2}E_{1113} & \sqrt{2}E_{1112} \\ E_{2211} & E_{2222} & E_{2233} & -\sqrt{2}E_{2223} & -\sqrt{2}E_{2213} & \sqrt{2}E_{2212} \\ E_{3311} & E_{3322} & E_{3333} & -\sqrt{2}E_{3323} & -\sqrt{2}E_{3313} & \sqrt{2}E_{3312} \\ -\sqrt{2}E_{2311} & -\sqrt{2}E_{2322} & -\sqrt{2}E_{2333} & 2E_{2323} & 2E_{2313} & -2E_{2312} \\ -\sqrt{2}E_{1311} & -\sqrt{2}E_{1322} & -\sqrt{2}E_{1333} & 2E_{1323} & 2E_{1313} & -2E_{1312} \\ \sqrt{2}E_{1211} & \sqrt{2}E_{1222} & \sqrt{2}E_{1233} & -2E_{1223} & -2E_{1213} & 2E_{1212} \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ \sqrt{2}\,\epsilon_{23} \\ \sqrt{2}\,\epsilon_{13} \\ \sqrt{2}\,\epsilon_{12} \end{bmatrix}. \tag{5.E.13}$$

Clearly, for the above elasticity matrix to be identical to the elasticity matrix $[\mathbb{E}]$, the coefficients in which the index 3 appears an odd number of times should vanish, as made explicit in (5.2.12).

Exercise 5.6 An invariance property

Show that the two sums of elastic coefficients E_{iikk} and E_{ikik} are invariants under changes of coordinate axes.

Proof:

Starting from the invariance relation (5.2.10) namely $E_{ijkl} = R_{im}\,R_{jn}\,R_{kp}\,R_{lq}\,E_{mnpq}$, and the property (5.2.9), namely $R_{im}\,R_{in} = I_{mn}$, the following relations results,

$$\begin{aligned} &1.\ E_{iikk} = R_{im}\,R_{in}\,R_{kp}\,R_{kq}\,E_{mnpq} = E_{mnpq}, \\ &2.\ E_{ikik} = R_{im}\,R_{kn}\,R_{ip}\,R_{kq}\,E_{mnpq} = E_{mnmn}\,. \end{aligned} \tag{5.E.14}$$

Exercise 5.7 Interpretation of the Young's moduli and Poisson's ratios

Hint: Consider an orthotropic material (5.2.46), and assume its orthotropy axes to be known. Apply a uniaxial traction σ_{11}. Then $E_1 = \sigma_{11}/\epsilon_{11}$, while $\nu_{1i} = -\epsilon_{\underline{ii}}/\epsilon_{11}$ for $i = 2, 3$.

Exercise 5.8 Linear orthotropic elasticity using representation theorems

Using the theorem of representation for an orthotropic scalar function of the strain $\boldsymbol{\epsilon}$, Section 2.11.3, obtain the expressions of the elastic potential shown in Section 5.2.6.

Proof:

Let $\{\mathbf{e}_1\,, \mathbf{e}_2\,, \mathbf{e}_3\}$ be an orthonormal triad defining the directions of orthotropy. Then the elastic potential is an orthotropic function of the strain $\boldsymbol{\epsilon}$, or equivalently an isotropic function of the augmented set $\{\boldsymbol{\epsilon}\,, \mathbf{A}_1 \equiv \mathbf{e}_1 \otimes \mathbf{e}_1\,, \mathbf{A}_2 \equiv \mathbf{e}_2 \otimes \mathbf{e}_2\ \}$, Section 2.11.3. Retaining only invariants of first and second degrees, and building a homogeneous quadratic expression, the

elastic potential for linear orthotropic elasticity is seen to involve, as expected, nine constant coefficients a_i, $i \in [1,9]$,

$$\left\{\begin{array}{rcl}
\mathcal{W} &=& \frac{a_1}{2}(\mathrm{tr}\,\mathbf{A}_1\cdot\boldsymbol{\epsilon})^2+\frac{a_2}{2}(\mathrm{tr}\,\mathbf{A}_2\cdot\boldsymbol{\epsilon})^2+\frac{a_3}{2}(\mathrm{tr}\,\mathbf{A}_3\cdot\boldsymbol{\epsilon})^2+\\
&+& a_4\,\mathrm{tr}\,\mathbf{A}_1\cdot\boldsymbol{\epsilon}\;\mathrm{tr}\,\mathbf{A}_2\cdot\boldsymbol{\epsilon}+a_5\,\mathrm{tr}\,\mathbf{A}_1\cdot\boldsymbol{\epsilon}\;\mathrm{tr}\,\mathbf{A}_3\cdot\boldsymbol{\epsilon}+a_6\,\mathrm{tr}\,\mathbf{A}_2\cdot\boldsymbol{\epsilon}\;\mathrm{tr}\,\mathbf{A}_3\cdot\boldsymbol{\epsilon}+\\
&+& a_7\,\mathrm{tr}\,\mathbf{A}_1\cdot\boldsymbol{\epsilon}^2+a_8\,\mathrm{tr}\,\mathbf{A}_2\cdot\boldsymbol{\epsilon}^2+a_9\,\mathrm{tr}\,\mathbf{A}_3\cdot\boldsymbol{\epsilon}^2\,;\\
\boldsymbol{\sigma} &=& (\mathrm{tr}\,\mathbf{A}_1\cdot\boldsymbol{\epsilon})\,(a_1\,\mathbf{A}_1+a_4\,\mathbf{A}_2+a_5\,\mathbf{A}_3)+\\
&+& (\mathrm{tr}\,\mathbf{A}_2\cdot\boldsymbol{\epsilon})\,(a_4\,\mathbf{A}_1+a_2\,\mathbf{A}_2+a_6\,\mathbf{A}_3)+\\
&+& (\mathrm{tr}\,\mathbf{A}_3\cdot\boldsymbol{\epsilon})\,(a_5\,\mathbf{A}_1+a_6\,\mathbf{A}_2+a_3\,\mathbf{A}_3)+\\
&+& a_7\,(\mathbf{A}_1\cdot\boldsymbol{\epsilon}+\boldsymbol{\epsilon}\cdot\mathbf{A}_1)+a_8\,(\mathbf{A}_2\cdot\boldsymbol{\epsilon}+\boldsymbol{\epsilon}\cdot\mathbf{A}_2)+a_9\,(\mathbf{A}_3\cdot\boldsymbol{\epsilon}+\boldsymbol{\epsilon}\cdot\mathbf{A}_3)\,;\\
\mathbb{E} &=& \mathbf{A}_1\otimes(a_1\,\mathbf{A}_1+a_4\,\mathbf{A}_2+a_5\,\mathbf{A}_3)+\\
&+& \mathbf{A}_2\otimes(a_4\,\mathbf{A}_1+a_2\,\mathbf{A}_2+a_6\,\mathbf{A}_3)+\\
&+& \mathbf{A}_3\otimes(a_5\,\mathbf{A}_1+a_6\,\mathbf{A}_2+a_3\,\mathbf{A}_3)+\\
&+& a_7\,(\mathbf{A}_1\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_1)+a_8\,(\mathbf{A}_2\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_2)+a_9\,(\mathbf{A}_3\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_3)\,.
\end{array}\right. \tag{5.E.15}$$

The compact expression of the elastic potential (5.2.37) corresponds to the following notation:

$$\mu_a=a_{6+a},\ a\in[1,3],\quad \lambda_{aa}=a_a,\ a\in[1,3],\quad \lambda_{12}=a_4,\ \lambda_{13}=a_5,\ \lambda_{23}=a_6\,. \tag{5.E.16}$$

Exercise 5.9 Inversion of the linear orthotropic elastic relations

The linear elastic relations for an orthotropic solid $\boldsymbol{\sigma}=\mathbb{E}:\boldsymbol{\epsilon}$, Eqn (5.2.40), can be inverted to the relations $\boldsymbol{\epsilon}=\mathbb{E}^{-1}:\boldsymbol{\sigma}$, Eqn (5.2.46), at the price of some algebras, as indicated below.

1. Calculate the Young's moduli and Poisson's ratios in terms of the generalized Lamé moduli

Answer: Let us introduce a simplified notation for the components of the compliance tensor,

$$\begin{array}{rcl}
\mathbb{E}^{-1} &=& \Big[\sum_{a\le b}\frac{\lambda_{ab}}{2}\,(\mathbf{A}_a\otimes\mathbf{A}_b+\mathbf{A}_b\otimes\mathbf{A}_a)+\sum_a\mu_a\,(\mathbf{A}_a\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_a)\Big]^{-1}\\
&=& \sum_{a\le b}\frac{x_{ab}}{2}\,(\mathbf{A}_a\otimes\mathbf{A}_b+\mathbf{A}_b\otimes\mathbf{A}_a)+\sum_a y_a\,(\mathbf{A}_a\,\underline{\overline{\otimes}}\,\mathbf{I}+\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}_a)
\end{array} \tag{5.E.17}$$

with $x_{ab}=x_{ba}=-\nu_{\underline{a}b}/E_{\underline{a}}$, $y_a=(1+\nu_{\underline{aa}})/2\,E_{\underline{a}}$, $a,\,b\in[1,3]$, through $(5.2.43)_3$. Inversion of the upper 3×3 principal minor $\mathbb{E}^{\mathrm{U}}_{3\times3}$ of the tensor moduli (5.2.40) with determinant $\Delta_{\mathrm{U}}=\det\mathbb{E}^{\mathrm{U}}_{3\times3}$ results in,

$$\left\{\begin{array}{l}
\frac{1}{E_1}=\frac{1}{\Delta_{\mathrm{U}}}\left((\lambda_{22}+2\,\mu_2)\,(\lambda_{33}+2\,\mu_3)-\lambda_{23}^2\right)\\
\frac{1}{E_2}=\frac{1}{\Delta_{\mathrm{U}}}\left((\lambda_{11}+2\,\mu_1)\,(\lambda_{33}+2\,\mu_3)-\lambda_{13}^2\right)\\
\frac{1}{E_3}=\frac{1}{\Delta_{\mathrm{U}}}\left((\lambda_{11}+2\,\mu_1)\,(\lambda_{22}+2\,\mu_2)-\lambda_{12}^2\right)
\end{array}\right. \tag{5.E.18}$$

and

$$\left\{\begin{array}{l}
-\frac{\nu_{12}}{E_1}=-\frac{\nu_{21}}{E_2}=\frac{1}{\Delta_{\mathrm{U}}}\left(\lambda_{13}\,\lambda_{23}-\lambda_{12}\,(\lambda_{33}+2\,\mu_3)\right)\\
-\frac{\nu_{13}}{E_1}=-\frac{\nu_{31}}{E_3}=\frac{1}{\Delta_{\mathrm{U}}}\left(\lambda_{12}\,\lambda_{23}-\lambda_{13}\,(\lambda_{22}+2\,\mu_2)\right)\\
-\frac{\nu_{23}}{E_2}=-\frac{\nu_{32}}{E_3}=\frac{1}{\Delta_{\mathrm{U}}}\left(\lambda_{12}\,\lambda_{13}-\lambda_{23}\,(\lambda_{11}+2\,\mu_1)\right)
\end{array}\right. \tag{5.E.19}$$

Inversion of the lower 3×3 principal minor of the tensor moduli (5.2.40) yields

$$\left.\begin{aligned} y_1+y_2&=\frac{1}{\mu_1+\mu_2}\\ y_2+y_3&=\frac{1}{\mu_2+\mu_3}\\ y_3+y_1&=\frac{1}{\mu_3+\mu_1}\end{aligned}\right\}\quad \begin{aligned}&\Rightarrow y_1+y_2=\frac{1}{\mu_1+\mu_2}\\ &\Rightarrow y_1-y_2=\frac{1}{\mu_3+\mu_1}-\frac{1}{\mu_2+\mu_3}\end{aligned} \tag{5.E.20}$$

and therefore

$$2\,y_a=\frac{1+\nu_{\underline{aa}}}{E_{\underline{a}}}=\frac{1}{\mu_{\rm a}+\mu_{\rm b}}+\frac{1}{\mu_{\rm a}+\mu_{\rm c}}-\frac{1}{\mu_{\rm b}+\mu_{\rm c}},\quad a\neq b\neq c\,. \tag{5.E.21}$$

Therefore, the nine moduli $\lambda_{\rm ab}$, $\mu_{\rm a}$, $a\le b\in[1,3]$, being known, the generalized Young's moduli and Poisson's ratios are obtained in the following sequence:

- calculate first the three $E_{\rm a}$'s from (5.E.18);
- calculate the three $\nu_{\rm ab}$'s, $a<b$, from (5.E.19);
- calculate the three $\nu_{\underline{aa}}$'s from (5.E.21).

2. Calculate the generalized Lamé moduli in terms of the Young's moduli and Poisson's ratios

Answer: Inversion of the lower principal minor and upper principal minor yields,

$$\mu_{\rm a}=\mu_{\rm ab}+\mu_{\rm ac}-\mu_{\rm bc},\quad a\neq b\neq c\in[1,3]\,, \tag{5.E.22}$$

$$\left\{\begin{aligned}\lambda_{11}+2\,\mu_1&=\Delta_{\rm U}\,\big(\frac{1}{E_2}\,\frac{1}{E_3}-(\frac{\nu_{23}}{E_2})^2\big)\\ \lambda_{22}+2\,\mu_2&=\Delta_{\rm U}\,\big(\frac{1}{E_1}\,\frac{1}{E_3}-(\frac{\nu_{13}}{E_1})^2\big)\\ \lambda_{33}+2\,\mu_3&=\Delta_{\rm U}\,\big(\frac{1}{E_1}\,\frac{1}{E_2}-(\frac{\nu_{12}}{E_1})^2\big)\end{aligned}\right. \tag{5.E.23}$$

and

$$\left\{\begin{aligned}\lambda_{12}=\lambda_{21}&=\Delta_{\rm U}\,\big(\frac{\nu_{13}}{E_1}\,\frac{\nu_{23}}{E_2}+\frac{\nu_{12}}{E_1}\,\frac{1}{E_3}\big)\\ \lambda_{13}=\lambda_{31}&=\Delta_{\rm U}\,\big(\frac{\nu_{12}}{E_1}\,\frac{\nu_{23}}{E_2}+\frac{\nu_{13}}{E_1}\,\frac{1}{E_2}\big)\\ \lambda_{23}=\lambda_{32}&=\Delta_{\rm U}\,\big(\frac{\nu_{12}}{E_1}\,\frac{\nu_{13}}{E_1}+\frac{\nu_{23}}{E_2}\,\frac{1}{E_1}\big)\end{aligned}\right. \tag{5.E.24}$$

Here $\Delta_{\rm U}$ is the determinant of upper principal minor of the compliance matrix (5.2.46).

Exercise 5.10 Positive definiteness of the elastic *orthotropic* stiffness and compliance matrices

Convexity of the elastic potential of an orthotropic linear elastic material is ensured by the positive definiteness of the stiffness $\mathbb{E}$ (or compliance tensor $\mathbb{E}^{-1}$), that is by the fact that the six eigenvalues of $\mathbb{E}$ are strictly positive.

The elastic stiffness is defined by (5.2.41). The following six Routh-Hurwitz conditions ensure the positive definiteness of the three eigenvalues of the upper principal minor and of the three eigenvalues of the lower diagonal minor,

$$\Delta_1>0,\ \Delta_1\,\Delta_2-\Delta_3>0,\ \Delta_3>0,\ c_{44}>0,\ c_{55}>0,\ c_{66}>0\,, \tag{5.E.25}$$

where

$$\begin{aligned}\Delta_1&=c_{11}+c_{22}+c_{33},\\ \Delta_2&=c_{11}\,c_{22}+c_{22}\,c_{33}+c_{33}\,c_{11}-c_{23}^2-c_{13}^2-c_{12}^2,\\ \Delta_3&=c_{11}\,c_{22}\,c_{33}-c_{11}\,c_{23}^2-c_{22}\,c_{13}^2-c_{33}\,c_{12}^2+2\,c_{23}\,c_{13}\,c_{12}.\end{aligned} \tag{5.E.26}$$

Apply the Routh-Hurwitz criterion, Gantmacher [1959], vol. II, p. 194, knowing that the eigenvalues are real since the matrix is symmetric.

Exercise 5.11 Linear transversely isotropic elasticity using representation theorems

Using the theorem of representation for a transversely isotropic scalar function of the strain $\boldsymbol{\epsilon}$, Section 2.11.3, obtain the expression of the elastic potential shown in Section 5.2.6.

Proof: Let $\mathbf{m}$ be the axis of material symmetry. The elastic potential is assumed to be a transversely isotropic function of $\boldsymbol{\epsilon}$, or equivalently an isotropic function of $\{\boldsymbol{\epsilon}\,,\mathbf{M}=\mathbf{m}\otimes\mathbf{m}\}$. As expected, the representation theorems show that the elastic

potential of linear elasticity involves 5 constant coefficients a_i, $i \in [1,5]$,

$$\left\{\begin{array}{lcl} \mathcal{W} &=& \frac{a_1}{2}(\mathrm{tr}\,\boldsymbol{\epsilon})^2 + \frac{a_2}{2}\,\mathrm{tr}\,\boldsymbol{\epsilon}^2 + a_3\,(\mathrm{tr}\,\boldsymbol{\epsilon})\;(\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon}) + \frac{a_4}{2}\,(\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon})^2 + a_5\,\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon}^2\,; \\ \boldsymbol{\sigma} &=& a_1\,(\mathrm{tr}\,\boldsymbol{\epsilon})\,\mathbf{I} + a_2\,\boldsymbol{\epsilon} + a_3\,\big((\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon})\,\mathbf{I} + (\mathrm{tr}\,\boldsymbol{\epsilon})\,\mathbf{M}\big) + \\ &+& a_4\,(\mathrm{tr}\,\mathbf{M}\cdot\boldsymbol{\epsilon})\,\mathbf{M} + a_5\,(\mathbf{M}\cdot\boldsymbol{\epsilon} + \boldsymbol{\epsilon}\cdot\mathbf{M})\,; \\ \mathbb{E} &=& a_1\,\mathbf{I}\otimes\mathbf{I} + a_2\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I} + a_3\,\big(\mathbf{M}\otimes\mathbf{I} + \mathbf{I}\otimes\mathbf{M}\big) + \\ &+& a_4\,\mathbf{M}\otimes\mathbf{M} + a_5\,(\mathbf{M}\,\underline{\overline{\otimes}}\,\mathbf{I} + \mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{M})\,. \end{array}\right. \tag{5.E.27}$$

The coefficients c's of the stiffness matrix (5.2.51) are identified in terms of the a's defined by (5.E.27),

$$\left\{\begin{array}{l} c_{11} = \lambda_{\mathrm{T}} + 2\,\mu_{\mathrm{T}} = a_1 + a_2, \\ c_{12} = \lambda_{\mathrm{T}} = a_1, \\ c_{13} = \lambda_{\mathrm{LT}} = a_1 + a_3, \\ c_{33} = \lambda_{\mathrm{L}} + 2\,\mu_{\mathrm{L}} = a_1 + a_2 + 2a_3 + a_4 + 2a_5, \\ c_{44} = \mu_{\mathrm{L}} = \frac{1}{2}\,(a_2 + a_5)\,. \end{array}\right. \tag{5.E.28}$$

The a's identify in terms of the generalized Lamé moduli, Eqn (5.2.50), and conversely,

$$\left\{\begin{array}{l} \mu_{\mathrm{T}} = a_2/2, \\ \mu_{\mathrm{L}} = (a_2 + a_5)/2, \\ \lambda_{\mathrm{T}} = a_1, \\ \lambda_{\mathrm{L}} = a_1 + 2a_3 + a_4 + a_5, \\ \lambda_{\mathrm{LT}} = a_1 + a_3, \end{array}\right. \Leftrightarrow \left\{\begin{array}{l} a_1 = \lambda_{\mathrm{T}}, \\ a_2 = 2\,\mu_{\mathrm{T}}, \\ a_3 = \lambda_{\mathrm{LT}} - \lambda_{\mathrm{T}}, \\ a_4 = \lambda_{\mathrm{T}} + \lambda_{\mathrm{L}} - 2\lambda_{\mathrm{LT}} + 2\,\mu_{\mathrm{T}} - 2\,\mu_{\mathrm{L}}, \\ a_5 = 2\,\mu_{\mathrm{L}} - 2\,\mu_{\mathrm{T}}\,. \end{array}\right. \tag{5.E.29}$$

Exercise 5.12 Inversion of the linear transversely elastic relations

Calculate the inverse of the stiffness matrix (5.2.51), and link its coefficients with those of the compliance matrix (5.2.52), and conversely.

Answer:

Direct inversion of the elastic stiffness and of the elastic compliance leads to the equivalences:

$$\left\{\begin{array}{l} c_{11} = (2\mu_{\mathrm{T}})^2\,\dfrac{E_{\mathrm{L}} - \nu_{\mathrm{L}}^2 E_{\mathrm{T}}}{4\mu_{\mathrm{T}}(E_{\mathrm{L}} - \nu_{\mathrm{L}}^2 E_{\mathrm{T}}) - E_{\mathrm{L}}E_{\mathrm{T}}} \\ c_{12} = -2\mu_{\mathrm{T}}\,\dfrac{2\mu_{\mathrm{T}}(E_{\mathrm{L}} - \nu_{\mathrm{L}}^2 E_{\mathrm{T}}) - E_{\mathrm{L}}E_{\mathrm{T}}}{4\mu_{\mathrm{T}}(E_{\mathrm{L}} - \nu_{\mathrm{L}}^2 E_{\mathrm{T}}) - E_{\mathrm{L}}E_{\mathrm{T}}} \\ c_{13} = 2\mu_{\mathrm{T}}\,\dfrac{\nu_{\mathrm{L}} E_{\mathrm{L}} E_{\mathrm{T}}}{4\mu_{\mathrm{T}}(E_{\mathrm{L}} - \nu_{\mathrm{L}}^2 E_{\mathrm{T}}) - E_{\mathrm{L}}E_{\mathrm{T}}} \\ c_{33} = E_{\mathrm{L}}^2\,\dfrac{4\mu_{\mathrm{T}} - E_{\mathrm{T}}}{4\mu_{\mathrm{T}}(E_{\mathrm{L}} - \nu_{\mathrm{L}}^2 E_{\mathrm{T}}) - E_{\mathrm{L}}E_{\mathrm{T}}} \\ c_{44} = \mu_{\mathrm{L}} \end{array}\right. \Leftrightarrow \left\{\begin{array}{l} E_{\mathrm{L}} = \dfrac{(c_{11}+c_{12})\,c_{33} - 2\,c_{13}^2}{c_{11}+c_{12}} \\ E_{\mathrm{T}} = \dfrac{c_{11}-c_{12}}{c_{11}c_{33} - c_{13}^2}\,\big((c_{11}+c_{12})\,c_{33} - 2\,c_{13}^2\big) \\ \mu_{\mathrm{L}} = c_{44} \\ \mu_{\mathrm{T}} = \dfrac{1}{2}\,(c_{11} - c_{12}) \\ \nu_{\mathrm{L}} = \dfrac{c_{13}}{c_{11}+c_{12}} \end{array}\right. \tag{5.E.30}$$

Exercise 5.13 Positive definiteness of the linear elastic *transverse isotropic* matrix

The transversely isotropic elastic matrix has the form (5.2.51). Using Exercise 5.10, or through a direct analysis, show that the conditions that ensure the linear elastic transverse isotropic stiffness, or compliance, matrix to be positive definite, are, Chadwick [1989],

$$c_{11} > |c_{12}|, \quad (c_{11} + c_{12})\,c_{33} - 2\,c_{13}^2 > 0, \quad c_{44} > 0\,. \tag{5.E.31}$$

Still another proof is provided by Exercise 5.20.

Exercise 5.14 Positive definiteness of the linear elastic *cubic* stiffness and compliance matrices

Prove directly that the inequalities (5.2.66) are necessary and sufficient conditions to ensure the linear elastic cubic compliance matrix (5.2.64) to be positive definite.

Answer: A necessary and sufficient condition for a (symmetric) matrix to be positive definite (PD) is that all its principal sub-matrices be PD as well, that is, all their eigenvalues should be positive. This condition implies in particular that the diagonal terms should be positive. Thus, from (5.2.41), $c_{44} = c_{55} = c_{66} > 0$. Moreover

$$\begin{gathered} c_{11} > 0\,; \\ \begin{bmatrix} c_{11} & c_{12} \\ c_{12} & c_{11} \end{bmatrix} \text{(PD)} \quad \Rightarrow \quad c_{11} > 0,\ c_{11} - \frac{c_{12}^2}{c_{11}} > 0\,; \\ \begin{bmatrix} c_{11} & c_{12} & c_{12} \\ c_{12} & c_{11} & c_{12} \\ c_{12} & c_{12} & c_{11} \end{bmatrix} \text{(PD)} \quad \Rightarrow \quad c_{11} - c_{12} > 0 \text{ double eigenvalue},\ c_{11} + 2\,c_{12} > 0\,. \end{gathered} \tag{5.E.32}$$

Exercise 5.15 Symmetry property sufficient for coaxiality

Two second order tensors are said to be *coaxial* if they have the same eigenspace. If the eigenvalues are distinct, the principal directions, or eigenvectors, are uniquely defined, and they coincide, say $\mathbf{e}_i^{\epsilon} = \mathbf{e}_i^{\sigma}$, $i \in [1,3]$, in (5.2.5).

Find the material symmetries that ensure the stress and strain to be coaxial in linear elasticity.

Exercise 5.16 A property of cubic symmetry

Show that for cubic symmetry and higher, the stress and strain are isotropic simultaneously.

Proof: Use (5.2.62) or (5.2.63).

Exercise 5.17 Structural and fabric orthotropies

Show that the elastic anisotropy defined in Section 5.2.11 by the fabric tensor $\mathbf{B}$ is a particular case of orthotropic elasticity, when the eigenvalues of $\mathbf{B}$ are distinct, Bigoni and Loret [1999].

Answer:

The nine coefficients defining the orthotropic response are easily obtained by comparing the matrix forms (5.2.40) and (5.2.82) of the elastic relations expressed in the orthotropy axes $\mathbf{e} = \mathbf{b}$,

$$\begin{gathered} \mu_i/\mu = b_i\,(b_j + b_k) - b_j\,b_k\,, \quad i \neq j \neq k \in [1,3]\,; \\ \lambda_{\underline{ii}} = (\lambda + 2\,\mu)\,b_i^2 - 2\,\mu_i\,, \quad i \in [1,3]; \quad \lambda_{ij} = \lambda\,b_i\,b_j\,, \quad i \neq j \in [1,3]\,. \end{gathered} \tag{5.E.33}$$

Exercise 5.18 Structural and fabric transverse isotropies

Show that the elastic anisotropy defined in Section 5.2.11 by the fabric tensor $\mathbf{B}$ is a particular case of transverse isotropic elasticity, when the two eigenvalues b_1 and b_2 of $\mathbf{B}$ are equal, Bigoni and Loret [1999].

Answer:

With help of the relation $\mathbf{B}_1 + \mathbf{B}_2 + \mathbf{B}_3 = \mathbf{I}$, the fabric tensor $\mathbf{B} = b_1\,\mathbf{B}_1 + b_2\,\mathbf{B}_2 + b_3\,\mathbf{B}_3$ can then be cast in the form $\mathbf{B} = b_T\,\mathbf{I} + (b_L - b_T)\,\mathbf{M}$, where the index T denotes a transverse direction and the index L the longitudinal direction, and with $\mathbf{M} = \mathbf{B}_3$.

The strain energy (5.2.81) can then be recast in the transversely isotropic format (5.E.27), and with the following coefficients a_i, $i \in [1,5]$:

$$a_1 = \lambda\,b_T^2\,, \quad a_2 = 2\,\mu\,b_T^2\,, \quad a_3 = \lambda\,b_T\,(b_L - b_T)\,, \quad a_4 = (\lambda + 2\mu)(b_L - b_T)^2\,, \quad a_5 = 2\mu\,b_T(b_L - b_T)\,. \tag{5.E.34}$$

Exercise 5.19 A versatile form of anisotropic nonlinear hyperelasticity, Loret and Simões [2005]a

The elastic anisotropic model exposed in Section 5.2.11 is defined by a fabric tensor $\mathbf{B}$. It is easily tractable. Use this model as a backbone to build a nonlinear hyperelastic model, such that the secant anisotropic elastic operator retains the linear format, up to a multiplicative scalar.

Answer:

A way to reach this property is to assume a constant Poisson's ratio ν, but a stress-dependent Young's modulus E. Thus the nonlinearity affects the axial stress-axial strain curve, and the strains in the lateral directions plot essentially linearly as

functions of the axial strain. This approach extends to anisotropic materials the earlier analysis of Loret [1985] devoted to isotropic elasticity at infinitesimal strains, Section 5.1.

Algebraic manipulations simplify if the bulk modulus $K=E/3\,(1-2\,\nu)$ and the shear modulus $\mu=E/2(1+\nu)$ are used. So $K/\mu=K_r/\mu_r$, the subscript 'r' denoting the reference state with zero stress. The nonlinear compliance tensor $\mathbb{E}^{-1}$ is built so that

$$\mathbb{E}^{-1}=\frac{E_r}{E}\,\mathbb{E}_r^{-1}\,. \tag{5.E.35}$$

Let $\mathcal{W}_r$ be the elastic energy associated with the moduli in the reference state:

$$\mathcal{W}_r(\boldsymbol{\sigma})=\frac{1}{18\,K_r}\,(\mathrm{tr}\,\mathbf{X})^2+\frac{1}{4\,\mu_r}\,\mathrm{tr}\,(\mathrm{dev}\,\mathbf{X}\cdot\mathrm{dev}\,\mathbf{X})\,, \tag{5.E.36}$$

where $\mathbf{X}\equiv\mathbf{B}^{-1/2}\cdot\boldsymbol{\sigma}\cdot\mathbf{B}^{-1/2}$. The nonlinear potential $\mathcal{W}_{\rm nl}(\boldsymbol{\sigma})$ is assumed to be a function of the linear potential $\mathcal{W}_r(\boldsymbol{\sigma})$,

$$\mathcal{W}_{\rm nl}=\mathcal{W}_{\rm nl}(\mathcal{W}_r)\,. \tag{5.E.37}$$

The secant operator deriving from this potential has indeed the requested form, and,

$$\frac{\partial\mathcal{W}_{\rm nl}}{\partial\boldsymbol{\sigma}}=\mathbb{E}^{-1}:\boldsymbol{\sigma}=-\frac{\nu}{E}\,(\mathbf{B}^{-1}:\boldsymbol{\sigma})\,\mathbf{B}^{-1}+\frac{1+\nu}{E}\,\mathbf{B}^{-1}\cdot\boldsymbol{\sigma}\cdot\mathbf{B}^{-1}\,. \tag{5.E.38}$$

The relations $\partial\,\mathrm{tr}\,\mathbf{X}/\partial\boldsymbol{\sigma}=\mathbf{B}^{-1}$ and $\partial(\mathrm{dev}\,\mathbf{X})_{ij}/\partial\sigma_{kl}=\frac{1}{2}((\mathbf{B}^{-\frac{1}{2}})_{ik}\,(\mathbf{B}^{-\frac{1}{2}})_{jl}+(\mathbf{B}^{-\frac{1}{2}})_{il}\,(\mathbf{B}^{-\frac{1}{2}})_{jk})-\frac{1}{3}I_{ij}\,(\mathbf{B}^{-1})_{kl}$ have been used to derive (5.E.38). The Young's modulus is such that E_r/E is equal to the derivative of $\mathcal{W}_{\rm nl}$ with respect to $\mathcal{W}_r$. If we set

$$E=E_r\;\phi(\mathcal{W}_r)\,, \tag{5.E.39}$$

then $\mathcal{W}_{\rm nl}$ is equal to $\int_0^{\mathcal{W}_r}dy/\phi(y)$.

To close the nonlinear model, a specific function $\phi(\mathcal{W}_r)$ has to be postulated based on experimental data. The simplest assumption is to consider a power form, e.g.,

$$\phi(\mathcal{W}_r)=1+\frac{E_{rr}}{E_r}\left(\frac{\mathcal{W}_r}{p_a}\right)^{\frac{n}{2}}\,, \tag{5.E.40}$$

where p_a is an arbitrary reference pressure, and $E_{rr}\geq 0$ [unit : Pa] and $n\geq 0$ are parameters to be calibrated from experimental data. As it is, this formula indicates that the moduli K, μ and E take their minimum values, K_r, μ_r and E_r respectively, at zero stress. This point needs to be assessed, based on measurements.

Exercise 5.20 Spectral decomposition of the transversely isotropic elastic tensor, Walpole [1984]

Walpole [1984] has presented a decomposition of the transversely isotropic elastic tensor that can be easily manipulated. Let $\mathbf{e}_3$ be the material symmetry axis. He defines two projection operators, one on this axis and another one on the basal plane,

$$\mathbf{M}=\mathbf{e}_3\otimes\mathbf{e}_3,\quad \mathbf{N}=\mathbf{I}-\mathbf{e}_3\otimes\mathbf{e}_3\,, \tag{5.E.41}$$

which are further used to build the generators,

$$\left[\begin{array}{ll}\mathbf{E}_1=\mathbf{M}\otimes\mathbf{M} & \mathbf{E}_3=\frac{1}{\sqrt{2}}\,\mathbf{M}\otimes\mathbf{N}\\ \mathbf{E}_4=\frac{1}{\sqrt{2}}\,\mathbf{N}\otimes\mathbf{M} & \mathbf{E}_2=\frac{1}{2}\,\mathbf{N}\otimes\mathbf{N}\end{array}\right],\quad \mathbf{F}=\mathbf{N}\,\underline{\otimes}\,\mathbf{N}-\frac{1}{2}\,\mathbf{N}\otimes\mathbf{N},\quad \mathbf{G}=\mathbf{M}\,\underline{\otimes}\,\mathbf{N}+\mathbf{N}\,\underline{\otimes}\,\mathbf{M}\,. \tag{5.E.42}$$

1. Prove the basic properties

$$\mathbf{M}\cdot\mathbf{M}=\mathbf{M},\quad \mathbf{N}\cdot\mathbf{N}=\mathbf{N},\quad \mathbf{M}\cdot\mathbf{N}=\mathbf{N}\cdot\mathbf{M}=\mathbf{0},\quad \mathbf{M}:\mathbf{M}=1,\quad \mathbf{N}:\mathbf{N}=1,\quad \mathbf{M}:\mathbf{N}=0\,. \tag{5.E.43}$$

2. Show that $\mathbf{E}_1$, $\mathbf{E}_2$, $\mathbf{E}_3$ and $\mathbf{E}_4$ are linearly independent and, with help of (5.2.34), that they constitute a partition of the unit tensor of order four $\mathbf{I}_4$,

$$\mathbf{E}_1+\mathbf{E}_2+\mathbf{E}_3+\mathbf{E}_4=\mathbf{I}_4\,. \tag{5.E.44}$$

3. Prove the multiplication table

	$\mathbf{E}_1$	$\mathbf{E}_2$	$\mathbf{E}_3$	$\mathbf{E}_4$	$\mathbf{F}$	$\mathbf{G}$
$\mathbf{E}_1$	$\mathbf{E}_1$	$\mathbf{0}$	$\mathbf{E}_3$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$
$\mathbf{E}_2$	$\mathbf{0}$	$\mathbf{E}_2$	$\mathbf{0}$	$\mathbf{E}_4$	$\mathbf{0}$	$\mathbf{0}$
$\mathbf{E}_3$	$\mathbf{0}$	$\mathbf{E}_3$	$\mathbf{0}$	$\mathbf{E}_1$	$\mathbf{0}$	$\mathbf{0}$
$\mathbf{E}_4$	$\mathbf{E}_4$	$\mathbf{0}$	$\mathbf{E}_2$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$
$\mathbf{F}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{F}$	$\mathbf{0}$
$\mathbf{G}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{0}$	$\mathbf{G}$

(5.E.45)

4. Let the linear combination,

$$\mathbf{A} = w_1\,\mathbf{E}_1 + w_2\,\mathbf{E}_2 + w_3\,\mathbf{E}_3 + w_4\,\mathbf{E}_4 + f\,\mathbf{F} + g\,\mathbf{G}\,. \tag{5.E.46}$$

Show that

$$\begin{aligned} &w_1 = \mathbf{M}:\mathbf{A}:\mathbf{M}, \quad w_2 = \tfrac{1}{2}\,\mathbf{N}:\mathbf{A}:\mathbf{N}, \quad w_3 = \tfrac{1}{\sqrt{2}}\,\mathbf{M}:\mathbf{A}:\mathbf{N}, \quad w_4 = \tfrac{1}{\sqrt{2}}\,\mathbf{N}:\mathbf{A}:\mathbf{M}, \\ &f = \tfrac{1}{2}\,A_{ijkl}\,F_{ijkl}\,, \quad g = \tfrac{1}{2}\,A_{ijkl}\,G_{ijkl}\,. \end{aligned} \tag{5.E.47}$$

5. The above set of components will be denoted through the format,

$$\mathbf{A} = \left\{ \begin{bmatrix} w_1 & w_3 \\ w_4 & w_2 \end{bmatrix},\ f,\ g \right\}. \tag{5.E.48}$$

Let $\mathbf{A}'$ be another arbitrary transversely isotropic fourth order tensor. Prove the following relations:

$$\mathbf{A}:\mathbf{A}' = \left\{ \begin{bmatrix} w_1\,w_1' + w_3\,w_4' & w_1\,w_3' + w_3\,w_2' \\ w_2\,w_4' + w_4\,w_1' & w_2\,w_2' + w_4\,w_3' \end{bmatrix},\ f\,f',\ g\,g' \right\}; \tag{5.E.49}$$

$$\mathbf{A}:\mathbf{A}^{-1} = \mathbf{I}_4 = \left\{ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},\ 1,\ 1 \right\}; \quad \mathbf{A}^{-1} = \left\{ \frac{1}{w_1\,w_2 - w_3\,w_4} \begin{bmatrix} w_2 & -w_3 \\ -w_4 & w_1 \end{bmatrix},\ \frac{1}{f},\ \frac{1}{g} \right\}; \tag{5.E.50}$$

$$\det \mathbf{A} = (w_1\,w_2 - w_3\,w_4)\,f\,g\,. \tag{5.E.51}$$

6. Deduce the characteristic polynomial,

$$\det\big(\mathbf{A} - \lambda\,\mathbf{I}_4\big) = \big((w_1 - \lambda)\,(w_2 - \lambda) - w_3\,w_4\big)\,(f - \lambda)\,(g - \lambda)\,, \tag{5.E.52}$$

the generalized Cayley-Hamilton relation, namely that a tensor satisfies its characteristic polynomial,

$$\big(\mathbf{A}^2 - (w_1 + w_2)\,\mathbf{A} + (w_1\,w_2 - w_3\,w_4)\,\mathbf{I}\big)\,(f\,\mathbf{I} - \mathbf{A})\,(g\,\mathbf{I} - \mathbf{A}) = \mathbf{0}\,; \tag{5.E.53}$$

and the conditions of positive definiteness,

$$w_1 + w_2 > 0, \quad w_1\,w_2 - w_3\,w_4 > 0, \quad f > 0, \quad g > 0\,. \tag{5.E.54}$$

7. Introducing the elastic stiffness $\mathbf{A} = \mathbb{E}$ expressed by (5.E.27) in (5.E.47), calculate the coefficients w's, f, and g first in terms of the coefficients a's, and next in terms of the coefficients c's using (5.E.28).

For that purpose, it is instrumental to write the tensors $\mathbf{F}$ and $\mathbf{G}$ in matrix form in the orthotropy axes:

$$[\mathbf{F}] = \begin{bmatrix} \frac{1}{2} & -\frac{1}{2} & 0 & 0 & 0 & 0 \\ -\frac{1}{2} & \frac{1}{2} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \quad [\mathbf{G}] = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}. \tag{5.E.55}$$

Then, since $\mathbf{F}:\mathbf{F} = \mathbf{G}:\mathbf{G} = \mathbf{N}:\mathbf{N} = 2$,

$$w_1 = c_{33}, \quad w_2 = c_{11} + c_{12}, \quad w_3 = w_4 = \sqrt{2}\,c_{13}, \quad f = c_{11} - c_{12}, \quad g = c_{44}\,. \tag{5.E.56}$$

The conditions (5.E.54) can then be shown to be equivalent to the conditions (5.E.31).

Chapter 6

Hyperelasticity, a purely mechanical point of view

Most studies on the constitutive behavior of biological tissues, whether isotropic or anisotropic, hyperelastic or visco-hyperelastic, use a strain energy per reference volume, or per reference mass, where various mechanical and biomechanical effects are built in. For example, for the modeling of the passive behavior of arterial walls, Holzapfel et al. [2002] decompose additively the strain energy in three parts representing respectively the volumetric, isochoric and viscous responses. To model the mechanical behavior of the human anterior cruciate ligament, Limbert and Middleton [2004] devise a two-branch parallel model: both the elastic and the viscous stresses derive from strain energies per reference volume. Gathering the ideas of a parallel assembly of Maxwell models, of visco-hyperelasticity and of quasi-linear viscoelasticity (QLV) of Fung, a more general model consists in adding a long range memory that obeys the fading memory principle. Such a model is built by Pioletti and Rakotomanana [2000] to describe the mechanical response of isotropic tendons. For a two-component mixture, Kannan and Rajagopal [2004] make use of a free energy per unit mass, that is built from the individual free energies weighted by the mass fraction.

Before entering the mathematical details of the analysis, we should take a step backward and issue a warning. Soft tissues are porous media saturated by an electrolyte. Porous media intrinsically give rise to time dependent processes and overall nonlinearities. These phenomena are due to interactions between phases and can be produced even if the phases themselves display an individual linear and time independent constitutive response. As a simplification, some studies disregard the multiphase aspects and engage in an analysis as if the tissue was a single phase solid. Then to recover the above experimental effects, the solid should be endowed with intrinsic time effects (viscoelasticity) and nonlinear effects. Thus an apparent simplification may lead not only to undue complexities, but also to errors in interpretation. The time change of the volume fractions is a key point that plagues the single phase analysis. These remarks should nevertheless not deter us to address nonlinear elasticity and intrinsically time dependent mechanical responses, that are indeed observed at certain material scales.

6.1 Restrictions to the strain energy function

While the number of degrees of freedom in devising nonlinear elastic constitutive equations is large, certain requirements of mathematical nature should always be satisfied. Further requirements of mechanical nature in line with the stress-strain response that is sought may be placed on the elements (strain energy function, constitutive tensors, etc.) that are used to develop the equations.

6.1.1 Mathematical requirements

The strain energy function $\underline{\mathcal{W}}(\mathbf{F})$ may be set to vanish in the reference configuration, i.e., where the deformation gradient $\mathbf{F}$ is equal to the identity $\mathbf{I}$ tensor,

$$(1) \quad \underline{\mathcal{W}}(\mathbf{F} = \mathbf{I}) = 0\,. \tag{6.1.1}$$

Like the strain energy of a spring, the strain energy of three-dimensional elastic solids is considered to increase with the deformation. Consequently, it should be positive or zero,

$$(2) \quad \underline{\mathcal{W}}(\mathbf{F}) \geq 0\,. \tag{6.1.2}$$

The strain energy should also satisfy growth conditions: it should be infinite when $\det \mathbf{F}$ tends to either $+\infty$ or to 0^+,

$$\begin{aligned} &(3) \quad \lim_{\det \mathbf{F} \to +\infty} \underline{\mathcal{W}}(\mathbf{F}) = +\infty; \\ &(4) \quad \lim_{\det \mathbf{F} \to 0+} \underline{\mathcal{W}}(\mathbf{F}) = +\infty\,. \end{aligned} \tag{6.1.3}$$

These conditions tend to imply that the energy necessary to expand a finite volume infinitely or to shrink it to a tiny volume should be infinite.

The strain energy is required to be objective, i.e., independent of rigid body motions in the current configuration,

$$(5) \text{ objectivity} \quad \underline{\mathcal{W}}(\mathbf{Q} \cdot \mathbf{F}) = \underline{\mathcal{W}}(\mathbf{F}), \quad \forall\ \mathbf{Q} \text{ rotation}\,. \tag{6.1.4}$$

As a consequence of (5), $\underline{\mathcal{W}}$ depends only on the stretching part of the deformation gradient $\mathbf{F}$, i.e., it depends only on the symmetric right stretch tensor $\mathbf{U}$ or, equivalently, on the right Cauchy-Green tensor $\mathbf{C}$ or Green strain $\mathbf{E}_{\mathrm{G}}$. For isotropic materials, the strain energy $\underline{\mathcal{W}}$ should also be independent of rigid body motions of the reference configuration,

$$(6) \text{ isotropic material} \quad \underline{\mathcal{W}}(\mathbf{F} \cdot \mathbf{Q}) = \underline{\mathcal{W}}(\mathbf{F}), \quad \forall\ \mathbf{Q} \text{ rotation}\,. \tag{6.1.5}$$

Combination of the relations (5) and (6) yields,

$$(7) \text{ objectivity } + \text{ isotropic material} \quad \underline{\mathcal{W}}(\mathbf{Q} \cdot \mathbf{U} \cdot \mathbf{Q}^{\mathrm{T}}) = \underline{\mathcal{W}}(\mathbf{U}), \quad \forall\ \mathbf{Q} \text{ rotation}\,. \tag{6.1.6}$$

Motivations for these restrictions and further developments may be found in textbooks like Bowen [1989] or Holzapfel [2000].

6.1.2 Constitutive requirements of mechanical nature

A number of optional restrictions with an immediate mechanical interpretation have been devised to restrict the constitutive properties of specific materials. Among them, we may mention for isotropic solids,

- tension-extension inequalities: two principal stretches being fixed $\lambda_b = \lambda_b^*$, an increase of the third principal stretch λ_a to λ_a^* leads to an increase of the principal stress along that direction from σ_a to σ_a^*,

$$\left(\sigma_a^* - \sigma_a\right)\left(\lambda_a^* - \lambda_a\right) > 0, \quad \lambda_a^* \neq \lambda_a, \quad \lambda_b^* = \lambda_b, \quad a \neq b\,. \tag{6.1.7}$$

- the Baker-Ericksen inequalities which state that the principal stress is larger in the direction of the larger stretch, i.e., here

$$\left(\sigma_a - \sigma_b\right)\left(\lambda_a - \lambda_b\right) > 0, \quad \lambda_a \neq \lambda_b\,. \tag{6.1.8}$$

  The inequality in terms of the 1st Piola-Kirchhoff stress has been questioned by Ball [1977]. Strong ellipticity implies the Baker-Ericksen inequalities, Wang and Truesdell [1973], p. 247.

- the generalized Coleman-Noll condition (CGN), Truesdell and Toupin [1960], Section 52,

$$\left(\underline{\boldsymbol{\tau}}(\mathbf{F}^*) - \underline{\boldsymbol{\tau}}(\mathbf{F})\right) : \left(\mathbf{F}^* - \mathbf{F}\right) > 0\,, \tag{6.1.9}$$

  with $\underline{\boldsymbol{\tau}}$ the 1st Piola-Kirchhoff stress and the deformation gradients $\mathbf{F}$ and $\mathbf{F}^* = \mathbf{S} \cdot \mathbf{F}$ differ by a symmetric positive definite tensor $\mathbf{S} \neq \mathbf{I}$. It indicates that the transformation from the deformation gradient to the 1st Piola-Kirchhoff stress should be monotone for pairs of deformations that differ by a pure stretch. For a hyperelastic solid, the CGN property and its relation to a convex energy function are considered in Wang and Truesdell [1973], p. 218.

Further properties of the constitutive relations and associated partial differential equations of equilibrium, of an a priori mathematical nature but with mechanical consequences, have been scrutinized, among which are

- positive definiteness
- ellipticity and strong ellipticity
- convexity
- polyconvexity

These properties are briefly introduced in the sections below. The links to the invertibility of the stress-strain relation, algebraic properties of the acoustic tensor and of existence and nature of wave-speeds are pointed out. Local existence and uniqueness theorems in nonlinear elasticity rely on strong ellipticity while global results are based on convexity. Section 5 of Marsden and Hughes [1983] displays the inter-relations between a number of these properties.

6.2 Algebraic properties of constitutive functions and partial differential equations

The definitions are first given in the context of infinitesimal strains. They will be restated in the context of finite deformations in subsequent sections.

Consider a general constitutive law in rate, or rather incremental, form linking an increment of strain $\delta\boldsymbol{\epsilon}$ to an increment of stress $\delta\boldsymbol{\sigma}$,

$$\delta\boldsymbol{\sigma} = \mathbb{E}^t : \delta\boldsymbol{\epsilon}\,. \tag{6.2.1}$$

The increments of stress and strain are considered symmetric second order tensors, so that the tangent stiffness $\mathbb{E}^t$ may, without loss of generality, be considered to be endowed with the minor symmetries under the two first and two last indices, see Section 5.2.2. The constitutive tensor is assumed to be independent of the velocity gradient $\boldsymbol{\nabla}\mathbf{v}$, but it might depend on a set of state variables $\mathcal{V}$.

The next sections address solids. Positive definiteness of the stiffness matrix and strong ellipticity of the momentum balance in an infinite body for saturated porous media are considered in Chapters 7 and 11 respectively. Moreover emphasis is laid here on the quasi-static interpretations of these properties, while Chapter 11 focuses on their dynamic aspects. In fact, during a loading process in a standard boundary value problem, one typically can assign to a certain material quantity the role of a time-like parameter, under the proviso that this parameter varies monotonically. Interest is then in defining the critical values of this time-like parameter at which the properties of positive definiteness, strong ellipticity or ellipticity cease to hold. The mechanical consequences and interpretations of the loss of these properties then depend on the context. For example, loss of strong ellipticity corresponds to the accumulation of deformations along bands of characteristic directions: the phenomenon is termed *strain localization*. In a dynamic context, loss of strong ellipticity corresponds to the onset of a vanishing wave-speed, and it is referred to as a *stationary discontinuity*.

6.2.1 Positive definiteness

Positive definiteness of the stiffness $\mathbb{E}^t$ amounts to

$$\text{(PD)} \quad \boldsymbol{\epsilon} : \mathbb{E}^t : \boldsymbol{\epsilon} = \epsilon_{ij}\, E^t_{ijkl}\, \epsilon_{kl} > 0, \quad \forall \boldsymbol{\epsilon} \neq \mathbf{0}\,. \tag{6.2.2}$$

The major symmetry of the stiffness is defined as the symmetry under the two first and two last indices, namely $E^t_{ijkl} = E^t_{klij}$. The mathematical and mechanical implications of this property are explored in Section 5.1. Let $(\mathbb{E}^t)^{\mathrm{T}}$ be the transpose of the stiffness $\mathbb{E}^t$, namely componentwise $(E^t)^{\mathrm{T}}_{ijkl} = E^t_{klij}$. Positive definiteness depends only on the symmetric part of $\mathbb{E}^t$, namely $\frac{1}{2}(\mathbb{E}^t + (\mathbb{E}^t)^{\mathrm{T}})$, and the skew-symmetric part $\frac{1}{2}(\mathbb{E}^t - (\mathbb{E}^t)^{\mathrm{T}})$ is elusive. Although the focus here is on stiffness matrices endowed with major symmetry, it is of interest to have a look at Exercise 9.1 that reminds some basic results of algebra on non symmetric matrices. In particular, the existence of real positive eigenvalues is equivalent to positive definiteness only for symmetric matrices. Quite generally, invertibility requires non zero eigenvalues.

For linear isotropic elastic materials, the stiffness (5.2.27) may be decomposed in an isotropic (volume) part and a deviatoric (shear) part,

$$\begin{aligned} \mathbb{E} &= (3\,K)\,\frac{\mathbf{I}\otimes\mathbf{I}}{3} + 2\,\mu\,\big(\mathbf{I}\,\underline{\otimes}\,\mathbf{I} - \frac{\mathbf{I}\otimes\mathbf{I}}{3}\big)\,, \\ \mathbb{E}^{-1} &= \frac{1}{3\,K}\,\frac{\mathbf{I}\otimes\mathbf{I}}{3} + \frac{1}{2\,\mu}\,\big(\mathbf{I}\,\underline{\otimes}\,\mathbf{I} - \frac{\mathbf{I}\otimes\mathbf{I}}{3}\big)\,, \end{aligned} \tag{6.2.3}$$

and

$$\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} = K\,(\mathbf{I} : \boldsymbol{\epsilon})^2 + 2\,\mu\,\mathrm{dev}\,\boldsymbol{\epsilon} : \mathrm{dev}\,\boldsymbol{\epsilon}\,. \tag{6.2.4}$$

The conditions of positive definiteness (and hence of invertibility of the stiffness) restrict the bulk, Lamé and Young's moduli and Poisson's ratio,

$$\mathbb{E} \text{ Positive Definite (PD)} \quad K = \lambda + \frac{2}{3}\mu > 0 \text{ and } \mu > 0 \Leftrightarrow\ E > 0 \text{ and } \nu \in]-1,\ \frac{1}{2}[\,. \tag{6.2.5}$$

The spectral analysis of the isotropic elastic stiffness has been addressed in Section 5.3. The elastic stiffness has components $(3\,K,\,2\,\mu)$ on the basis $(\frac{1}{3}\,\mathbf{I}\otimes\mathbf{I}, \mathbf{I}\underline{\otimes}\mathbf{I} - \frac{1}{3}\,\mathbf{I}\otimes\mathbf{I})$ while a tensor $x\,\mathbf{I}\underline{\otimes}\mathbf{I}$ proportional to the identity tensor $\mathbf{I}\underline{\otimes}\mathbf{I} = \frac{1}{3}\,\mathbf{I}\otimes\mathbf{I} + \mathbf{I}\underline{\otimes}\mathbf{I} - \frac{1}{3}\,\mathbf{I}\otimes\mathbf{I}$, has components $(x,\,x)$ on this basis. Then,

$$(\mathbb{E} - x\,\mathbf{I}\underline{\otimes}\mathbf{I})^{-1} = \frac{1}{3\,K - x}\,\frac{\mathbf{I}\otimes\mathbf{I}}{3} + \frac{1}{2\,\mu - x}\,\big(\mathbf{I}\underline{\otimes}\mathbf{I} - \frac{1}{3}\,\mathbf{I}\otimes\mathbf{I}\big)\,. \tag{6.2.6}$$

The actual constitutive stiffness of a number of materials, e.g., elastic-plastic solids, is a symmetric rank one modification of their elastic stiffness, namely

$$\begin{aligned} \mathbb{E}^t &= \mathbb{E} - \frac{1}{H}\,\mathbb{E}:\mathbf{P}\otimes\mathbb{E}:\mathbf{P}, \quad H = h + \mathbf{P}:\mathbb{E}:\mathbf{P} > 0\,, \\ (\mathbb{E}^t)^{-1} &= \mathbb{E}^{-1} + \frac{1}{h}\,\mathbf{P}\otimes\mathbf{P}\,, \end{aligned} \tag{6.2.7}$$

with $\mathbf{P}$ a symmetric second order tensor and the modulus $H > 0$ is assumed to be strictly positive. Given the positive definiteness of the symmetric elastic stiffness $\mathbb{E}$, positive definiteness of the stiffness $\mathbb{E}^t$,

$$H\,\boldsymbol{\epsilon}:\mathbb{E}^t:\boldsymbol{\epsilon} = h\,\underbrace{\boldsymbol{\epsilon}:\mathbb{E}:\boldsymbol{\epsilon}}_{\geq 0} + \underbrace{(\boldsymbol{\epsilon}:\mathbb{E}:\boldsymbol{\epsilon})\,(\mathbf{P}:\mathbb{E}:\mathbf{P}) - (\boldsymbol{\epsilon}:\mathbb{E}:\mathbf{P})^2}_{\geq 0} \geq 0\,, \tag{6.2.8}$$

requires the modulus $h \geq 0$ to be positive or 0. Indeed, the positive definite elastic stiffness $\mathbb{E}$ may be used to define a norm over symmetric second order tensors, e.g., $|\boldsymbol{\epsilon}| = \sqrt{\boldsymbol{\epsilon}:\mathbb{E}:\boldsymbol{\epsilon}}$. The last term in (6.2.8) is therefore positive as a consequence of the Cauchy-Schwarz inequality,

$$(\boldsymbol{\epsilon}_1:\mathbb{E}:\boldsymbol{\epsilon}_1)\,(\boldsymbol{\epsilon}_2:\mathbb{E}:\boldsymbol{\epsilon}_2) - (\boldsymbol{\epsilon}_1:\mathbb{E}:\boldsymbol{\epsilon}_2)^2 \geq 0, \quad \forall \boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2\,. \tag{6.2.9}$$

The eigenmode $\boldsymbol{\epsilon}$ associated with loss of positive definiteness implies the Cauchy-Schwarz inequality to be an equality, which implies $\boldsymbol{\epsilon} \sim \mathbf{P}$. Invertibility of the stiffness requires strict positive definiteness, namely $h > 0$, which is indeed mandatory as shown in the inverse displayed in (6.2.7). This condition holds for any type of elastic anisotropy.

The spectral analysis of the tensor $\mathbb{E}^t$ amounts to define its eigenvalues x and (left or right) eigenvectors $\boldsymbol{\epsilon}$ such that $\mathbb{E}^t:\boldsymbol{\epsilon} = x\,\boldsymbol{\epsilon}$, or

$$\boldsymbol{\epsilon} = \frac{\mathbf{P}:\mathbb{E}:\boldsymbol{\epsilon}}{H}\,(\mathbb{E} - x\,\mathbf{I}\underline{\otimes}\mathbf{I})^{-1} : (\mathbb{E}:\mathbf{P})\,. \tag{6.2.10}$$

For isotropic elasticity, this expression derives easily using (6.2.6), and, multiplied by $\mathbb{E}:\mathbf{P}$, it yields the quadratic equation for the eigenvalues x,

$$H\,x^2 - \big(h\,(3\,K + 2\,\mu) + 6\,K\,\mu\,\mathbf{P}:\mathbf{P}\big)\,x + 6\,K\,\mu\,h = 0\,, \tag{6.2.11}$$

and the associated eigenmode,

$$\boldsymbol{\epsilon} \sim 6\,K\,\mu\,\mathbf{P} - x\,\mathbb{E}:\mathbf{P}\,. \tag{6.2.12}$$

Since the eigenproblem involves a symmetric matrix, the two eigenvalues are real. They are both positive if $h > 0$, one is positive and one negative for $h < 0$, and one is zero for $h = 0$. In fact, the product of the eigenvalues can be obtained directly with help of (2.3.26), namely

$$\det\mathbb{E}^t = \det\mathbb{E}\,\det\big(\mathbf{I}\underline{\otimes}\mathbf{I} - \frac{1}{H}\,\mathbf{P}\otimes\mathbb{E}:\mathbf{P}\big) = \det\mathbb{E}\,\Big(1 - \frac{\mathbf{P}:\mathbb{E}:\mathbf{P}}{H}\Big) = (3\,K)\,(2\,\mu)\,\frac{h}{H}\,, \tag{6.2.13}$$

in agreement with (6.2.11).

6.2.2 Ellipticity and Strong Ellipticity

The quasi-static balance of momentum, or its rate, can typically be expressed as a quasi-linear partial differential equation, wrt the space variable $\mathbf{x}$, for the displacement $\mathbf{u}$, or velocity $\mathbf{v}$,

$$\frac{\partial}{\partial x_i}\,\big(E^t_{ijkl}\,\frac{\partial v_l}{\partial x_k}\big) = 0\,, \tag{6.2.14}$$

that is satisfied pointwise inside the body (V). Focus is on the solutions $\mathbf{v} = \mathbf{v}(\mathbf{x})$ which are continuous and whose partial derivatives are piecewise continuous.

6.2.2.1 Ellipticity

The partial differential equation (6.2.14) is termed elliptic[6.1] at state $\mathcal{V}$ if

$$\text{(E)} \quad \det(n_i\, E^t_{ijkl}\, n_k) \neq 0, \quad \forall\, \mathbf{n},\ |\mathbf{n}| = 1\,. \tag{6.2.15}$$

If there exists a vector $\mathbf{n}$ such that $\det(n_i\, E^t_{ijkl}\, n_k) = 0$, then $\mathbf{n}$ is normal to a curve, called characteristic curve, across which $\mathbf{v}$ shows a discontinuity in its normal derivative, $[\![\boldsymbol{\nabla}\mathbf{v}]\!] \cdot \mathbf{n} \neq \mathbf{0}$, in other words, there exists a vector $\boldsymbol{\eta} \neq \mathbf{0}$ such that $[\![\boldsymbol{\nabla}\mathbf{v}]\!] = \boldsymbol{\eta} \otimes \mathbf{n}$.

6.2.2.2 Strong Ellipticity

The partial differential equation (6.2.14) is termed strongly elliptic at $\mathcal{V}$ if[6.2]

$$\text{(SE)} \quad \boldsymbol{\epsilon}^{\otimes} : \mathbb{E}^t : \boldsymbol{\epsilon}^{\otimes} = m_j\, n_i\, E^t_{ijkl}\, n_k\, m_l > 0\,, \quad \forall\, \boldsymbol{\epsilon}^{\otimes} = \frac{1}{2}\,(\mathbf{m}\otimes\mathbf{n} + \mathbf{n}\otimes\mathbf{m}) \neq \mathbf{0}, \quad |\mathbf{m}| = |\mathbf{n}| = 1\,. \tag{6.2.16}$$

Since strong ellipticity is defined as positive definiteness over a restricted set of second order tensors, namely tensors of dyadic form, strong ellipticity is a weaker requirement than positive definiteness.

Moreover, if the stiffness $\mathbb{E}^t$ displays the major symmetry, the following implications hold,

$$\text{(PD)} \quad \Rightarrow \quad \text{(SE)} \quad \Rightarrow \quad \text{(E)}\,. \tag{6.2.17}$$

With ρ the mass density, the second order tensor $\rho\, A_{jl} = n_i\, E^t_{ijkl}\, n_k$ that emerges from these definitions is termed *acoustic tensor*. Strong ellipticity in presence of a symmetric acoustic tensor implies the existence of three real positive eigenvalues, interpreted as wave-speeds in Chapter 11, and associated with three orthogonal eigenvectors.

Strong ellipticity of the isotropic elastic tensor amounts to

$$\mathbb{E} \text{ Strongly Elliptic (SE)} \quad \lambda + 2\mu > 0 \text{ and } \mu > 0 \ \Leftrightarrow\ E > 0 \text{ and } \nu \in]-1,\, \tfrac{1}{2}[\cup]1,\, \infty[\,, \tag{6.2.18}$$

while ellipticity is defined by the conditions,

$$\mathbb{E} \text{ Elliptic (E)} \quad \lambda + 2\mu \neq 0 \text{ and } \mu \neq 0 \ \Leftrightarrow\ E \neq 0,\ \nu \neq 1\,. \tag{6.2.19}$$

The acoustic tensor $\mathbf{A}(\mathbf{n})$ associated with the isotropic elastic stiffness and its inverse express as,

$$\begin{aligned} \mathbf{A}(\mathbf{n}) &= \frac{\lambda + 2\mu}{\rho}\,\mathbf{n}\otimes\mathbf{n} + \frac{\mu}{\rho}\,(\mathbf{I} - \mathbf{n}\otimes\mathbf{n})\,, \\ \mathbf{A}^{-1}(\mathbf{n}) &= \frac{\rho}{\lambda + 2\mu}\,\mathbf{n}\otimes\mathbf{n} + \frac{\rho}{\mu}\,(\mathbf{I} - \mathbf{n}\otimes\mathbf{n})\,, \end{aligned} \tag{6.2.20}$$

while the acoustic tensor $\mathbf{A}^t(\mathbf{n})$ associated with the rank one modification (6.2.7) is also a rank one modification of its elastic counterpart,

$$\mathbf{A}^t(\mathbf{n}) = \mathbf{A}(\mathbf{n}) - \frac{1}{H}\,\mathbf{a}\otimes\mathbf{a}, \quad \mathbf{a} = \frac{1}{\sqrt{\rho}}\,(\mathbb{E} : \mathbf{P})\cdot\mathbf{n}\,. \tag{6.2.21}$$

[6.1] The underlying constitutive operator itself is routinely said to be *elliptic*.

[6.2] Alternatively, strong ellipticity is also defined through the existence of a strictly positive scalar $\kappa > 0$ such that

$$\text{(SE}')\quad m_j\, n_i\, E^t_{ijkl}\, n_k\, m_l \geq \kappa\,|\mathbf{m}|\,|\mathbf{n}|,$$

for any vectors $\mathbf{m}$ and $\mathbf{n}$. The property is called *semi-ellipticity* if $\kappa = 0$, namely

$$\text{(sE)}\quad m_j\, n_i\, E^t_{ijkl}\, n_k\, m_l \geq 0,$$

for any vectors $\mathbf{m}$ and $\mathbf{n}$. This property is also referred to as *Legendre-Hadamard condition* (LH). Although the subject of stability is not entered here, it is worth mentioning *Hadamard's theorem*, according to which semi-ellipticity (sE) is a necessary condition of local stability of an equilibrium point.

Furthermore, if $\mathbb{E}^t$ is constant in a domain Ω at the boundary of which the displacement field $\mathbf{u}$ vanishes, then, we have the implication referred as *van Hove theorem*,

$$\text{(SE)} \quad \Rightarrow \quad \int_\Omega \boldsymbol{\nabla}\mathbf{u} : \mathbb{E}^t : \boldsymbol{\nabla}\mathbf{u}\; d\Omega > 0,$$

which, in absence of body forces, is a sufficient stability condition, see, e.g., Mandel [1974], p. 114, for an analysis.

Loss of ellipticity amounts to the existence of at least one direction $\mathbf{n}$ and one eigenvector $\boldsymbol{\eta} \neq \mathbf{0}$ such that,

$$\mathbf{A}^t \cdot \boldsymbol{\eta} \;=\; \mathbf{A} \cdot \big(\mathbf{I} - \frac{1}{H}\, \mathbf{A}^{-1} \cdot \mathbf{a} \otimes \mathbf{a}\big) \cdot \boldsymbol{\eta} = \mathbf{0}\,. \tag{6.2.22}$$

The solution is obtained by inspection,

$$\boldsymbol{\eta} \sim \mathbf{A}^{-1} \cdot \mathbf{a}\,, \quad H = \mathbf{a} \cdot \mathbf{A}^{-1} \cdot \mathbf{a}\,, \tag{6.2.23}$$

or by calculating the determinant of $\mathbf{A}^t$,

$$\det \mathbf{A}^t = \big(1 - \frac{1}{H}\, \mathbf{a} \cdot \mathbf{A}^{-1} \cdot \mathbf{a}\big)\ \det \mathbf{A}\,, \tag{6.2.24}$$

leading to

$$h = -\mathbf{P} : \mathbb{E} : \mathbf{P} + \mathbf{P} : \big((\mathbb{E} \cdot \mathbf{n}) \cdot (\mathbf{n} \cdot \mathbb{E} \cdot \mathbf{n})^{-1} \cdot (\mathbf{n} \cdot \mathbb{E})\big) : \mathbf{P}\,. \tag{6.2.25}$$

This modulus, which may be made more explicit using the inverse elastic acoustic tensor $(6.2.20)_2$, can not be positive as a consequence of the implications (6.2.17), since positive definiteness of $\mathbb{E}^t$ holds for $h > 0$. In an actual loading process, assuming that h decreases monotonously, the issue consists in maximizing $h = h(\mathbf{n})$ to discover the most critical normal $\mathbf{n}$ that leads to loss of ellipticity.

6.2.3 Convexity

A few basic definitions and properties of convex sets and convex functions in $\mathbb{R}^n$, $n \geq 1$, are collected below. For details and proofs, the reader may refer to, e.g., Luenberger [1984], Fletcher [1990].

A generic element $\mathbf{x}$ of the sets considered in the definitions below may be viewed as a geometrical point. When it comes to mechanical constitutive equations, this generic element will be viewed as representing a measure of stress or of strain.

Convex set:

A set $\mathbf{C}$ is convex if, given any two points $\mathbf{x}$ and $\mathbf{y}$ in or on $\mathbf{C}$, any point $\lambda_x\, \mathbf{x} + \lambda_y\, \mathbf{y}$ on the line connecting $\mathbf{x}$ and $\mathbf{y}$, with $\lambda_x + \lambda_y = 1$, $0 \leq \lambda_x,\ \lambda_y \leq 1$, belongs to $\mathbf{C}$.

Convex function:

A function $\phi(\mathbf{x})$ defined on $\mathbb{R}^n$ is said convex iff

$$\begin{gathered} \forall\, (\mathbf{x},\, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^n, \quad \forall\, (\lambda_x \geq 0,\, \lambda_y \geq 0) \in \mathbb{R} \times \mathbb{R}, \quad \text{such that} \quad \lambda_x + \lambda_y = 1, \\ \text{then} \quad \lambda_x\, \phi(\mathbf{x}) + \lambda_y\, \phi(\mathbf{y}) \geq \phi(\lambda_x\, \mathbf{x} + \lambda_y\, \mathbf{y})\,. \end{gathered} \tag{6.2.26}$$

When the function ϕ is defined over second order tensors, a weaker definition, termed *rank one convexity*, requires that the inequality (6.2.26) holds, not for arbitrary $\mathbf{x}$ and $\mathbf{y}$, but only for $\mathbf{x} - \mathbf{y}$ being of rank one.

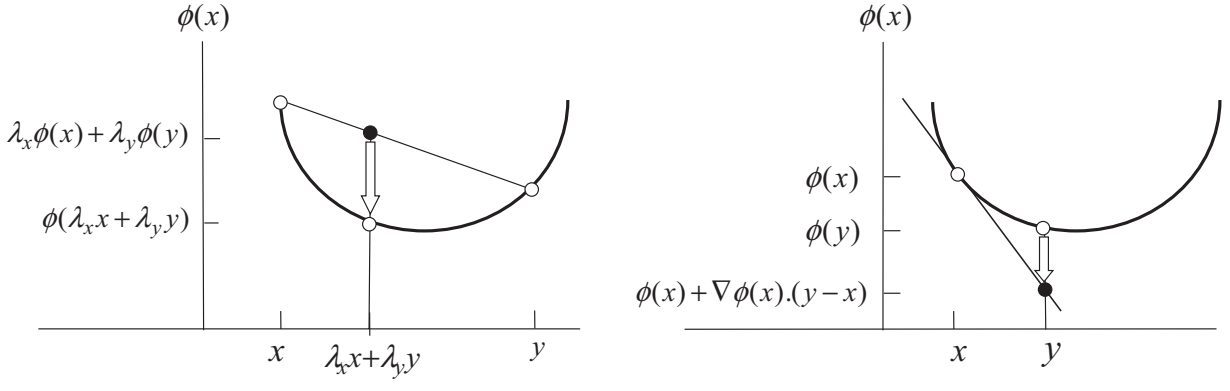

Fig. 6.2.1: Convexity of a differentiable function of the real variable: two equivalent conditions. The curve is below the chord (left), and the tangent defines a supporting hyperplane (right).

The definition is illustrated for a scalar function ($n = 1$) by Fig. 6.2.1. Qualitatively, one may think of a convex function if its graph is bowl-shaped.

A sketch of the multidimensional case ($n = 2$) is displayed in Fig. 6.2.2.

Let us consider the special case of an ellipse $\phi(x, y) = x^2/a^2 + y^2/b^2 - 1 = 0$. For this quadratic function, the inequality (6.2.26) may be transformed to $\phi(\mathbf{x}^{(1)}) - \phi(\mathbf{x}^{(2)}) - \boldsymbol{\nabla}\phi(\mathbf{x}^{(2)}) \cdot (\mathbf{x}^{(1)} - \mathbf{x}^{(2)}) \geq 0$. Actually this inequality holds for any convex function as stated below. If the two points $\mathbf{x}^{(1)}$ and $\mathbf{x}^{(2)}$ are on the ellipse, then $\boldsymbol{\nabla}\phi(\mathbf{x}^{(2)}) \cdot (\mathbf{x}^{(1)} - \mathbf{x}^{(2)}) \leq 0$. As a geometrical implication, all the points $\mathbf{x}^{(1)}$ of the ellipse are located on the inner side of the hyperplane orthogonal to the outer normal $\boldsymbol{\nabla}\phi(\mathbf{x}^{(2)})$ at $\mathbf{x}^{(2)}$.

Convexity property 1:

If ϕ is two times continuously differentiable, it is convex at a point $\mathbf{x}$ iff the quadratic form associated with the Hessian

$$\frac{\partial^2 \phi}{\partial \mathbf{x}\, \partial \mathbf{x}}(\mathbf{x}) \tag{6.2.27}$$

estimated at this point is positive (semi-)definite.

Consequently, a quadratic form $\frac{1}{2}\,\mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{x} + \mathbf{x}^{\mathrm{T}}\mathbf{a} + a$ is convex iff the symmetric part of the square matrix $\mathbf{A}$ is positive (semi-)definite, irrespective of the affine contribution $\mathbf{x}^{\mathrm{T}}\mathbf{a} + a$.

Convexity property 2:

If ϕ is continuously differentiable, it is convex iff $\forall\ \mathbf{x} \neq \mathbf{y}$,

$$\phi(\mathbf{y}) - \phi(\mathbf{x}) \geq \nabla\phi(\mathbf{x}) \cdot (\mathbf{y} - \mathbf{x})\,. \tag{6.2.28}$$

The property is illustrated by Fig. 6.2.1 for a one-dimensional space $n = 1$, and by Fig. 6.2.2 for a two-dimensional space $n = 2$. Observe in particular that $\phi(\mathbf{y}) - \phi(\mathbf{x})$ is positive while $\nabla\phi(\mathbf{x}) \cdot (\mathbf{y} - \mathbf{x})$ is negative in the fan just 'below' the tangent hyperplane.

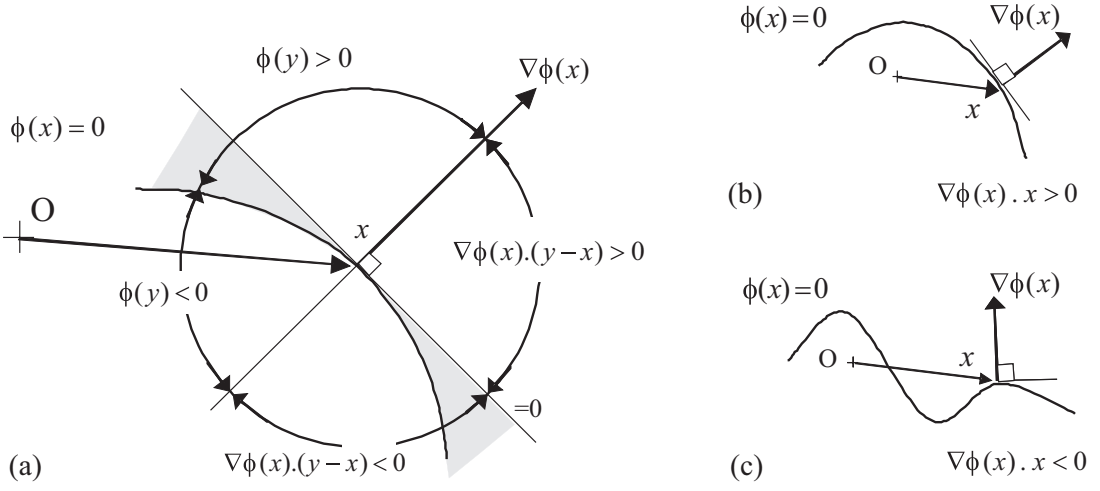

Fig. 6.2.2: Convexity of a differentiable function in $\mathbb{R}^2$. In a certain fan below the hyperplane defined by the tangent at a point $\mathbf{x}$, the function $\phi(\mathbf{y})$ is positive while $\nabla\phi(\mathbf{x}) \cdot (\mathbf{y} - \mathbf{x})$ is negative, (a). The set defined by the function $\phi(\mathbf{x}) \leq 0$ may a priori be convex in the configuration (b) but definitely not in the configuration (c) if it includes the origin O.

The proof of the implication (6.2.26) $\Rightarrow$ (6.2.28) goes as follows. Rewrite the inequality (6.2.26) as

$$\lambda_y \left(\phi(\mathbf{y}) - \phi(\mathbf{x})\right) \geq \phi\big(\mathbf{x} + \lambda_y\,(\mathbf{y} - \mathbf{x})\big) - \phi(\mathbf{x})\,, \tag{6.2.29}$$

divide both sides by λ_y and let λ_y go to 0^+ $\square$. To prove the converse implication (6.2.28) $\Rightarrow$ (6.2.26), write the inequality (6.2.28) with the pairs $(\mathbf{y}_1, \mathbf{x})$ and $(\mathbf{y}_2, \mathbf{x})$, sum the first inequality multiplied by λ_x and the second inequality multiplied by λ_y and finally set $\mathbf{x} = \lambda_x\,\mathbf{y}_1 + \lambda_y\,\mathbf{y}_2$ and $\lambda_x + \lambda_y = 1$ $\square$.

A proof of the implication (6.2.26) $\Rightarrow$ (6.2.27) starting from (6.2.28) can now be provided. For two points $\mathbf{x}$ and $\mathbf{y}$ sufficiently close, $\boldsymbol{\nabla}\phi(\mathbf{x}) \simeq \boldsymbol{\nabla}\phi(\mathbf{y}) + (\mathbf{x} - \mathbf{y}) \cdot \boldsymbol{\nabla}^2\phi(\mathbf{y})$. Substituting in the inequality (6.2.28), one now has $(\mathbf{x} - \mathbf{y}) \cdot \boldsymbol{\nabla}^2\phi(\mathbf{y}) \cdot (\mathbf{x} - \mathbf{y}) \geq \phi(\mathbf{x}) - \phi(\mathbf{y}) - \boldsymbol{\nabla}\phi(\mathbf{y}) \cdot (\mathbf{x} - \mathbf{y}) \geq 0$. $\square$.

Exchanging the roles of $\mathbf{x}$ and $\mathbf{y}$ in the convexity property 2 for the function ϕ and summing the two resulting inequalities implies the monotonicity of its gradient $\nabla\phi$. The latter property implies in turn the convexity property 1. In summary,

Convexity property 3:

If ϕ is continuously differentiable, it is convex iff $\forall\ \mathbf{x} \neq \mathbf{y}$,

$$\big(\nabla\phi(\mathbf{y}) - \nabla\phi(\mathbf{x})\big) \cdot (\mathbf{y} - \mathbf{x}) \geq 0\,. \tag{6.2.30}$$

Strict convexity:

The above properties hold on convex sets. They apply in the *weak sense*, namely, the inequalities are not strict. *Strict convexity* assumes a strict inequality in (6.2.26) for $\mathbf{x} \neq \mathbf{y}$ and $\lambda \in]0,1[$. Then property 2 with a strict inequality is equivalent to strict convexity. As for convexity property 1, $\partial^2\phi/\partial\mathbf{x}\,\partial\mathbf{x}$ positive definite implies strict convexity, but the converse does not hold: a function may be strictly convex while its Hessian is semi-definite positive. As an example, the real function $\phi(x) = x^4$ is strictly convex, but its second derivative vanishes at $x = 0$, Exercise 6.1.

6.2.4 Polyconvexity

The existence of solutions to a particular boundary value problem in nonlinear elasticity depends on whether or not there exist deformations which minimize a given functional (the total potential energy) subjected to specific boundary conditions. Several conditions on the strain energy functions $\underline{\mathcal{W}}$ guaranteeing existence of solutions to boundary value problems have been proposed. The simplest condition is convexity. However, convexity is often oversufficient and even overrestrictive: on one hand, it conflicts with the requirement of objectivity, Truesdell and Noll [1965], p. 163; on the other hand, convexity rules out the nonuniqueness essential for the description of some phenomena like, for example, buckling.

A less restrictive condition on the strain energy function, that is also a sufficient condition for existence of solutions in nonlinear elasticity, was introduced by Morrey [1952] and termed *quasi-convexity*. If $\underline{\mathcal{W}}$ is quasi-convex, then it satisfies the strong ellipticity condition, that is, the acoustic tensor is positive definite. However the quasi-convexity condition is not a pointwise condition and it is therefore difficult to verify in particular cases.

Another important concept for practical use is the notion of *polyconvexity* introduced by Ball [1977]. Ball established the existence of minimizers of the total elastic energy when $\underline{\mathcal{W}}$ has the form,

$$\underline{\mathcal{W}}(\underline{\mathbf{x}}, \mathbf{F}) = g(\underline{\mathbf{x}}, \mathbf{F}, \operatorname{adj}\mathbf{F}, \det\mathbf{F})\,, \tag{6.2.31}$$

with g convex function of $(\mathbf{F}, \operatorname{adj}\mathbf{F}, \det\mathbf{F})$ at each geometrical point $\underline{\mathbf{x}}$. He termed such functions $\underline{\mathcal{W}}$ as polyconvex. In (6.2.31), $\operatorname{adj}\mathbf{F} = \det\mathbf{F}\,\mathbf{F}^{-1}$ denotes the adjoint of the deformation gradient $\mathbf{F}$. Some continuity and growth conditions (coerciveness)[6.3] are also required. Strict polyconvexity implies strong ellipticity. Polyconvexity is equivalent to a sufficient condition for quasi-convexity, that is, it is implied by quasi-convexity, but it is a local condition that it is easier to handle. Polyconvexity of $\underline{\mathcal{W}}(\mathbf{F})$ does not imply convexity of the function $\underline{\mathcal{W}} = \underline{\mathcal{W}}(\mathbf{F})$: as a counterexample, consider the function $\underline{\mathcal{W}}(\mathbf{F}) = g(\det\mathbf{F})$ with g convex in $\det\mathbf{F}$.

While the physical implications of polyconvexity are not established, a wide variety of realistic models of nonlinear elastic materials satisfy the hypotheses of polyconvexity: the neo-Hookean model, the Mooney-Rivlin model and Ogden's model, Ball [1977]. On the other hand, some models like the Saint Venant-Kirchhoff model or models involving the logarithmic strain tensor do not satisfy the polyconvexity condition, e.g., Raoult [1986].

Some algebraic tools ease the construction of a variety of polyconvex strain energy functions. For example, polyconvexity is preserved under summation and multiplication by positive real numbers: therefore, a large variety of polyconvex strain energy functions may be assembled from a limited set of functions of the invariants of the right Cauchy-Green tensor and of the structural tensors describing the material anisotropy which are initially known/proved to be polyconvex. Notice that, in addition to polyconvexity, these functions must also be coercive and satisfy the condition of stress free reference configuration.

For isotropic materials, I_1^k, I_2^k, I_3^{-1} and $-\operatorname{Ln} I_3$, for any real $k \geq 1$, involving the invariants $I_1 = \operatorname{tr}\mathbf{C}$, $I_2 = \operatorname{tr}(\operatorname{adj}\mathbf{C})$ and $I_3 = \det\mathbf{C}$ are examples of polyconvex functions, Kambouchev et al. [2006]. Schröder and

[6.3] A function is said to be *coercive* if it grows rapidly at the boundary of the domain over which it is defined. For a vector-valued function of a vector, the condition takes the form $\lim_{|\underline{\mathbf{x}}|\to\infty} \mathbf{f}(\underline{\mathbf{x}})\cdot\underline{\mathbf{x}}/|\underline{\mathbf{x}}| \to \infty$. Coerciveness is sometimes (in particular for bilinear forms) viewed as synonymous of the strong ellipticity condition defined in the footnote on page 177.

Neff [2003] constructed polyconvex anisotropic strain energy functions, particularly for transverse isotropic materials with structural tensor $\mathbf{M} = \mathbf{m} \otimes \mathbf{m}$, $\mathbf{m}$ being a unit vector in the preferred direction. They give a large list of polyconvex terms involving the mixed invariants $I_4 = \mathbf{C} : \mathbf{M}$ and $I_5 = \mathbf{C}^2 : \mathbf{M}$ such as I_4^k, $(I_5 - I_1\, I_4 + I_2)^{\,k}$, $(I_1 - I_4)^k$ and $(I_1\, I_4 - I_5)^k$, for any real $k \geq 1$. On the other hand, the invariants I_5 and $I_1\, I_4$ often used to build transversely isotropic strain energy functions are not polyconvex terms. In Hartmann and Neff [2003], a strain energy function for nearly incompressible solids based on polyconvexity and coerciveness is proposed. A set of orthotropic and transversely isotropic strain energy functions satisfying polyconvexity is also proposed by Itskov and Aksel [2004] including the case of incompressible materials.

6.3 Total potential energy

The total potential energy is equal to the sum of the elastic energy plus the energy contributed by the conservative external forces. It is an ubiquitous entity in continuum mechanics, for instance to obtain the energy release rate in fracture mechanics. It may be expressed in terms of the strain energy function in at least two forms,

$$\begin{aligned} & \int_{\underline{V}} \underline{\mathcal{W}}(\mathbf{F})\; d\underline{V} - \int_{\underline{V}} \mathbf{x} \cdot \underline{\rho}\, \mathbf{b}\; d\underline{V} - \int_{\partial \underline{V}_T} \mathbf{x} \cdot \underline{\boldsymbol{\tau}} \cdot \underline{\mathbf{n}}\; d\underline{S} \\ = \; & \int_{\underline{V}} \underline{\mathcal{W}}(\mathbf{F})\; d\underline{V} - \int_{\underline{V}} \mathbf{F} : \underline{\boldsymbol{\tau}}\; d\underline{V} + \int_{\partial \underline{V}_x} \mathbf{x} \cdot \underline{\boldsymbol{\tau}} \cdot \underline{\mathbf{n}}\; d\underline{S}\,. \end{aligned} \tag{6.3.1}$$

Here $\underline{\rho} = \rho \det\mathbf{F}$, $\mathbf{b}$ is the body force, $\underline{\boldsymbol{\tau}}$ the 1st Piola-Kirchhoff stress, and $\partial \underline{V}_T$ and $\partial \underline{V}_x$ denote the parts of the boundary which are subjected to traction and displacement respectively.

Indeed the incremental work done by the boundary traction on the boundary expresses as,

$$\int_{\partial \underline{V}} \mathbf{x} \cdot \underline{\boldsymbol{\tau}} \cdot d\underline{\mathbf{A}} = \int_{\partial \underline{V}} \mathbf{x} \cdot \underline{\boldsymbol{\tau}} \cdot \underline{\mathbf{n}}\; d\underline{S} = \int_{\partial V} \mathbf{x} \cdot \boldsymbol{\sigma} \cdot d\mathbf{A}\,. \tag{6.3.2}$$

By the divergence theorem

$$\int_{\underline{V}} \frac{\partial f}{\partial \underline{x}_i}\; d\underline{V} = \int_{\partial \underline{V}} f\, \underline{n}_i\; d\underline{S}\,, \tag{6.3.3}$$

the work of body forces and boundary traction under quasi-static conditions transforms as follows:

$$\begin{aligned} \int_{\underline{V}} \mathbf{x} \cdot \underline{\rho}\, \mathbf{b}\; d\underline{V} + \int_{\partial \underline{V}} \mathbf{x} \cdot \underline{\boldsymbol{\tau}} \cdot \underline{\mathbf{n}}\; d\underline{S} &= \int_{\underline{V}} x_j \underline{\rho}\, b_j + \frac{\partial}{\partial \underline{x}_i}(x_j \underline{\tau}_{ji})\; d\underline{V} \\ &= \int_{\underline{V}} \frac{\partial x_j}{\partial \underline{x}_i} \underline{\tau}_{ji} + x_j \underbrace{\Big(\frac{\partial \underline{\tau}_{ji}}{\partial \underline{x}_i} + \underline{\rho}\, b_j \Big)}_{=0}\; d\underline{V} \\ &= \int_{\underline{V}} \frac{\partial x_j}{\partial \underline{x}_i}\, \underline{\tau}_{ji}\; d\underline{V} \\ &= \int_{\underline{V}} \mathbf{F} : \underline{\boldsymbol{\tau}}\; d\underline{V}\,. \end{aligned} \tag{6.3.4}$$

6.4 Isotropic hyperelasticity

While the solid part of biological tissues remains to be defined, preliminary efforts have been made that concentrate on single phase elastic materials. Typically, the 2nd Piola-Kirchhoff stress $\underline{\underline{\boldsymbol{\tau}}}$ is expressed in terms of the strain energy $\underline{\mathcal{W}}(\mathbf{C}) = \underline{\hat{\mathcal{W}}}(\mathbf{E}_{\mathrm{G}})$ which depends on the right Cauchy-Green tensor $\mathbf{C} = \mathbf{F}^{\mathrm{T}} \cdot \mathbf{F}$, or on the Green strain $\mathbf{E}_{\mathrm{G}} = \frac{1}{2}\,(\mathbf{C} - \mathbf{I})$,

$$\underline{\underline{\boldsymbol{\tau}}} = 2\, \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}} = \frac{\partial \underline{\hat{\mathcal{W}}}}{\partial \mathbf{E}_{\mathrm{G}}}\,. \tag{6.4.1}$$

Let

$$I_1 = \operatorname{tr} \mathbf{C}\,, \quad I_2 = \tfrac{1}{2}\,(\operatorname{tr} \mathbf{C})^2 - \tfrac{1}{2} \operatorname{tr} \mathbf{C}^2\,, \quad I_3 = \det \mathbf{C}\,, \tag{6.4.2}$$

be the isotropic scalar invariants of the right and left Cauchy-Green tensors $\mathbf{C} = \mathbf{F}^{\mathrm{T}} \cdot \mathbf{F}$ and $\mathbf{B} = \mathbf{F} \cdot \mathbf{F}^{\mathrm{T}}$, with derivatives,

$$\frac{\partial I_1}{\partial \mathbf{C}} = \mathbf{I}\,, \quad \frac{\partial I_2}{\partial \mathbf{C}} = I_1\,\mathbf{I} - \mathbf{C}\,, \quad \frac{\partial I_3}{\partial \mathbf{C}} = I_3\,\mathbf{C}^{-1}\,, \tag{6.4.3}$$

the third relation being established by (2.7.3).

For a compressible material defined by the general isotropic strain energy $\underline{\mathcal{W}} = \underline{\mathcal{W}}(I_1, I_2, I_3)$, the 2nd Piola-Kirchhoff stress is expressed in the form,

$$\begin{aligned} \underline{\underline{\boldsymbol{\tau}}} &= 2\,\frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}} \\ &= 2\,\underline{\mathcal{W}}_1\,\mathbf{I} + 2\,\underline{\mathcal{W}}_2\,(I_1\,\mathbf{I} - \mathbf{C}) + 2\,\underline{\mathcal{W}}_3\,I_3\,\mathbf{C}^{-1} \\ &= 2\,(\underline{\mathcal{W}}_1 + \underline{\mathcal{W}}_2\,I_1)\,\mathbf{I} - 2\,\underline{\mathcal{W}}_2\,\mathbf{C} + 2\,\underline{\mathcal{W}}_3\,I_3\,\mathbf{C}^{-1}\,, \end{aligned} \tag{6.4.4}$$

where $\underline{\mathcal{W}}_i = \partial \underline{\mathcal{W}}/\partial I_i$, $i \in [1,3]$, while the Kirchhoff stress $\boldsymbol{\tau} = \det \mathbf{F}\,\boldsymbol{\sigma}$ becomes,

$$\begin{aligned} \boldsymbol{\tau} &= 2\,\mathbf{F} \cdot \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}} \cdot \mathbf{F}^{\mathrm{T}} \\ &= 2\,\underline{\mathcal{W}}_1\,\mathbf{B} + 2\,\underline{\mathcal{W}}_2\,(I_1\,\mathbf{B} - \mathbf{B}^2) + 2\,\underline{\mathcal{W}}_3\,I_3\,\mathbf{I} \\ &= 2\,(\underline{\mathcal{W}}_2\,I_2 + \underline{\mathcal{W}}_3\,I_3)\,\mathbf{I} + 2\,\underline{\mathcal{W}}_1\,\mathbf{B} - 2\,\underline{\mathcal{W}}_2\,I_3\,\mathbf{B}^{-1}\,. \end{aligned} \tag{6.4.5}$$

Again use of the Cayley-Hamilton theorem exposed in Section 2.3.1, namely $\mathbf{C}^3 - I_1\,\mathbf{C}^2 + I_2\,\mathbf{C} - I_3\,\mathbf{I} = \mathbf{0}$, has been made to reach the third line.

Incompressibility, namely $I_3 = 1$, gives rise to a reaction pressure p, Section 2.10. The so-called neo-Hookean solids and Mooney-Rivlin solids are popular special cases,

neo-Hookean solid	Mooney-Rivlin solid
$\underline{\mathcal{W}} = b_1\,(I_1 - 3)$	$\underline{\mathcal{W}} = b_1\,(I_1 - 3) + b_2\,(I_2 - 3)$
$\underline{\underline{\boldsymbol{\tau}}} = -p\,\mathbf{C}^{-1} + 2\,b_1\,\mathbf{I}$	$\underline{\underline{\boldsymbol{\tau}}} = -p\,\mathbf{C}^{-1} + 2\,b_1\,\mathbf{I} + 2\,b_2\,(I_1\,\mathbf{I} - \mathbf{C})$
$\boldsymbol{\sigma} = -p\,\mathbf{I} + 2\,b_1\,\mathbf{B}$	$\boldsymbol{\sigma} = -p\,\mathbf{I} + 2\,b_1\,\mathbf{B} + 2\,b_2\,(\underbrace{I_1\,\mathbf{B} - \mathbf{B}^2}_{=I_2\,\mathbf{I} - I_3\,\mathbf{B}^{-1}})$

(6.4.6)

While the neo-Hookean solid is a rather acceptable model of the mechanical response of rubberlike materials, the Mooney-Rivlin solid is the most general model that relates linearly the shear strain and the shear stress. The compressible version of the neo-Hookean solid is usually expressed in the format,

$$\underline{\mathcal{W}} = \frac{\mu}{2}\left(I_1 - 3 + \frac{1}{\gamma}\left((I_3)^{-\gamma} - 1\right)\right), \quad \underline{\underline{\boldsymbol{\tau}}} = -\mu\,(I_3)^{-\gamma}\,\mathbf{C}^{-1} + \mu\,\mathbf{I}\,, \tag{6.4.7}$$

with the material constants $\mu > 0$ and $\gamma = \nu/(1 - 2\,\nu)$, where ν can be seen as a Poisson's ratio in the infinitesimal strain limit. Since $\nu = \gamma/(1 + 2\,\gamma)$, slight compressibility is introduced by a Poisson's ratio ν close to 0.5 or a large exponent γ.

The compressible Blatz-Ko solid includes the three isotropic invariants,

$$\underline{\mathcal{W}} = \frac{\mu\,f}{2}\left(I_1 - 3 + \frac{1}{\gamma}\left((I_3)^{-\gamma} - 1\right)\right) + \frac{\mu\,(1-f)}{2}\left(\frac{I_2}{I_3} - 3 + \frac{1}{\gamma}\left((I_3)^{\gamma} - 1\right)\right), \tag{6.4.8}$$

and involves the three material constants $\mu > 0$, $f \in]0,1]$ and $\gamma = \nu/(1 - 2\nu)$. For $\nu = 1/2$, the solid becomes incompressible $I_3 = 1$ and it reduces to the Mooney-Rivlin solid. The stresses are defined by (6.4.4) and (6.4.5) with

$$\frac{\partial \underline{\mathcal{W}}}{\partial I_1} = \frac{\mu\,f}{2}\,, \quad \frac{\partial \underline{\mathcal{W}}}{\partial I_2} = \frac{\mu\,(1-f)}{2}\,\frac{1}{I_3}, \quad \frac{\partial \underline{\mathcal{W}}}{\partial I_3} = -\frac{\mu\,f}{2}\,(I_3)^{-\gamma-1} + \frac{\mu\,(1-f)}{2}\,(I_3)^{\gamma-1}\,. \tag{6.4.9}$$

Some hyperelastic models satisfy the so-called Valanis-Landel separation hypothesis, according to which the strain energy function can be expressed as an additive symmetric function (due to isotropy) of the principal stretches λ_1, λ_2 and λ_3, actually the positive square-roots of the right or left Cauchy-Green tensors,

$$\underline{\mathcal{W}}(\lambda_1, \lambda_2, \lambda_3) = \underline{w}(\lambda_1) + \underline{w}(\lambda_2) + \underline{w}(\lambda_3)\,. \tag{6.4.10}$$

The experimental validity of this hypothesis has been verified in restricted ranges of stretch on vulcanized rubbers, see Ogden [1982] for an account. Ogden's strain energy function for an incompressible material, Ogden [1972]a, adopts this additive decomposition,

$$\underline{\mathcal{W}}(\lambda_1, \lambda_2, \lambda_3) = \sum_n \frac{\mu_n}{\alpha_n} \left(\lambda_1^{2\alpha_n} + \lambda_2^{2\alpha_n} + \lambda_3^{2\alpha_n} - 3\right), \tag{6.4.11}$$

where the μ_n's and the exponents α_n may be positive or negative real material constants. Ogden's strain energy contains the neo-Hookean energy for $n = 1$, $\alpha_1 = 1$, and the Mooney-Rivlin energy for $n = 2$, $\alpha_1 = 1$ and $\alpha_2 = -1$. Indeed, recall the relations between the invariants I_1 and I_2 of the Cauchy-Green tensors and the principal stretches: $I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2$, $I_2 = (\lambda_1\,\lambda_2\,\lambda_3)^2\,(1/\lambda_1^2 + 1/\lambda_2^2 + 1/\lambda_3^2)$. The format was extended to compressible materials in Ogden [1972]b through addition of a function of the volume change,

$$\underline{\mathcal{W}}(\lambda_1, \lambda_2, \lambda_3) = \sum_n \frac{\mu_n}{\alpha_n} \left(\lambda_1^{2\alpha_n} + \lambda_2^{2\alpha_n} + \lambda_3^{2\alpha_n} - 3\right) + \underline{\mathcal{W}}_v(\lambda_1\,\lambda_2\,\lambda_3)\,, \tag{6.4.12}$$

with $\underline{\mathcal{W}}_v(x)$ a convex function having a minimum at $x = 1$ and satisfying the asymptotic conditions (6.1.3). For $n = 1$ and $\alpha_1 = 1$, this model is also referred to as Hadamard's solid.

Prange and Margulies [2002] introduce the time dependence of the white and gray brain matter in the μ_n via two characteristic times much like in Section 8.3.6.

Another standard example of isotropic nonlinear hyperelastic equations is due to Murnaghan [1951]. The strain energy,

$$\underline{\hat{\mathcal{W}}}(\mathbf{E}_{\mathrm{G}}) = \frac{1}{2}\left(\lambda + 2\,\mu\right) I_1^2 - 2\,\mu\, I_2 + \frac{1}{3}\left(l + 2\,m\right) I_1^3 - 2\,m\, I_1\, I_2 + n\, I_3\,, \tag{6.4.13}$$

expresses in terms of the invariants of the Green strain,

$$I_1 = \operatorname{tr}\mathbf{E}_{\mathrm{G}}\,, \quad I_2 = \tfrac{1}{2}\left(\operatorname{tr}\mathbf{E}_{\mathrm{G}}\right)^2 - \tfrac{1}{2}\operatorname{tr}\mathbf{E}_{\mathrm{G}}^2\,, \quad I_3 = \det\mathbf{E}_{\mathrm{G}} = \frac{1}{3}\operatorname{tr}\,\mathbf{E}_{\mathrm{G}}^3 - \frac{1}{2}\operatorname{tr}\,\mathbf{E}_{\mathrm{G}}\operatorname{tr}\,\mathbf{E}_{\mathrm{G}}^2 + \frac{1}{6}\left(\operatorname{tr}\,\mathbf{E}_{\mathrm{G}}\right)^3, \tag{6.4.14}$$

and of the material constants λ, μ, l, m and n. The last relation in (6.4.14) uses $(2.2.33)_6$. The derivatives,

$$\frac{\partial I_1}{\partial \mathbf{E}_{\mathrm{G}}} = \mathbf{I}\,, \quad \frac{\partial I_2}{\partial \mathbf{E}_{\mathrm{G}}} = I_1\,\mathbf{I} - \mathbf{E}_{\mathrm{G}}\,, \quad \frac{\partial I_3}{\partial \mathbf{E}_{\mathrm{G}}} = I_2\,\mathbf{I} - I_1\,\mathbf{E}_{\mathrm{G}} + \mathbf{E}_{\mathrm{G}}^2\,, \tag{6.4.15}$$

provide the 2nd Piola-Kirchhoff stress,

$$\underline{\underline{\boldsymbol{\tau}}} = \frac{\partial \underline{\hat{\mathcal{W}}}}{\partial \mathbf{E}_{\mathrm{G}}} = \left(\lambda\, I_1 + (n - 2\,m)\, I_2 + l\, I_1^2\right)\mathbf{I} + \left(2\,\mu - (n - 2\,m)\, I_1\right)\mathbf{E}_{\mathrm{G}} + n\,\mathbf{E}_{\mathrm{G}}^2\,. \tag{6.4.16}$$

In fact, for $n - 2\,m = 0$, the factor of n in the strain energy simplifies to $\frac{1}{3}\operatorname{tr}\mathbf{E}_{\mathrm{G}}^3$.

6.5 Anisotropic hyperelasticity and Fung's strain energy

Debes and Fung [1995] report a linear elastic behavior of the pulmonary artery in the physiological range from zero to the homeostatic stress. At variance, Zhou and Fung [1997] quantify nonlinear effects in blood vessel elasticity and they observe a significant degree of nonlinearity in the canine aorta. In both the linear and nonlinear ranges, the mechanical response displayed anisotropy.

6.5.1 Exponential strain energy

Fung's strain energy adopts the form,

$$\underline{\mathcal{W}}(\mathbf{C}) = \underline{\hat{\mathcal{W}}}(\mathbf{E}_{\rm G}) = b\,{\rm e}^{Q(\mathbf{E}_{\rm G})}, \tag{6.5.1}$$

with $Q(\mathbf{E}_{\rm G})$ a quadratic function of the components of the strain tensor in the orthotropy axes,

$$Q(\mathbf{E}_{\rm G}) = b_1\,E_{11}^2 + b_2\,E_{22}^2 + b_3\,E_{33}^2 + 2\,b_4\,E_{11}E_{22} + 2\,b_5\,E_{11}E_{33} + 2\,b_6\,E_{22}E_{33}\,, \tag{6.5.2}$$

the b's being material constants. Humphrey [1995] has introduced a more complete type of anisotropy, with three additional material constants, than in (6.5.2),

$$Q(\mathbf{E}_{\rm G}) \to Q(\mathbf{E}_{\rm G})_{\rm Fung} + 4\,b_7\,E_{23}^2 + 4\,b_8\,E_{13}^2 + 4\,b_9\,E_{12}^2\,. \tag{6.5.3}$$

In view of generalization, Fung's strain energy (6.5.3) is cast in the form $\hat{\gamma}(Q) = b\,\exp(Q)$, $b > 0$. The matrix form in the orthotropic axes of (6.5.3) reads in isometric notation,

$$Q(\mathbf{E}_{\rm G}) = \begin{bmatrix} E_{11} \\ E_{22} \\ E_{33} \\ \sqrt{2}\,E_{23} \\ \sqrt{2}\,E_{13} \\ \sqrt{2}\,E_{12} \end{bmatrix}^{\rm T} \begin{bmatrix} b_1 & b_4 & b_5 & 0 & 0 & 0 \\ b_4 & b_2 & b_6 & 0 & 0 & 0 \\ b_5 & b_6 & b_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\,b_7 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\,b_8 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\,b_9 \end{bmatrix} \begin{bmatrix} E_{11} \\ E_{22} \\ E_{33} \\ \sqrt{2}\,E_{23} \\ \sqrt{2}\,E_{13} \\ \sqrt{2}\,E_{12} \end{bmatrix}. \tag{6.5.4}$$

An extension of the quadratic form of Fung,

$$\underline{\hat{\mathcal{W}}}(\mathbf{E}_{\rm G}) = \hat{\gamma}(Q(\mathbf{E}_{\rm G})), \quad Q(\mathbf{E}_{\rm G}) = \mathbf{E}_{\rm G} : \mathcal{A} : \mathbf{E}_{\rm G}\,, \tag{6.5.5}$$

involves the constant fourth order tensor $\mathcal{A}$ endowed with minor and major symmetries (21 independent material constants), and assumes

$$\hat{\gamma}' \equiv \frac{\partial\hat{\gamma}}{\partial Q} > 0, \quad \hat{\gamma}'' \equiv \frac{\partial^2\hat{\gamma}}{\partial Q\partial Q} > 0\,. \tag{6.5.6}$$

Actually, while the modification below might appear as a formal issue, it turns highly advantageous to formulate the constitutive equation in the form,

$$\underline{\mathcal{W}}(\mathbf{C}) = \gamma(Q(\mathbf{C})), \quad Q(\mathbf{C}) = \mathbf{C} : \mathcal{A} : \mathbf{C}\,. \tag{6.5.7}$$

The motivation stems from the analysis of the strong ellipticity condition by Wilber and Walton [2002] which is exposed in Section 6.5.3. Note that, when developed in terms of the right Cauchy-Green tensor, Q as defined by (6.5.5) is not quadratic as it contains a linear term.

6.5.2 Locking versus softening materials: exponentials and energy limiters

Assuming

$$\lim_{\mathbf{E}_{\rm G}\to\infty} Q(\mathbf{E}_{\rm G}) \to \infty, \tag{6.5.8}$$

the idea in the exponential form,

$$\underline{\hat{\mathcal{W}}}(\mathbf{E}_{\rm G}) \simeq \exp\,Q(\mathbf{E}_{\rm G}) - 1, \tag{6.5.9}$$

is to represent the stiffening of the material as deformation proceeds, that is *locking*. Stress and stiffness have the form,

$$\frac{\partial\underline{\hat{\mathcal{W}}}}{\partial\mathbf{E}_{\rm G}} = \exp\big(Q(\mathbf{E}_{\rm G})\big)\,\frac{\partial Q}{\partial\mathbf{E}_{\rm G}}, \quad \frac{\partial^2\underline{\hat{\mathcal{W}}}}{\partial\mathbf{E}_{\rm G}^2} = \exp\big(Q(\mathbf{E}_{\rm G})\big)\,\Big(\frac{\partial^2 Q}{\partial\mathbf{E}_{\rm G}^2} + \frac{\partial Q}{\partial\mathbf{E}_{\rm G}}\otimes\frac{\partial Q}{\partial\mathbf{E}_{\rm G}}\Big)\,. \tag{6.5.10}$$

Conversely, an *energy limiter* can be introduced via the form, Volokh [2007] [2008],

$$\underline{\hat{\mathcal{W}}}(\mathbf{E}_{\rm G}) \simeq 1 - \exp\big(-Q(\mathbf{E}_{\rm G})\big). \tag{6.5.11}$$

Stress and stiffness become now,

$$\frac{\partial\underline{\hat{\mathcal{W}}}}{\partial\mathbf{E}_{\rm G}} = \exp\big(-Q(\mathbf{E}_{\rm G})\big)\,\frac{\partial Q}{\partial\mathbf{E}_{\rm G}}, \quad \frac{\partial^2\underline{\hat{\mathcal{W}}}}{\partial\mathbf{E}_{\rm G}^2} = \exp\big(-Q(\mathbf{E}_{\rm G})\big)\,\Big(\frac{\partial^2 Q}{\partial\mathbf{E}_{\rm G}^2} - \frac{\partial Q}{\partial\mathbf{E}_{\rm G}}\otimes\frac{\partial Q}{\partial\mathbf{E}_{\rm G}}\Big)\,. \tag{6.5.12}$$

Fig. 6.5.1 features the differences between the expressions (6.5.9) and (6.5.11) in a one-dimensional context.

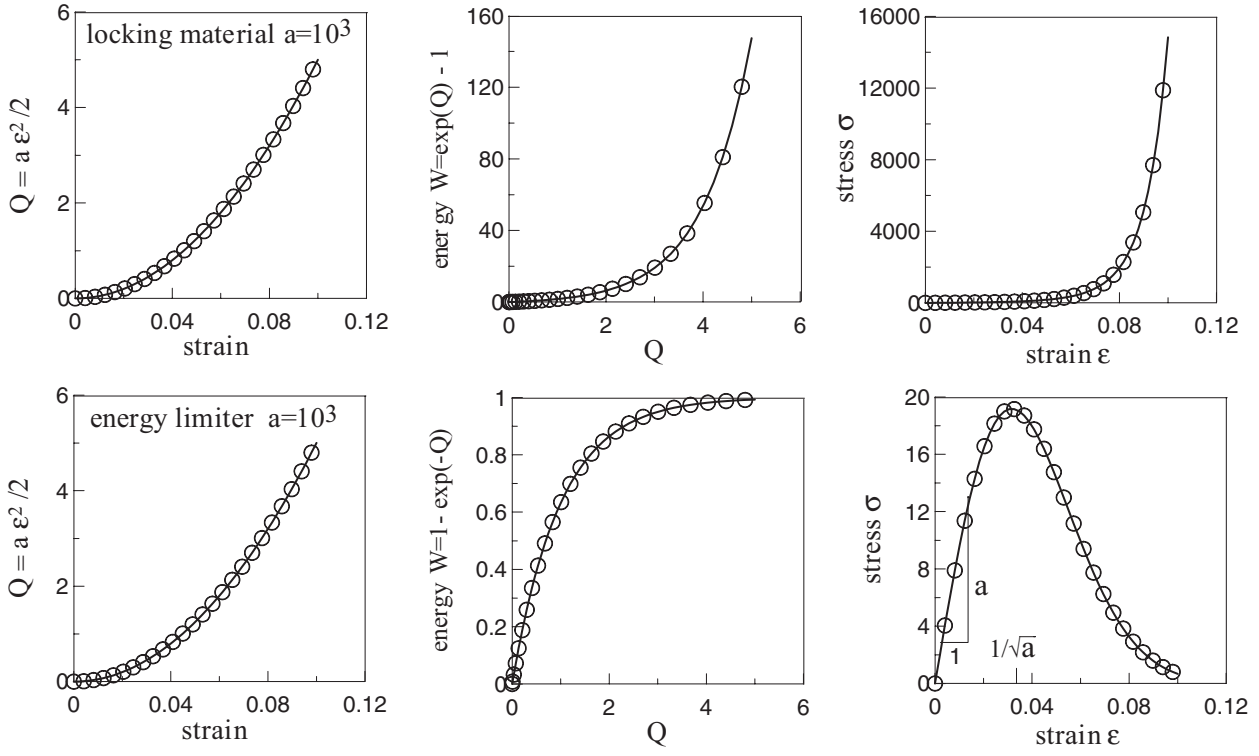

Fig. 6.5.1: Locking and softening materials (in a small strain context). Consider a uniaxial strain, and take $Q(\epsilon) = a\,\epsilon^2/2$ with $a > 0$. The stress reaches a maximum at $\epsilon = 1/\sqrt{a}$ for the softening material associated with a limited energy.

6.5.3 Strong Ellipticity of Fung's like strain energies (SE)

Let us consider a compressible material for which the constitutive equation provides equivalently the 1st Piola-Kirchhoff stress $\underline{\boldsymbol{\tau}} = \mathbf{F} \cdot \underline{\underline{\boldsymbol{\tau}}}$ or the 2nd Piola-Kirchhoff stress $\underline{\underline{\boldsymbol{\tau}}}$ in terms of the deformation gradient $\mathbf{F}$ via a strain energy $\underline{\mathcal{W}}(\mathbf{C})$,

$$\underline{\boldsymbol{\tau}} = 2\,\mathbf{F} \cdot \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}}, \quad \underline{\underline{\boldsymbol{\tau}}} = 2\,\frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}}\,. \tag{6.5.13}$$

A small dyadic change of the deformation gradient $\mathbf{F}_0 \to \mathbf{F} = \mathbf{F}_0 + \delta\lambda\,\mathbf{H}$, with $\mathbf{H} = \mathbf{m} \otimes \mathbf{n}$, $\mathbf{m}$ and $\mathbf{n}$ being two unit vectors, induces a change of the 1st Piola-Kirchhoff stress which is equal to,

$$\delta\underline{\boldsymbol{\tau}} = \delta\lambda\,\frac{\partial \underline{\boldsymbol{\tau}}}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H}\,. \tag{6.5.14}$$

Strong ellipticity of the balance of momentum at the deformation gradient $\mathbf{F}_0$,

$$\mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H} > 0, \quad \forall\ \mathbf{H} = \mathbf{m} \otimes \mathbf{n}, \quad |\mathbf{m}| = 1,\ |\mathbf{n}| = 1\,, \tag{6.5.15}$$

consists in restricting the component of the change of the stress along the direction of change of the deformation gradient to a strictly positive value.

For an incompressible material $\det \mathbf{F} = 1$, the constitutive equation decomposes into a part that involves the pressure p and that does no work if the kinematical constraint is satisfied, namely $\delta \det \mathbf{F} = \det \mathbf{F}\, \mathrm{tr}\, \delta\mathbf{F} \cdot \mathbf{F}^{-1} = \det \mathbf{F}\, \mathbf{F}^{-\mathrm{T}} : \delta\mathbf{F}$, and in a reaction part, often referred to as effective stress,

$$\underline{\boldsymbol{\tau}}' = \underline{\boldsymbol{\tau}} + p\,\mathbf{F}^{-\mathrm{T}} = 2\,\mathbf{F} \cdot \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}}, \quad \underline{\underline{\boldsymbol{\tau}}}' = \underline{\underline{\boldsymbol{\tau}}} + p\,\mathbf{C}^{-1} = 2\,\frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}}\,. \tag{6.5.16}$$

Then, depending whether the inequality is strict or not, the following terminology along Antman [1995] is adopted,

$$\mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H} = \mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}'}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H} \begin{cases} > 0, & \text{strong ellipticity (SE)} \\ \geq 0, & \text{Legendre} - \text{Hadamard condition (LH)} \end{cases} \tag{6.5.17}$$

for any $\mathbf{H} = \mathbf{m} \otimes \mathbf{n} \neq \mathbf{0}$ such that $\mathbf{F}_0^{-\mathrm{T}} : \mathbf{H} = 0$.

The last restriction in (6.5.17) ensures that the change of the deformation gradient respects (in the small) the incompressibility condition. It also makes it possible for the strong ellipticity condition to apply for both the effective stress $\underline{\boldsymbol{\tau}}' = \underline{\boldsymbol{\tau}} + p\,\mathbf{F}^{-\mathrm{T}}$ and the total stress $\underline{\boldsymbol{\tau}}$. Indeed,

$$\begin{aligned}
&\mathbf{H} : \underline{\boldsymbol{\tau}}(\mathbf{F}) \\
= \;& \mathbf{H} : \big(\underline{\boldsymbol{\tau}}'(\mathbf{F}) - p\,\mathbf{F}^{-\mathrm{T}}\big) \\
= \;& \mathbf{H} : \Big(\underline{\boldsymbol{\tau}}'(\mathbf{F}_0) + \delta\lambda\,\frac{\partial \underline{\boldsymbol{\tau}}'}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H} - p\,\big(\mathbf{F}_0^{-\mathrm{T}} - \delta\lambda\,(\mathbf{F}_0^{-\mathrm{T}}\cdot\mathbf{n})\otimes(\mathbf{F}_0^{-1}\cdot\mathbf{m})\big)\Big) + O((\delta\lambda)^2) \\
= \;& \mathbf{H} : \Big(\underline{\boldsymbol{\tau}}'(\mathbf{F}_0) - p\,\mathbf{F}_0^{-\mathrm{T}}\Big) + \delta\lambda\,\mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}'}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H} + \delta\lambda\; p\,(\underbrace{\mathbf{F}_0^{-\mathrm{T}}\cdot\mathbf{H}}_{=0})^2 + O((\delta\lambda)^2) \\
= \;& \mathbf{H} : \underline{\boldsymbol{\tau}}(\mathbf{F}_0) + \delta\lambda\;\mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}'}{\partial \mathbf{F}}(\mathbf{F}_0) : \mathbf{H} + O((\delta\lambda)^2)\,.
\end{aligned} \tag{6.5.18}$$

Note that

$$\mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}'}{\partial \mathbf{F}} : \mathbf{H} = \mathbf{H} : \frac{\partial}{\partial \mathbf{F}}\Big(2\,\mathbf{F}\cdot\frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}}\Big) : \mathbf{H} = 2\,(\mathbf{H}^{\mathrm{T}}\cdot\mathbf{H}) : \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}} + 4\,(\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H}) : \frac{\partial^2 \underline{\mathcal{W}}}{\partial \mathbf{C}^2} : (\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H})\,. \tag{6.5.19}$$

Indeed, using the fact that $\partial/\partial\mathbf{F} = 2\,\mathbf{F}\cdot\partial/\partial\mathbf{C}$,

$$\begin{aligned}
\frac{\partial}{\partial F_{ij}}\Big(2\,F_{kl}\frac{\partial \underline{\mathcal{W}}}{\partial C_{lm}}\Big) &= 2\,\frac{\partial F_{kl}}{\partial F_{ij}}\,\frac{\partial \underline{\mathcal{W}}}{\partial C_{lm}} + 2\,F_{kl}\,\frac{\partial}{\partial F_{ij}}\frac{\partial \underline{\mathcal{W}}}{\partial C_{lm}} \\
&= 2\,I_{ik}\,\frac{\partial \underline{\mathcal{W}}}{\partial C_{jm}} + 4\,F_{ip}\,\frac{\partial}{\partial C_{pj}}\big(\frac{\partial \underline{\mathcal{W}}}{\partial C_{lm}}\big)\,F_{kl}\,.
\end{aligned} \tag{6.5.20}$$

For the Fung's like model (6.5.5),

$$2\,\frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}} = \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{E}_{\mathrm{G}}} = 2\,\hat{\gamma}'\,\mathcal{A} : \mathbf{E}_{\mathrm{G}}, \quad 4\,\frac{\partial^2 \underline{\mathcal{W}}}{\partial \mathbf{C}^2} = 2\,\hat{\gamma}'\,\mathcal{A} + 4\,\hat{\gamma}''\,(\mathcal{A} : \mathbf{E}_{\mathrm{G}})\otimes(\mathcal{A} : \mathbf{E}_{\mathrm{G}})\,, \tag{6.5.21}$$

and

$$\begin{aligned}
\mathbf{H} : \frac{\partial \underline{\boldsymbol{\tau}}'}{\partial \mathbf{F}} : \mathbf{H} &= 2\,\hat{\gamma}'\,(\mathbf{H}^{\mathrm{T}}\cdot\mathbf{H}) : (\mathcal{A} : \mathbf{E}_{\mathrm{G}}) \\
&+ 4\,\hat{\gamma}''\,\Big((\mathcal{A} : \mathbf{E}_{\mathrm{G}}) : (\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H})\Big)^2 + 2\,\hat{\gamma}'\,(\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H}) : \mathcal{A} : (\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H})\,.
\end{aligned} \tag{6.5.22}$$

Wilber and Walton [2002] obtain the following surprising results:
1. Fung's strain energy (6.5.1) satisfies the Legendre-Hadamard condition only if all the coefficients of the upper principal matrix of $\mathcal{A}$ are equal and positive, i.e.,

$$\mathcal{A} = b\,\mathbf{I}\otimes\mathbf{I} \quad \Leftrightarrow \quad b_1 = b_2 = b_3 = b_4 = b_5 = b_6 = b \geq 0\,. \tag{6.5.23}$$

2. Fung's strain energy (6.5.1) satisfies the strong ellipticity condition at $\mathbf{F} \neq \mathbf{I}$ only if all the coefficients are equal and positive. Even then, the condition fails at $\mathbf{F} = \mathbf{I}$, i.e., $\mathbf{E}_{\mathrm{G}} = \mathbf{0}$, as can be checked on (6.5.22). Failure of (SE) at $\mathbf{F} = \mathbf{I}$ is interpreted as follows. Let $\mathbf{H} = \mathbf{e}_1\otimes\mathbf{e}_2$, with $\mathbf{e}_1\cdot\mathbf{e}_2 = 0$, so that the last condition in (6.5.17) associated with incompressibility is satisfied. The condition $\mathbf{H} : \partial\boldsymbol{\tau}/\partial\mathbf{F} : \mathbf{H} < 0$ implies that shear along $\mathbf{H}$ continues at decreasing Kirchhoff stress $\underline{\boldsymbol{\tau}}$;
3. they give necessary, but not sufficient, conditions for the model (6.5.3) to satisfy the Legendre-Hadamard and strong ellipticity conditions, their Eqns (5.8).
4. the restrictions on the coefficients of the strain energy of the form (6.5.7) are far less drastic than for the form (6.5.5). Instead of (6.5.23), the necessary and sufficient conditions for the Legendre-Hadamard condition to hold for the Fung's model (6.5.2) are

$$b_i \geq 0,\; i \in [1,6]; \quad b_1 \geq \tfrac{1}{2}\,(b_4 + b_5); \quad b_2 \geq \tfrac{1}{2}\,(b_4 + b_6); \quad b_3 \geq \tfrac{1}{2}\,(b_5 + b_6)\,. \tag{6.5.24}$$

If, in addition, the diagonal terms b_i, $i \in [1,3]$, are strictly positive, the model is strongly elliptic.

6.5.4 Convexity of Fung's like strain energies

Convexity of a scalar or vector function over $\mathbb{R}^n$ has been defined in Section 6.2.3. The definition and properties are simply restated for functions of a second order tensor. In fact, convexity of the strain energy $\underline{\mathcal{W}} = \underline{\mathcal{W}}(\mathbf{C})$ will be considered over the six-dimensional space of independent components of the right Cauchy-Green tensor. It takes the form

$$\lambda\,\underline{\mathcal{W}}(\mathbf{C}_1) + (1-\lambda)\,\underline{\mathcal{W}}(\mathbf{C}_2) \geq \underline{\mathcal{W}}\big(\lambda\,\mathbf{C}_1 + (1-\lambda)\,\mathbf{C}_2\big), \quad \forall\ \mathbf{C}_1,\ \mathbf{C}_2, \quad \lambda \in [0,1]\,. \tag{6.5.25}$$

If the function $\underline{\mathcal{W}}$ admits a continuous derivative, then it is convex iff the following inequality is satisfied

$$\underline{\mathcal{W}} \quad \text{convex} \quad \Leftrightarrow \quad \underline{\mathcal{W}}(\mathbf{C}_1) - \underline{\mathcal{W}}(\mathbf{C}_2) \geq \frac{\partial \underline{\mathcal{W}}}{\partial \mathbf{C}}(\mathbf{C}_2) : (\mathbf{C}_1 - \mathbf{C}_2), \quad \forall\ \mathbf{C}_1,\ \mathbf{C}_2\,. \tag{6.5.26}$$

If the function $\underline{\mathcal{W}}$ admits a continuous second derivative, then it is convex iff its Hessian matrix is positive (semi-)definite,

$$\underline{\mathcal{W}} \quad \text{convex} \quad \Leftrightarrow \quad \frac{\partial^2 \underline{\mathcal{W}}}{\partial \mathbf{C}^2} \quad \text{positive (semi-)definite}\,. \tag{6.5.27}$$

The analysis of the convexity of the elastic strain energies of the Fung's type, or extended Fung's type, takes advantage of the following property:

Convexity property 3:

If $f : \mathbb{R}^n \to \mathbb{R}$ is convex, and $g : \mathbb{R} \to \mathbb{R}$ is convex and nondecreasing, then $g \circ f : \mathbb{R}^n \to \mathbb{R}$ is convex.

Indeed,

$$\begin{aligned} & (g\circ f)(\mathbf{C}_1) - (g\circ f)(\mathbf{C}_2) \\ = \ & g\big(f(\mathbf{C}_1)\big) - g\big(f(\mathbf{C}_2)\big) \\ \geq \ & \underbrace{\frac{\partial g}{\partial f}\big(f(\mathbf{C}_2)\big)}_{\geq 0}\,\big(f(\mathbf{C}_1) - f(\mathbf{C}_2)\big) \geq \underbrace{\frac{\partial g}{\partial f}\big(f(\mathbf{C}_2)\big)\,\frac{\partial f}{\partial \mathbf{C}}(\mathbf{C}_2)}_{\big(\partial(g\circ f)/\partial \mathbf{C}\big)(\mathbf{C}_2)} : (\mathbf{C}_1 - \mathbf{C}_2) \quad \square\,. \end{aligned} \tag{6.5.28}$$

Here $f(\mathbf{C}) = \mathbf{C} : \mathcal{A} : \mathbf{C}$, and $g(f) = b \exp f$, $b > 0$. Therefore, a sufficient condition of convexity of the Fung's like strain energies is that the tensor $\mathcal{A}$ is definite positive. That $\mathcal{A}$ positive definite implies convexity of Fung's like strain energies can be also realized by considering directly the Hessian (6.5.10).

In contrast to the strong ellipticity condition, the convexity is not affected by the form $\underline{\mathcal{W}}(\mathbf{C}) = \gamma(\mathbf{C} : \mathcal{A} : \mathbf{C})$, or $\underline{\hat{\mathcal{W}}}(\mathbf{E}_{\mathrm{G}}) = \hat{\gamma}(\mathbf{E}_{\mathrm{G}} : \mathcal{A} : \mathbf{E}_{\mathrm{G}})$.

Pioletti and Rakotomanana [2000] show a practical list of isotropic elastic strain energies and the conditions (convexity, etc.) they satisfy.

6.6 Elastic potentials with the elastic-growth multiplicative decomposition

When the deformation gradient is decomposed into an elastic part and a growth part, namely $\mathbf{F} = \mathbf{F}^{\mathrm{e}} \cdot \mathbf{F}^{\mathrm{g}}$, the state variables are relative to the intermediate configuration (κ) implicitly introduced by the multiplicative decomposition. The deformation enters the set of state variables through its elastic part. Incompressibility is now phrased in terms of $\det \mathbf{F}^{\mathrm{e}}$, rather than $\det \mathbf{F}$. For a compressible solid, the stress-strain relation provides the Kirchhoff stress in terms of the elastic Green strain, while, for an incompressible solid, it provides the effective Kirchhoff stress. The stress-strain relation is cast in terms of the elastic potential (or elastic strain energy function) per unit reference volume $\underline{E}_\kappa$ in the form, Section 22.5,

$$\boldsymbol{\tau}' = \det \mathbf{F} \left\{ \begin{array}{ll} \text{elastic compressibility} & \boldsymbol{\sigma} \\ \text{elastic incompressibility} & \boldsymbol{\sigma}' \equiv \boldsymbol{\sigma} + p\,\mathbf{I} \end{array} \right\} = \mathbf{F}^{\mathrm{e}} \cdot \frac{\partial \underline{E}_\kappa}{\partial \mathbf{E}^{\mathrm{e}}_{\mathrm{G}}} \cdot (\mathbf{F}^{\mathrm{e}})^{\mathrm{T}}\,, \tag{6.6.1}$$

with $\mathbf{E}^{\mathrm{e}}_{\mathrm{G}} = \frac{1}{2}((\mathbf{F}^{\mathrm{e}})^{\mathrm{T}} \cdot \mathbf{F}^{\mathrm{e}} - \mathbf{I})$ the elastic Green strain.

When growth takes place with the deposited material having the same properties as the already existing material at the deposition site, or generally for nongrowing materials, then

$$\underline{E}_\kappa = E_\kappa \, \det \mathbf{F}^{\mathrm{g}} \,, \tag{6.6.2}$$

Thus, in this case, the Cauchy stress (6.6.1) recovers a more familiar form, e.g., for elastic compressibility,

$$\boldsymbol{\sigma} = \frac{1}{\det \mathbf{F}^{\mathrm{e}}} \, \mathbf{F}^{\mathrm{e}} \cdot \frac{\partial E_\kappa}{\partial \mathbf{E}^{\mathrm{e}}_{\mathrm{G}}} \cdot (\mathbf{F}^{\mathrm{e}})^{\mathrm{T}} \,. \tag{6.6.3}$$

6.6.1 Isotropic Fung's like potentials

For materials that are isotropic in their intermediate configuration, the elastic potential $\underline{E}_\kappa = \underline{E}_\kappa(I^{\mathrm{e}}_1, I^{\mathrm{e}}_2, I^{\mathrm{e}}_3)$ depends on the strain via the three scalar invariants of the Cauchy-Green tensor with eigenvalues c_i, $i \in [1,3]$,

$$\mathbf{C}^{\mathrm{e}} = (\mathbf{F}^{\mathrm{e}})^{\mathrm{T}} \cdot \mathbf{F}^{\mathrm{e}} = 2\,\mathbf{E}^{\mathrm{e}}_{\mathrm{G}} + \mathbf{I} \,, \tag{6.6.4}$$

namely,

$$\begin{aligned} I^{\mathrm{e}}_1 &= \operatorname{tr} \mathbf{C}^{\mathrm{e}} = c_1 + c_2 + c_3 \\ I^{\mathrm{e}}_2 &= \tfrac{1}{2} \left((\operatorname{tr} \mathbf{C}^{\mathrm{e}})^2 - \operatorname{tr} (\mathbf{C}^{\mathrm{e}})^2 \right) = c_1\, c_2 + c_2\, c_3 + c_3\, c_1 \\ I^{\mathrm{e}}_3 &= \det \, \mathbf{C}^{\mathrm{e}} = c_1\, c_2\, c_3 \end{aligned} \tag{6.6.5}$$

Note that

$$\frac{\partial}{\partial \mathbf{E}^{\mathrm{e}}_{\mathrm{G}}} = 2 \, \frac{\partial}{\partial \mathbf{C}^{\mathrm{e}}} \,. \tag{6.6.6}$$

Moreover, since[6.4]

$$\frac{\partial I^{\mathrm{e}}_1}{\partial \mathbf{C}^{\mathrm{e}}} = \mathbf{I}, \quad \frac{\partial I^{\mathrm{e}}_2}{\partial \mathbf{C}^{\mathrm{e}}} = I^{\mathrm{e}}_1 \, \mathbf{I} - \mathbf{C}^{\mathrm{e}}, \quad \frac{\partial I^{\mathrm{e}}_3}{\partial \mathbf{C}^{\mathrm{e}}} = I^{\mathrm{e}}_3 \, (\mathbf{C}^{\mathrm{e}})^{-1} \,, \tag{6.6.8}$$

then

$$\begin{aligned} \frac{\partial \underline{E}_\kappa}{\partial \mathbf{C}^{\mathrm{e}}} &= \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_1} \mathbf{I} + \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_2} \left(I^{\mathrm{e}}_1 \, \mathbf{I} - \mathbf{C}^{\mathrm{e}} \right) + \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_3} \, I^{\mathrm{e}}_3 \, (\mathbf{C}^{\mathrm{e}})^{-1} \\ &= \Big(\frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_1} + I^{\mathrm{e}}_1 \, \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_2} \Big) \mathbf{I} - \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_2} \mathbf{C}^{\mathrm{e}} + \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_3} \, I^{\mathrm{e}}_3 \, (\mathbf{C}^{\mathrm{e}})^{-1} \,. \end{aligned} \tag{6.6.9}$$

Note that, for a vanishing elastic deformation, i.e., $\mathbf{F}^{\mathrm{e}} = \mathbf{I}$,

$$\frac{\partial \underline{E}_\kappa}{\partial \mathbf{C}^{\mathrm{e}}} = \Big(\frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_1} + 2 \, \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_2} + \frac{\partial \underline{E}_\kappa}{\partial I^{\mathrm{e}}_3} \Big) \, \mathbf{I} \,. \tag{6.6.10}$$

Thus the scalar coefficient in this expression should vanish if the stress is to be zero in the unstrained state. For a counterexample, see (6.6.17) below.

Fung's potential originally addresses elastic materials. Applied to elastic-growing incompressible vascular tissues, it takes the form,

$$\underline{E}_\kappa = \frac{a_0}{2} \left(\exp(Q) - Q - 1 \right) + \frac{q}{2} \,, \tag{6.6.11}$$

where, the a's and b's being material constants,

$$\begin{aligned} Q &= a_1 \, (I^{\mathrm{e}}_1 - 3) + a_2 \, (I^{\mathrm{e}}_2 - 3) + a_3 \, (I^{\mathrm{e}}_1 - 3)^2, \\ q &= b_1 \, (I^{\mathrm{e}}_1 - 3) + b_2 \, (I^{\mathrm{e}}_2 - 3) + b_3 \, (I^{\mathrm{e}}_1 - 3)^2 \,. \end{aligned} \tag{6.6.12}$$

[6.4] The last relation uses (2.7.3),

$$\frac{\partial \det \mathbf{F}^{\mathrm{e}}}{\partial \mathbf{F}^{\mathrm{e}}} = \det \mathbf{F}^{\mathrm{e}} \, (\mathbf{F}^{\mathrm{e}})^{-\mathrm{T}} \,, \quad \frac{\partial \det \mathbf{F}^{\mathrm{e}}}{\partial \mathbf{E}^{\mathrm{e}}_{\mathrm{G}}} = \det \mathbf{F}^{\mathrm{e}} \, (\mathbf{F}^{\mathrm{e}})^{-1} \cdot (\mathbf{F}^{\mathrm{e}})^{-\mathrm{T}} \,. \tag{6.6.7}$$

The second part of the potential addresses the low stiffness at small strain, while the exponential is intended to represent the stiffening at larger strains. Typically, elastin fibers in arteries contribute to sustain loads at small strains while the stiffer collagen fibers are recruited progressively at increasing tensile strains. The derivatives are recorded,

$$\begin{aligned}\frac{\partial \underline{E}_\kappa}{\partial I_1^{\rm e}} &= \frac{a_0}{2}\big(\exp(Q)-1\big)\big(a_1+2\,a_3\,(I_1^{\rm e}-3)\big)+\frac{b_1}{2}+b_3\,(I_1^{\rm e}-3)\\ \frac{\partial \underline{E}_\kappa}{\partial I_2^{\rm e}} &= \frac{a_0}{2}\big(\exp(Q)-1\big)\,a_2+\frac{b_2}{2}\,.\end{aligned} \tag{6.6.13}$$

Klisch et al. [2001]b consider two strain energy functions, initially developed for purely elastic materials, which exhibit a large difference of stiffnesses in contraction and extension, and which are the isotropic versions of the elastic potentials used respectively by Almeida and Spilker [1998] for articular cartilages, namely

$$\underline{E}_\kappa = \frac{a_0}{2}\,(I_3^{\rm e})^{-\beta}\,\exp\,Q,\quad Q=a_1\,(I_1^{\rm e}-3)+a_2\,(I_2^{\rm e}-3)+a_3\,(I_1^{\rm e}-3)^2\,, \tag{6.6.14}$$

and by Klisch and Lotz [1999] for annulus fibrosus,

$$\underline{E}_\kappa = \frac{a_0}{2}\,Q,\quad Q=\exp(a_1\,(I_1^{\rm e}-3))+\exp(a_2\,(I_2^{\rm e}-3))+\exp(a_3\,(I_3^{\rm e}-1)\,. \tag{6.6.15}$$

The exponent β and the a's are material constants. Note that (6.6.14) is a particular case of Fung's potential (the exponential of a sum of invariants), while (6.6.15) is a sum of exponentials.

Rodriguez et al. [1994] use two types of potential, their Eqns 20, 21 and 30,

$$\underline{E}_\kappa = \frac{a_0}{2}\big(\exp(Q)-1\big),\quad Q=a\,\mathrm{tr}\,\mathbf{E}_{\rm G}^{\rm e},\quad \text{or}\quad \underline{E}_\kappa = a\,\mathrm{tr}\,(\mathbf{E}_{\rm G}^{\rm e})^2\,. \tag{6.6.16}$$

Omens et al. [2003] use a linear term in the elastic potential of a purely elastic aorta, so as to obtain a residual stress in the reference (unstrained) configuration. If the material was isotropic, the elastic potential for an elastic-growing solid would be of the form, with a and b material constants,

$$\underline{E}_\kappa = a\,\mathrm{tr}\;\mathbf{E}_{\rm G}^{\rm e}+b\,\mathrm{tr}\,(\mathbf{E}_{\rm G}^{\rm e})^2\,. \tag{6.6.17}$$

6.6.2 The multiplicative volumetric-isochoric decomposition of the deformation gradient

An extension of the *additive* decomposition of the infinitesimal strain into a spherical part and a deviatoric part is obtained via the *multiplicative* decomposition of the deformation gradient, Flory [1961],

$$\mathbf{F}^{\rm e}=J_{\rm e}^{\frac{1}{3}}\,\mathbf{F}_{\rm iso}^{\rm e},\quad \text{with}\quad J_{\rm e}=\det\mathbf{F}^{\rm e},\quad \det\mathbf{F}_{\rm iso}^{\rm e}=1\,. \tag{6.6.18}$$

The subscript 'iso' reflects the fact that the deformation gradient $\mathbf{F}_{\rm iso}^{\rm e}$ is isochoric. Hence

$$\mathbf{C}_{\rm iso}^{\rm e}=(\mathbf{F}^{\rm e})_{\rm iso}^{\rm T}\cdot\mathbf{F}_{\rm iso}^{\rm e}=(J_{\rm e})^{-\frac{2}{3}}\,\mathbf{C}^{\rm e}\,, \tag{6.6.19}$$

and

$$\frac{d\mathbf{C}_{\rm iso}^{\rm e}}{d\mathbf{C}^{\rm e}}=(J_{\rm e})^{-\frac{2}{3}}\,\big(\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}-\tfrac{1}{3}\,\mathbf{C}^{\rm e}\otimes(\mathbf{C}^{\rm e})^{-1}\big)=(J_{\rm e})^{-\frac{2}{3}}\,\big(\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}-\tfrac{1}{3}\,\mathbf{C}_{\rm iso}^{\rm e}\otimes(\mathbf{C}_{\rm iso}^{\rm e})^{-1}\big)\,. \tag{6.6.20}$$

Indeed,

$$\begin{aligned}\mathbf{C}_{\rm iso}^{\rm e}(\mathbf{C}^{\rm e}+d\mathbf{C}^{\rm e})-\mathbf{C}_{\rm iso}^{\rm e}(\mathbf{C}^{\rm e}) &= \big(\det(\mathbf{C}^{\rm e}+d\mathbf{C}^{\rm e})\big)^{-\frac{1}{3}}\,(\mathbf{C}^{\rm e}+d\mathbf{C}^{\rm e})-\mathbf{C}_{\rm iso}^{\rm e}(\mathbf{C}^{\rm e})\\ &= (J_{\rm e})^{-\frac{2}{3}}\,\big(\det\big(\mathbf{I}+(\mathbf{C}^{\rm e})^{-1}\cdot d\mathbf{C}^{\rm e}\big)\big)^{-\frac{1}{3}}\,(\mathbf{C}^{\rm e}+d\mathbf{C}^{\rm e})-\mathbf{C}_{\rm iso}^{\rm e}(\mathbf{C}^{\rm e})\\ &= (J_{\rm e})^{-\frac{2}{3}}\big(1-\tfrac{1}{3}(\mathbf{C}^{\rm e})^{-1}\!:d\mathbf{C}^{\rm e}\big)(\mathbf{C}^{\rm e}+d\mathbf{C}^{\rm e})-\mathbf{C}_{\rm iso}^{\rm e}(\mathbf{C}^{\rm e})+o(d\mathbf{C}^{\rm e})\\ &= (J_{\rm e})^{-\frac{2}{3}}\,\big(d\mathbf{C}^{\rm e}-\tfrac{1}{3}(\mathbf{C}^{\rm e})^{-1}:d\mathbf{C}^{\rm e}\,\mathbf{C}^{\rm e}\big)+o(d\mathbf{C}^{\rm e})\\ &= (J_{\rm e})^{-\frac{2}{3}}\,\big(\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}-\tfrac{1}{3}\mathbf{C}^{\rm e}\otimes(\mathbf{C}^{\rm e})^{-1}\big):d\mathbf{C}^{\rm e}+o(d\mathbf{C}^{\rm e})\\ &= (J_{\rm e})^{-\frac{2}{3}}\,\big(\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}-\tfrac{1}{3}\mathbf{C}_{\rm iso}^{\rm e}\otimes(\mathbf{C}_{\rm iso}^{\rm e})^{-1}\big):d\mathbf{C}^{\rm e}+o(d\mathbf{C}^{\rm e})\;\square\,.\end{aligned} \tag{6.6.21}$$

The third line has used (2.2.34).

6.6.3 Additive decomposition of anisotropic Fung's like potentials

A number of modifications of Fung's potential has been proposed, based on either experimental measurements or theoretical derivations. A few of these extensions are listed below.

A review of experimental details of biaxial testing of soft tissues including questions related to strain measurement by optical techniques, to homogeneity, to anisotropy, to boundary tethering or clamping and to orthotropy directions can be found in Sacks [2000].

An experimental technique to determine the axes of orthotropy has been proposed by Choi and Vito [1990]. Instead of the exponential of a sum, they use the sum of exponentials to build the elastic potential of canine pericardium, like in (6.6.15). The differences between these two forms remain to be explored.

Holzapfel and Weizsäcker [1998] introduce an anisotropic extension of Fung's potential to compressible solids. The isotropic and anisotropic terms contribute additively and are *decoupled*, namely

$$\underline{E}_\kappa = \underbrace{\frac{a_0}{2}\left(\exp Q(\mathbf{E}^{\rm e}_{\rm G}) - 1\right)}_{\text{anisotropic response}} + \underbrace{b_0 \operatorname{tr} \mathbf{E}^{\rm e}_{\rm G}}_{\text{isotropic response}} , \tag{6.6.22}$$

where,

$$Q(\mathbf{E}^{\rm e}_{\rm G}) = a_1 \left(E^{\rm e}_{\rm G1}\right)^2 + a_2 \left(E^{\rm e}_{\rm G2}\right)^2 + a_3 \left(E^{\rm e}_{\rm G3}\right)^2 + 2\, a_4\, E^{\rm e}_{\rm G1}\, E^{\rm e}_{\rm G2} + 2\, a_5\, E^{\rm e}_{\rm G1}\, E^{\rm e}_{\rm G3} + 2\, a_6\, E^{\rm e}_{\rm G2}\, E^{\rm e}_{\rm G3} , \tag{6.6.23}$$

with b_0 and the a's material constants. Here the $E^{\rm e}_{{\rm G}i}$'s, for i=1 to 3, are the components of the elastic Green strain along the fixed orthotropy (symmetry) axes of the material ($\mathbf{e}_1$, $\mathbf{e}_2$, $\mathbf{e}_3$).

van Dyke and Hoger [2002] develop a method to determine the opening angle induced by a residual stress field in an elastic-growing arterial wall. For illustration, they use the above elastic potential per unit reference volume initially developed for purely elastic tissues by Holzapfel and Weizsäcker [1998]. For aortic growth, Taber and Eggers [1996] use (6.6.22) and (6.6.23) for an elastically incompressible elastic-growing material, with $b_0 = 0$[6.5].

In fact, for an orthotropic material with symmetry axes ($\mathbf{e}_1$, $\mathbf{e}_2$, $\mathbf{e}_3$), there are seven independent scalar invariants of the Green strain listed in Table 2.11.3. They may be expressed in component form in the orthotropy axes and recombined,

$$E^{\rm e}_{\rm G11},\ E^{\rm e}_{\rm G22},\ E^{\rm e}_{\rm G33},\ (E^{\rm e}_{\rm G12})^2,\ (E^{\rm e}_{\rm G23})^2,\ (E^{\rm e}_{\rm G13})^2, E^{\rm e}_{\rm G12}\, E^{\rm e}_{\rm G23}\, E^{\rm e}_{\rm G13} . \tag{6.6.24}$$

Indeed, Humphrey [1995] accounts for the additional quadratic shear terms in Q, namely $a_7 \left(E^{\rm e}_{\rm G23}\right)^2 + a_8 \left(E^{\rm e}_{\rm G13}\right)^2 + a_9 \left(E^{\rm e}_{\rm G12}\right)^2$, that vanish if the orthotropy axes and Green strain are coaxial.

The two external layers of the arterial walls, namely the media and the adventitia, are reinforced by collagen fibers, mainly aligned circumferentially. These fibers can be considered to form two families of fixed directions $\mathbf{m}_1$ and $\mathbf{m}_2$. Moreover, only the isochoric part of the deformation gradient $\mathbf{F}^{\rm e}_{\rm iso}$ is considered to act on the fibers. Along these ideas, Holzapfel et al. [2000] change (6.6.22) to

$$\underline{E}_\kappa = \frac{a_1}{2\, a_2} \sum_{i=1,2} \underbrace{\exp\left(a_2 \left(I^{\rm iso}_{mi} - 1\right)^2\right)}_{\substack{\text{anisotropic}\\ \text{response}}} + \frac{b_0}{2} \underbrace{\left(\operatorname{tr} \mathbf{C}^{\rm e}_{\rm iso} - 3\right)}_{\substack{\text{isotropic}\\ \text{response}}} , \tag{6.6.25}$$

with $a_1 > 0$ and $a_2 > 0$ material constants, and

$$I^{\rm iso}_{mi} = \left(\mathbf{F}^{\rm e}_{\rm iso} \cdot \underline{\mathbf{m}}_i\right)^2 = \underline{\mathbf{m}}_i \cdot \mathbf{C}^{\rm e}_{\rm iso} \cdot \underline{\mathbf{m}}_i , \tag{6.6.26}$$

is the square of the material stretches along the direction $\underline{\mathbf{m}}_i$ of the fiber i. Holzapfel et al. [2002] modify the argument of the exponential in order to account for the fact that the collagen fibers do not sustain contractile strains,

$$\underline{E}_\kappa = \frac{a_1}{2\, a_2} \sum_{i=1,2} \underbrace{\exp\left(a_2 \left\langle I^{\rm iso}_{mi} - 1\right\rangle^2\right)}_{\substack{\text{traceless anisotropic}\\ \text{response}}} + \frac{b_0}{2} \underbrace{\left(\operatorname{tr} \mathbf{C}^{\rm e}_{\rm iso} - 3\right)}_{\substack{\text{traceless}\\ \text{isotropic}\\ \text{response}}} + \underbrace{U(\det \mathbf{F}^{\rm e})}_{\substack{\text{isotropic}\\ \text{volumetric}\\ \text{response}}} , \tag{6.6.27}$$

[6.5] Concerning volume change under infinitesimal and finite strains, see however Section 2.5.7.

where the symbol $\langle\cdot\rangle$ denotes the positive part of its argument. Note that the exponent 2 inside the exponentials allows for the stress to be continuous at the contraction-extension interface $I^{\rm iso}_{mi}-1=0$. In fact, any exponent larger than 1 is sufficient for that purpose.

Since

$$df=\frac{\partial f}{\partial \mathbf{C}^{\rm e}_{\rm iso}}:d\mathbf{C}^{\rm e}_{\rm iso}=\frac{\partial f}{\partial \mathbf{C}^{\rm e}_{\rm iso}}:\frac{d\mathbf{C}^{\rm e}_{\rm iso}}{d\mathbf{C}^{\rm e}}:d\mathbf{C}^{\rm e}=\frac{\partial f}{\partial (C^{\rm e}_{\rm iso})_{ij}}\,\frac{d(C^{\rm e}_{\rm iso})_{ij}}{dC^{\rm e}_{kl}}\,dC^{\rm e}_{kl}\,, \tag{6.6.28}$$

then

$$\mathbf{I}:d\mathbf{C}^{\rm e}_{\rm iso}=\mathbf{I}:\frac{d\mathbf{C}^{\rm e}_{\rm iso}}{d\mathbf{C}^{\rm e}}:d\mathbf{C}^{\rm e}=(J_{\rm e})^{-\frac{2}{3}}\left(\mathbf{I}-\tfrac{1}{3}(\mathbf{I}:\mathbf{C}^{\rm e})\,(\mathbf{C}^{\rm e})^{-1}\right):d\mathbf{C}^{\rm e}\,, \tag{6.6.29}$$

and

$$\begin{aligned} d\left(\underline{\mathbf{m}}\cdot\mathbf{C}^{\rm e}_{\rm iso}\cdot\underline{\mathbf{m}}\right) &= (J_{\rm e})^{-\frac{2}{3}}\,\underline{\mathbf{m}}\cdot\left(\left(\mathbf{I}\,\overline{\otimes}\,\mathbf{I}-\tfrac{1}{3}\mathbf{C}^{\rm e}\otimes(\mathbf{C}^{\rm e})^{-1}\right):d\mathbf{C}^{\rm e}\right)\cdot\underline{\mathbf{m}}\\ &= (J_{\rm e})^{-\frac{2}{3}}\left(\underline{\mathbf{m}}\otimes\underline{\mathbf{m}}-\tfrac{1}{3}\left(\underline{\mathbf{m}}\cdot\mathbf{C}^{\rm e}\cdot\underline{\mathbf{m}}\right)(\mathbf{C}^{\rm e})^{-1}\right):d\mathbf{C}^{\rm e}\,. \end{aligned} \tag{6.6.30}$$

The 2nd Piola-Kirchhoff stress becomes,

$$\begin{aligned} &(\mathbf{F}^{\rm e})^{-1}\cdot\boldsymbol{\tau}\cdot(\mathbf{F}^{\rm e})^{-\rm T}=2\,\frac{\partial \underline{E}_\kappa}{\partial \mathbf{C}^{\rm e}}\\ =\;&(J_{\rm e}\,\frac{dU}{dJ_{\rm e}})\,(\mathbf{C}^{\rm e})^{-1}+b_0\,(J_{\rm e})^{-\frac{2}{3}}\left(\mathbf{I}-\tfrac{1}{3}(\mathbf{I}:\mathbf{C}^{\rm e})\,(\mathbf{C}^{\rm e})^{-1}\right)\\ +\;&2\,a_1\sum_{i=1,2}\langle I^{\rm iso}_{mi}-1\rangle\,\exp\left(a_2\,\langle I^{\rm iso}_{mi}-1\rangle^2\right)(J_{\rm e})^{-\frac{2}{3}}\left(\underline{\mathbf{m}}_i\otimes\underline{\mathbf{m}}_i-\tfrac{1}{3}\left(\underline{\mathbf{m}}_i\cdot\mathbf{C}^{\rm e}\cdot\underline{\mathbf{m}}_i\right)(\mathbf{C}^{\rm e})^{-1}\right), \end{aligned} \tag{6.6.31}$$

whence the Kirchhoff stress $\boldsymbol{\tau}=\det\mathbf{F}\,\boldsymbol{\sigma}$,

$$\begin{aligned} \boldsymbol{\tau} &= (J_{\rm e}\,\frac{dU}{dJ_{\rm e}})\,\mathbf{I}+b_0\left(\mathbf{C}^{\rm e}_{\rm iso}-\tfrac{1}{3}(\mathbf{I}:\mathbf{C}^{\rm e}_{\rm iso})\,\mathbf{I}\right)+2\,a_1\sum_{i=1,2}\langle I^{\rm iso}_{mi}-1\rangle\,\exp\left(a_2\,\langle I^{\rm iso}_{mi}-1\rangle^2\right)\\ &\quad\times\Big((\mathbf{F}^{\rm e}_{\rm iso}\cdot\underline{\mathbf{m}}_i)\otimes(\mathbf{F}^{\rm e}_{\rm iso}\cdot\underline{\mathbf{m}}_i)-\tfrac{1}{3}\left(\underline{\mathbf{m}}_i\cdot\mathbf{C}^{\rm e}_{\rm iso}\cdot\underline{\mathbf{m}}_i\right)\mathbf{I}\Big)\,. \end{aligned} \tag{6.6.32}$$

A particular isotropic case of (6.6.27) reads,

$$\underline{E}_\kappa=\frac{a_0}{4}\underbrace{\left(\det\,\mathbf{C}^{\rm e}-1-{\rm Ln}\,\det\,\mathbf{C}^{\rm e}\right)}_{\substack{\text{isotropic}\\ \text{volumetric response}}}+\frac{b_0}{2}\quad\underbrace{\left(\text{tr}\,\mathbf{C}^{\rm e}_{\rm iso}-3\right)}_{\substack{\text{traceless}\\ \text{isotropic response}}}\quad, \tag{6.6.33}$$

so that the Kirchhoff stress has the form,

$$\boldsymbol{\tau}\;=\;\frac{a_0}{2}\,(\det\mathbf{C}^{\rm e}-1)\,\mathbf{I}\;+\;b_0\left(\mathbf{C}^{\rm e}_{\rm iso}-\tfrac{1}{3}(\mathbf{I}:\mathbf{C}^{\rm e}_{\rm iso})\,\mathbf{I}\right). \tag{6.6.34}$$

For transversely isotropic fiber-reinforced ligaments, Limbert and Middleton [2004] define a piecewise potential according to the value of the fiber extension indicator $I_m-1=\underline{\mathbf{m}}\cdot\mathbf{C}^{\rm e}\cdot\underline{\mathbf{m}}-1$,

$$\underline{E}_\kappa=\frac{b_0}{2}\,(\text{tr}\,\mathbf{C}^{\rm e}-3)+\begin{cases}0, & I_m\le 1,\\ \dfrac{a_1}{2\,a_2}\big(\exp(a_3(I_m-1)^2)-1\big), & I_m\le I^*_m,\\ a_4\,\sqrt{I_m}+a_5\,{\rm Ln}\;I_m, & I_m\ge I^*_m\,.\end{cases} \tag{6.6.35}$$

The motivation is the following. The collagen fibers do not sustain load in contraction. Under progressive extension, they are recruited progressively until the value $I_m=I^*_m>1$ is reached. The material constants a are chosen so as to ensure continuity of the stress at the critical value $I_m=I^*_m$.

Taber and Chabert [2002] consider the more complex picture of cardiac tissues viewed as elastic-growing materials with muscle activation. If we neglect the circumferential and axial reinforcements due to collagen fibers, the passive behavior is modeled through the elastic potential,

$$\underline{E}_\kappa=\frac{a_0}{2}\left(\exp Q-1\right),\quad Q=\frac{\mu}{2}\,(\text{tr}\,\mathbf{C}^{\rm e}-3)+\frac{\mu}{2\,\gamma}\,\left((\det\mathbf{C}^{\rm e})^{-\gamma}-1\right), \tag{6.6.36}$$

that involves the neo-Hookean function Q used for compressible foam rubbers, as defined by (6.4.7), with the material constants a_0, μ and $\gamma = \nu/(1-2\,\nu)$, where ν can be seen as a Poisson's ratio in the infinitesimal strain limit. Note that the linear term $\mathrm{tr}\,\mathbf{C}^{\mathrm{e}}$ in Q implies the volumetric and shear response to be coupled, in contrast to (6.6.27).

For a transversely isotropic fiber-reinforced myocardium, the five independent isotropic scalar invariants of the Green strain are listed in Table 2.11.4. They may be expressed in component form in the orthotropy axes (1 direction of the fibers) and recombined,

$$E^{\mathrm{e}}_{\mathrm{G}11},\ E^{\mathrm{e}}_{\mathrm{G}22}+E^{\mathrm{e}}_{\mathrm{G}33},\ (E^{\mathrm{e}}_{\mathrm{G}12})^2+(E^{\mathrm{e}}_{\mathrm{G}13})^2,(E^{\mathrm{e}}_{\mathrm{G}22})^2+(E^{\mathrm{e}}_{\mathrm{G}33})^2+2\,(E^{\mathrm{e}}_{\mathrm{G}23})^2,$$
$$E^{\mathrm{e}}_{\mathrm{G}22}\,(E^{\mathrm{e}}_{\mathrm{G}12})^2+E^{\mathrm{e}}_{\mathrm{G}33}\,(E^{\mathrm{e}}_{\mathrm{G}13})^2+2\,E^{\mathrm{e}}_{\mathrm{G}12}\,E^{\mathrm{e}}_{\mathrm{G}13}\,E^{\mathrm{e}}_{\mathrm{G}23}\,. \tag{6.6.37}$$

An application to the ventricular myocardium determined from a cylindrical model is shown in Guccione et al. [1991], namely

$$\underline{E}_{\kappa}=\frac{a_0}{2}\left(\exp(Q)-1\right),\quad Q(\mathbf{E}^{\mathrm{e}}_{\mathrm{G}})=a_1\,\mathrm{tr}\,\mathbf{E}^{\mathrm{e}}_{\mathrm{G}}+a_2\,(E^{\mathrm{e}}_{\mathrm{G}11})^2+a_3\left((E^{\mathrm{e}}_{\mathrm{G}22})^2+(E^{\mathrm{e}}_{\mathrm{G}33})^2+2\,(E^{\mathrm{e}}_{\mathrm{G}23})^2\right), \tag{6.6.38}$$

where the a's are material constants. Note that the constitutive stress is not traceless.

6.7 Return to the conewise response in presence of fibers

We have listed three methods that address the conewise constitutive response of fiber-reinforced materials:

1. linear conewise elasticity: Section 5.4.2 defines the concept of admissible constitutive cones. The idea is applied to materials endowed with structural and fabric anisotropic properties in the subsequent sections;
2. additive contribution of a ground substance and fibers, and direct incorporation of the influence of the sign of the strain along fibers in the strain energy of the latter. In (6.6.27), the transition is sharp while it is smoothed over a short step in (6.6.35);
3. a smooth variation of the stiffness at the transition between contraction and extension, associated with largely distinct moduli on each side of the transition, Eqns (6.6.14) and (6.6.15).

In all cases, the continuity of the stress at the transition between constitutive cones should be taken care of.

6.8 Elasticity and workless constitutive stress

Two instances where the constitutive equations are not hyperelastic are reported below.

For a spherical shell, made of an incompressible elastic-growing material, Chen and Hoger [2000] do not assume the existence of an elastic potential. Since the motion is a pure deformation, the polar decomposition of the elastic transformation simplifies to $\mathbf{F}^{\mathrm{e}}=\mathbf{U}^{\mathrm{e}}=\mathbf{V}^{\mathrm{e}}$. The effective stress can be expressed in terms of e.g., the left elastic stretch $\mathbf{V}^{\mathrm{e}}$,

$$\boldsymbol{\sigma}+p\,\mathbf{I}=f_1(I^{\mathrm{e}}_1,I^{\mathrm{e}}_2)\,\mathbf{V}^{\mathrm{e}}+f_2(I^{\mathrm{e}}_1,I^{\mathrm{e}}_2)\,(\mathbf{V}^{\mathrm{e}})^2\,, \tag{6.8.1}$$

where f_1 and f_2 are scalar functions of the invariants I^{e}'s of $\mathbf{V}^{\mathrm{e}}$, not of $\mathbf{C}^{\mathrm{e}}=(\mathbf{V}^{\mathrm{e}})^2$,

$$I^{\mathrm{e}}_1=\mathrm{tr}\,\mathbf{V}^{\mathrm{e}},\quad I^{\mathrm{e}}_2=\tfrac{1}{2}\left((\mathrm{tr}\,\mathbf{V}^{\mathrm{e}})^2-\mathrm{tr}\,(\mathbf{V}^{\mathrm{e}})^2\right). \tag{6.8.2}$$

The components of the effective Cauchy stress in the radial and tangential axes may be cast in the form,

$$\boldsymbol{\sigma}+p\,\mathbf{I}=\mathbf{diag}\,[f_1\,v_r+f_2\,v_r^2,\ f_1\,v_\theta+f_2\,v_\theta^2,\ f_1\,v_\theta+f_2\,v_\theta^2]\,. \tag{6.8.3}$$

The constitutive equation is enforced to satisfy the Baker-Ericksen inequality, which states that the stress is largest in the direction of the largest stretch, i.e., here

$$\frac{\sigma_r-\sigma_\theta}{v_r-v_\theta}=f_1+(v_r+v_\theta)\,f_2>0\,. \tag{6.8.4}$$

Criscione et al. [2003] consider that the stress is contributed by a component that derives from an elastic potential and by a symmetric workless component[6.6]. Section 2.10 introduces a component of the stress that does no work if

[6.6] The authors name this stress as 'hypoelastic'. As indicated in Chapter 5, hyperelasticity corresponds to a one-to-one stress-strain relation and the stress derives from a potential, that is, the work done on a closed strain cycle is zero. Elasticity corresponds to one-to-one stress-strain relation, but the stress does not derive from a potential, that is, the work done on a closed strain cycle may not be zero. Hypoelasticity implies a stress-strain relation which is not one-to-one, and the work done in a closed strain cycle does not vanish. Still, on the reverse strain cycle, the stress path is recovered as well as the work done, i.e., the initial stress is recovered, there is no irreversibility in stress and there is no dissipation.

the kinematical constraint is satisfied. This reaction stress is defined by boundary conditions. In contrast here, the component of the stress that does no work is constitutive, namely,

$$\boldsymbol{\tau} = (\det \mathbf{F})\, \boldsymbol{\sigma} = \mathbf{F} \cdot \frac{\partial \underline{\underline{E}}}{\partial \mathbf{E}_{\rm G}} \cdot \mathbf{F}^{\rm T} + \boldsymbol{\tau}_R \,, \tag{6.8.5}$$

with $\boldsymbol{\tau}_R : \mathbf{L} = 0$, $\mathbf{L}$ being the velocity gradient. The analysis is tailored to biomembranes. Let ($\underline{\mathbf{m}}$, $\underline{\mathbf{s}}$, $\underline{\mathbf{n}}$) be a reference cartesian triad, with the two first vectors in the plane of the membrane. Under loading, this reference triad undergoes the rotation $\mathbf{Q}$ and transforms to ($\mathbf{m}$, $\mathbf{s}$, $\mathbf{n}$). The deformation gradient $\mathbf{F}$, local deformation gradient $\mathbf{f} = \mathbf{Q}^{\rm T} \cdot \mathbf{F}$ and velocity gradient $\mathbf{L} = (d\mathbf{F}/dt) \cdot \mathbf{F}^{-1} = \mathbf{Q} \cdot (d\mathbf{f}/dt) \cdot \mathbf{f}^{-1} \cdot \mathbf{Q}^{\rm T} + (d\mathbf{Q}/dt) \cdot \mathbf{Q}^{\rm T}$ express in these axes as,

$$\begin{aligned}
\mathbf{F} &= \lambda_M\, \mathbf{m} \otimes \underline{\mathbf{m}} + \lambda_M\, \phi_{MS}\, \mathbf{m} \otimes \underline{\mathbf{s}} + \lambda_S\, \mathbf{s} \otimes \underline{\mathbf{s}} \\
\mathbf{f} &= \lambda_M\, \underline{\mathbf{m}} \otimes \underline{\mathbf{m}} + \lambda_M\, \phi_{MS}\, \underline{\mathbf{m}} \otimes \underline{\mathbf{s}} + \lambda_S\, \underline{\mathbf{s}} \otimes \underline{\mathbf{s}} \\
\mathbf{L} &= \frac{d{\rm Ln}\lambda_M}{dt}\, \mathbf{m} \otimes \mathbf{m} + \frac{\lambda_M}{\lambda_S}\, \frac{d\phi_{MS}}{dt}\, \mathbf{m} \otimes \mathbf{s} + \frac{d{\rm Ln}\lambda_S}{dt}\, \mathbf{s} \otimes \mathbf{s} + \frac{d\mathbf{Q}}{dt} \cdot \mathbf{Q}^{\rm T} \,.
\end{aligned} \tag{6.8.6}$$

For biaxial stretch under a radial path, namely for ${\rm Ln}\lambda_M/{\rm Ln}\lambda_S$ constant and $\phi_{MS} = 0$, Criscione et al. [2003] deduce that the workless stress should be of the form,

$$\boldsymbol{\tau}_R = a(\lambda_M,\, \lambda_S)\, \big({\rm Ln}\lambda_S\, \mathbf{m} \otimes \mathbf{m} - {\rm Ln}\lambda_M\, \mathbf{s} \otimes \mathbf{s}\big) \,, \tag{6.8.7}$$

with a multiplicative factor a which depends on the stretches λ_M and λ_S.

6.9 Use of right and left Cauchy-Green tensors

For an elastic material, the mechanical dissipation expresses as

$$-\frac{dE}{dt} - E\, \mathbf{I} : \mathbf{D} + \boldsymbol{\sigma} : \mathbf{D} \geq 0 \,, \tag{6.9.1}$$

in terms of the free energy (elastic potential) per current volume E, Cauchy stress $\boldsymbol{\sigma}$ and strain rate $\mathbf{D}$.

If the free energy depends on the right Cauchy-Green tensor $\mathbf{C} = \mathbf{F}^{\rm T} \cdot \mathbf{F}$, or Green strain $\mathbf{E}_{\rm G} = \frac{1}{2}\,(\mathbf{C} - \mathbf{I})$, the inequality becomes with help of $(2.5.14)_1$,

$$\big(-\mathbf{F} \cdot \frac{dE}{d\mathbf{E}_{\rm G}} \cdot \mathbf{F}^{\rm T} - E\, \mathbf{I} + \boldsymbol{\sigma}\big) : \mathbf{D} \geq 0 \,, \tag{6.9.2}$$

and, therefore, in absence of constraints on the deformation gradient, the constitutive Eshelby stress expresses as

$$\begin{aligned}
\boldsymbol{\sigma} - E\, \mathbf{I} &= \mathbf{F} \cdot \frac{dE}{d\mathbf{E}_{\rm G}} \cdot \mathbf{F}^{\rm T} \\
&= 2\, \mathbf{F} \cdot \frac{dE}{d\mathbf{C}} \cdot \mathbf{F}^{\rm T} \,.
\end{aligned} \tag{6.9.3}$$

As an example, if the free energy may depend only on the first and second scalar isotropic invariants of the strain $\mathbf{E}_{\rm G}$ via the material constants a and $\mu > 0$,

$$E = a\, {\rm tr}\, \mathbf{E}_{\rm G} + \mu\, {\rm tr}\, \mathbf{E}_{\rm G}^2 \,, \tag{6.9.4}$$

the stress turns to,

$$\boldsymbol{\sigma} - E\, \mathbf{I} = a\, \mathbf{F} \cdot \mathbf{F}^{\rm T} + 2\, \mu\, \mathbf{F} \cdot \mathbf{E}_{\rm G} \cdot \mathbf{F}^{\rm T} \,. \tag{6.9.5}$$

Now if the free energy depends on the left Cauchy-Green tensor $\mathbf{B} = \mathbf{F} \cdot \mathbf{F}^{\rm T}$, or on the covariant Almansi strain $\mathbf{E}_{\rm A}^{\rm co} = \frac{1}{2}\,(\mathbf{I} - \mathbf{B}^{-1})$, the inequality becomes with help of $(2.5.14)_2$,

$$\big(-\frac{dE}{d\mathbf{B}} \cdot \mathbf{B} - \mathbf{B} \cdot \frac{dE}{d\mathbf{B}} - E\, \mathbf{I} + \boldsymbol{\sigma}\big) : \mathbf{D} \geq 0 \,, \tag{6.9.6}$$

and, therefore, in absence of constraints on the deformation gradient, the constitutive Eshelby stress expresses as

$$\boldsymbol{\sigma} - E\,\mathbf{I} \;=\; \frac{dE}{d\mathbf{B}}\cdot\mathbf{B} + \mathbf{B}\cdot\frac{dE}{d\mathbf{B}}\,. \tag{6.9.7}$$

As an example, the free energy (elastic potential) may depend only on the first and second scalar isotropic invariants of the strain $\mathbf{E}^{\rm co}_{\rm A}$,

$$E = a\,\mathrm{tr}\,\mathbf{E}^{\rm co}_{\rm A} + \mu\,\mathrm{tr}\,(\mathbf{E}^{\rm co}_{\rm A})^2\,. \tag{6.9.8}$$

Since to first order in $\mathbf{H}$,

$$\begin{aligned}
&\mathbf{E}^{\rm co}_{\rm A}(\mathbf{B}+\mathbf{H}) - \mathbf{E}^{\rm co}_{\rm A}(\mathbf{B}) = -\frac{1}{2}\,\mathbf{B}^{-1}\cdot\mathbf{H}\cdot\mathbf{B}^{-1},\\
&\big(\mathbf{E}^{\rm co}_{\rm A}(\mathbf{B}+\mathbf{H})\big)^2 - \big(\mathbf{E}^{\rm co}_{\rm A}(\mathbf{B})\big)^2 = \frac{1}{2}\left(\mathbf{E}^{\rm co}_{\rm A}(\mathbf{B})\cdot\mathbf{B}^{-1}\cdot\mathbf{H}\cdot\mathbf{B}^{-1} + \mathbf{B}^{-1}\cdot\mathbf{H}\cdot\mathbf{B}^{-1}\cdot\mathbf{E}^{\rm co}_{\rm A}(\mathbf{B})\right),
\end{aligned} \tag{6.9.9}$$

then

$$\frac{d}{d\mathbf{B}}\mathrm{tr}\,\mathbf{E}^{\rm co}_{\rm A} = \frac{1}{2}\,\mathbf{B}^{-2}, \quad \frac{d}{d\mathbf{B}}\mathrm{tr}\,(\mathbf{E}^{\rm co}_{\rm A})^2 = \mathbf{B}^{-1}\cdot\mathbf{E}^{\rm co}_{\rm A}\cdot\mathbf{B}^{-1}\,, \tag{6.9.10}$$

and the Elshelby stress becomes now,

$$\begin{aligned}
\boldsymbol{\sigma} - E\,\mathbf{I} &= a\,\mathbf{B}^{-1} + \mu\,(\mathbf{B}^{-1}\cdot\mathbf{E}^{\rm co}_{\rm A} + \mathbf{E}^{\rm co}_{\rm A}\cdot\mathbf{B}^{-1})\\
&= a\,\mathbf{F}^{-\mathrm{T}}\cdot\mathbf{F}^{-1} + 2\,\mu\,\mathbf{V}^{-1}\cdot\mathbf{E}^{\rm co}_{\rm A}\cdot\mathbf{V}^{-1}\,,
\end{aligned} \tag{6.9.11}$$

with $\mathbf{V}$ the left stretch in the polar decomposition of $\mathbf{F}$.

Exercises on Chapter 6

Exercise 6.1 Strict convexity and curvature

A positive definite Hessian implies the function it derives from to be strictly convex. On the other hand, a function may be strictly convex while its Hessian is not positive definite, but only positive semi-definite. As an example, show that the real function $\phi(x) = x^4$ is strictly convex while its second derivative vanishes at $x = 0$, Fletcher [1990].

Answer:

$$\begin{aligned} & \lambda\,\phi(x) + (1-\lambda)\,\phi(y) - \phi(\lambda\,x + (1-\lambda)\,y) \\ = \;& \lambda\,x^4 + (1-\lambda)\,y^4 - \big(\lambda\,x + (1-\lambda)\,y\big)^4 \\ = \;& \lambda\,(1-\lambda)\,\big(\lambda^2\,(x-y)^4 + \lambda\,(x-y)^3(x+3\,y) + (x-y)^2\,(x^2+2\,x\,y+3\,y^2)\big)\,. \end{aligned} \tag{6.E.1}$$

The discriminant of the quadratic polynomial in λ,

$$-\,3\,(x-y)^6\,(x^2 + \frac{2}{3}\,x\,y + y^2)\,, \tag{6.E.2}$$

is strictly negative for $x \neq y$. The expression (6.E.1) does not change sign and, for $x \neq 0$, $y = 0$, $\lambda \in]0,1[$, it is equal to $\lambda\,(1-\lambda^3)\,x^4$ and therefore strictly positive, while the 2nd derivative $12\,x^2$ clearly vanishes at $x = 0$.

Exercise 6.2 Derivatives of $\mathbf{A}^n$, $n > 0$

Let $\mathbf{A}$ be a symmetric second order tensor. Calculate the derivatives of $\mathbf{A}^2$ and $\mathbf{A}^3$ with respect to $\mathbf{A}$. Deduce the derivative of $\mathbf{A}^n$, for $n > 0$ integer.

Answer:

1. Derivative of $\mathbf{A}^2$:

$$\begin{aligned} (\mathbf{A}+\mathbf{H})^2 &= \mathbf{A}^2 + \mathbf{A}\cdot\mathbf{H} + \mathbf{H}\cdot\mathbf{A} + \mathbf{H}^2 \\ (\mathbf{A}+\mathbf{H})^2 - \mathbf{A}^2 &= \mathbf{A}\cdot\mathbf{H} + \mathbf{H}\cdot\mathbf{A} + O(\mathbf{H}^2) = \frac{d\mathbf{A}^2}{d\mathbf{A}} : \mathbf{H} + O(\mathbf{H}^2) \\ \frac{d\mathbf{A}^2}{d\mathbf{A}} &= \mathbf{A}\,\underline{\overline{\otimes}}\,\mathbf{I} + \mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A} \\ \big(\frac{d\mathbf{A}^2}{d\mathbf{A}}\big)_{ijkl} &= A_{ik}\,I_{jl} + I_{ik}\,A_{lj}\,. \end{aligned} \tag{6.E.3}$$

2. Derivative of $\mathbf{A}^3$:

$$\begin{aligned} (\mathbf{A}+\mathbf{H})^3 &= \mathbf{A}^3 + \mathbf{A}^2\cdot\mathbf{H} + \mathbf{A}\cdot\mathbf{H}\cdot\mathbf{A} + \mathbf{H}\cdot\mathbf{A}^2 + \mathbf{A}\cdot\mathbf{H}^2 + \mathbf{H}\cdot\mathbf{A}\cdot\mathbf{H} + \mathbf{H}^2\cdot\mathbf{A} + \mathbf{H}^3 \\ (\mathbf{A}+\mathbf{H})^3 - \mathbf{A}^3 &= \mathbf{A}^2\cdot\mathbf{H} + \mathbf{A}\cdot\mathbf{H}\cdot\mathbf{A} + \mathbf{H}\cdot\mathbf{A}^2 + O(\mathbf{H}^2) = \frac{d\mathbf{A}^3}{d\mathbf{A}} : \mathbf{H} + O(\mathbf{H}^2) \\ \frac{d\mathbf{A}^3}{d\mathbf{A}} &= \mathbf{A}^2\,\underline{\overline{\otimes}}\,\mathbf{I} + \mathbf{A}\,\underline{\overline{\otimes}}\,\mathbf{A} + \mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{A}^2 \\ \big(\frac{d\mathbf{A}^3}{d\mathbf{A}}\big)_{ijkl} &= (\mathbf{A}^2)_{ik}\,I_{jl} + A_{ik}\,A_{jl} + I_{ik}\,(\mathbf{A}^2)_{jl}\,. \end{aligned} \tag{6.E.4}$$

The component form of the last line above has used the property that, if $\mathbf{A}$ is a symmetric second order tensor, so is $\mathbf{A}^2$.

3. Derivative of $\mathbf{A}^n$, $n \geq 0$ positive integer:

$$\begin{aligned} \frac{d\mathbf{A}^n}{d\mathbf{A}} &= \sum_{p=0}^{n-1} \mathbf{A}^{n-1-p}\,\underline{\overline{\otimes}}\,\mathbf{A}^p \\ \big(\frac{d\mathbf{A}^n}{d\mathbf{A}}\big)_{ijkl} &= \sum_{p=0}^{n-1} (\mathbf{A}^{n-1-p})_{ik}\,(\mathbf{A}^p)_{jl}. \end{aligned} \tag{6.E.5}$$

Exercise 6.3 Derivatives of $\mathbf{A}^n$, $n < 0$

Let $\mathbf{A}$ be a symmetric second order tensor. Calculate the derivatives of $\mathbf{A}^{-1}$ and $\mathbf{A}^{-2}$ with respect to $\mathbf{A}$. Deduce the derivative of $\mathbf{A}^n$, for $n < 0$ integer.

Answer:
1. Calculation of $(\mathbf{A}+\mathbf{H})^{-1}$:

$$\begin{aligned}
\mathbf{A}+\mathbf{H} &= \mathbf{A}\cdot(\mathbf{I}+\mathbf{A}^{-1}\mathbf{H}) \\
(\mathbf{A}+\mathbf{H})^{-1} &= (\mathbf{I}+\mathbf{A}^{-1}\mathbf{H})^{-1}\cdot\mathbf{A}^{-1} \\
(\mathbf{I}+\mathbf{A}^{-1}\mathbf{H})^{-1} &= \mathbf{I}-\mathbf{A}^{-1}\cdot\mathbf{H}+(\mathbf{A}^{-1}\cdot\mathbf{H})^2-(\mathbf{A}^{-1}\cdot\mathbf{H})^3+\cdots \\
(\mathbf{A}+\mathbf{H})^{-1} &= \mathbf{A}^{-1}-\mathbf{A}^{-1}\cdot\mathbf{H}\cdot\mathbf{A}^{-1}+\mathbf{A}^{-1}\cdot\mathbf{H}\cdot\mathbf{A}^{-1}\cdot\mathbf{H}\cdot\mathbf{A}^{-1}+\cdots .
\end{aligned} \tag{6.E.6}$$

2. Derivative of $\mathbf{A}^{-1}$:

$$\begin{aligned}
(\mathbf{A}+\mathbf{H})^{-1}-\mathbf{A}^{-1} &= -\mathbf{A}^{-1}\cdot\mathbf{H}\cdot\mathbf{A}^{-1}+O(\mathbf{H}^2) \\
\frac{d\mathbf{A}^{-1}}{d\mathbf{A}} &= -\mathbf{A}^{-1}\,\underline{\overline{\otimes}}\,\mathbf{A}^{-1} \\
\Big(\frac{d\mathbf{A}^{-1}}{d\mathbf{A}}\Big)_{ijkl} &= -(\mathbf{A}^{-1})_{ik}\,(\mathbf{A}^{-1})_{jl}\,.
\end{aligned} \tag{6.E.7}$$

3. Derivative of $\mathbf{A}^{-2}$:
Using $(6.E.6)_4$,

$$\begin{aligned}
(\mathbf{A}+\mathbf{H})^{-2}-\mathbf{A}^{-2} &= (\mathbf{A}+\mathbf{H})^{-1}\cdot(\mathbf{A}+\mathbf{H})^{-1}-\mathbf{A}^{-2} \\
&= -\mathbf{A}^{-2}\cdot\mathbf{H}\cdot\mathbf{A}^{-1}-\mathbf{A}^{-1}\cdot\mathbf{H}\cdot\mathbf{A}^{-2}+O(\mathbf{H}^2) \\
\frac{d\mathbf{A}^{-2}}{d\mathbf{A}} &= -\mathbf{A}^{-2}\,\underline{\overline{\otimes}}\,\mathbf{A}^{-1}-\mathbf{A}^{-1}\,\underline{\overline{\otimes}}\,\mathbf{A}^{-2} \\
\Big(\frac{d\mathbf{A}^{-2}}{d\mathbf{A}}\Big)_{ijkl} &= -(\mathbf{A}^{-2})_{ik}\,(\mathbf{A}^{-1})_{jl}-(\mathbf{A}^{-1})_{ik}\,(\mathbf{A}^{-2})_{jl}\,.
\end{aligned} \tag{6.E.8}$$

Exercise 6.4 Derivative $\partial\mathbf{E}_{\mathrm{G}}/\partial\mathbf{F}$ of Green strain wrt the deformation gradient
Calculate the derivative of Green strain $\mathbf{E}_{\mathrm{G}}=\frac{1}{2}\,(\mathbf{F}^{\mathrm{T}}\cdot\mathbf{F}-\mathbf{I})$ wrt the deformation gradient $\mathbf{F}$.

Answer:

$$\begin{aligned}
\mathbf{E}_{\mathrm{G}}(\mathbf{F}+\mathbf{H})-\mathbf{E}_{\mathrm{G}}(\mathbf{F}) &= \frac{1}{2}\,(\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H}+\mathbf{H}^{\mathrm{T}}\cdot\mathbf{F}+\mathbf{H}^{\mathrm{T}}\cdot\mathbf{H}), \\
&= \frac{1}{2}\,(\mathbf{F}^{\mathrm{T}}\cdot\mathbf{H}+\mathbf{H}^{\mathrm{T}}\cdot\mathbf{F})+O(\mathbf{H}^2), \\
\Big(\frac{\partial\mathbf{E}_{\mathrm{G}}}{\partial\mathbf{F}}\Big)_{ijkl} &= \frac{1}{2}\,(F_{ki}\,I_{jl}+F_{kj}\,I_{il})\,.
\end{aligned} \tag{6.E.9}$$

Exercise 6.5 An elementary differential relation
If $\mathbf{A}$ is a symmetric second order tensor, and $\boldsymbol{\epsilon}$ the infinitesimal strain, show that

$$\frac{d}{d\boldsymbol{\epsilon}}(\mathbf{A}:\boldsymbol{\epsilon}^2)=\mathbf{A}\cdot\boldsymbol{\epsilon}+\boldsymbol{\epsilon}\cdot\mathbf{A}\,. \tag{6.E.10}$$

Proof: Let $\mathbf{H}$ be an arbitrary symmetric second order tensor. Then

$$\frac{d(\mathbf{A}:\boldsymbol{\epsilon}^2)}{d\boldsymbol{\epsilon}}:\mathbf{H}=\lim_{\mathbf{H}\to\mathbf{0}}\mathbf{A}:(\boldsymbol{\epsilon}+\mathbf{H})^2-\mathbf{A}:\boldsymbol{\epsilon}^2\,. \tag{6.E.11}$$

To first order in $\mathbf{H}$, the latter is equal to $\mathbf{A}:(\mathbf{H}\cdot\boldsymbol{\epsilon}+\boldsymbol{\epsilon}\cdot\mathbf{H})$, or componentwise $A_{ij}(H_{ik}\epsilon_{kj}+\epsilon_{ik}H_{kj})$ i.e., to $(\mathbf{A}\cdot\boldsymbol{\epsilon}+\boldsymbol{\epsilon}\cdot\mathbf{A}):\mathbf{H}$, componentwise $(\epsilon_{ij}A_{jk}+A_{ij}\epsilon_{jk})H_{ik}$.

Chapter 7

Poroelasticity with a single porosity

This chapter addresses deformation and seepage in isothermal poroelastic tissues with a single porosity and devoid of an electric fixed charge. Thermal effects in fluid-saturated porous media are introduced in Chapter 9. Tissues in which two distinct porosities may be highlighted are considered in Sections 10.6 and 24.8.2. In fact, Chapter 9 assumes local thermal equilibrium, namely a temperature which is uniform over constituents, while Chapter 10 enlarges the landscape and allows each constituent to be endowed with its own temperature.

Emphasis is laid here on the anisotropic properties of the fluid-saturated porous media and on their identification through a minimal number of *independent* laboratory experiments. As an example, a simple test, namely the unconfined compression of cylindrical sample, is worked out and solved through analytical tools. Along a guiding principle in this textbook, the test is formatted as an initial and boundary value problem that provides a framework in which the roles of the various developments of this chapter and of the previous chapters can be appreciated.

7.1 Geometrical, kinematical and mechanical descriptors

Let a porous medium be constituted by a solid skeleton and a set of miscible or non miscible fluid species. In this chapter, the porous medium is viewed as a *closed* thermodynamic system: there may well be internal exchanges between species, or phases, of mass, momentum, energy and entropy. However the sum of the contributions over species vanishes.

The set of species of the porous medium is denoted by $\mathcal{K}$. Thus $\mathcal{K} = \{\mathrm{s}\} \cup \mathcal{K}^{**}$ where s denotes the solid skeleton and $\mathcal{K}^{**}$ the set of non miscible fluid species.

Phases represent the species when viewed as part of the mixture. The solid phase is also referred to as the solid skeleton. Following the classical approach of mixture theory, e.g., Bowen [1982], the phases are viewed as independent overlapping continua as sketched in Fig. 7.1.1. In fact, defining the phases from the set of species is part of the modeling. A phase may contain several species: the case of a fluid phase containing solutes (dissolved species) is addressed in relation with articular cartilages and cornea in Chapters 14 et seq. Conversely, a single species may be present in two or several phases, like in the double porosity model where the two fluid phases serve different transport purposes.

The simplest setting is standard poroelasticity where a solid is circulated by a non-reacting ideal fluid: here, species and phases are one and the same.

The volume occupied by the fluid phases is also called porosity. Volume fractions sum up to one,

$$\sum_{k\in\mathcal{K}} n^k = 1 \,. \tag{7.1.1}$$

Within the species, strains and stresses are called *intrinsic* while strains and stresses attached to the phases of the porous medium are said *apparent* or *partial*. Intrinsic and apparent quantities act at different levels or, say, scales. A distinction is made between species and mixture variables.

The intrinsic strain of the species k is denoted by $\boldsymbol{\epsilon}_k$, and its intrinsic stress by $\boldsymbol{\sigma}_k$. Their apparent counterparts are denoted by superscripts, $\boldsymbol{\epsilon}^k$ and $\boldsymbol{\sigma}^k = n^k\,\boldsymbol{\sigma}_k$ respectively. The intrinsic and apparent fluid stresses are respectively $\boldsymbol{\sigma}_k = -p_k\,\mathbf{I}$ and $\boldsymbol{\sigma}^k = -p^k\,\mathbf{I}$, p_k and $p^k = n^k\,p_k$ denoting the intrinsic and apparent fluid pressures. As a standard

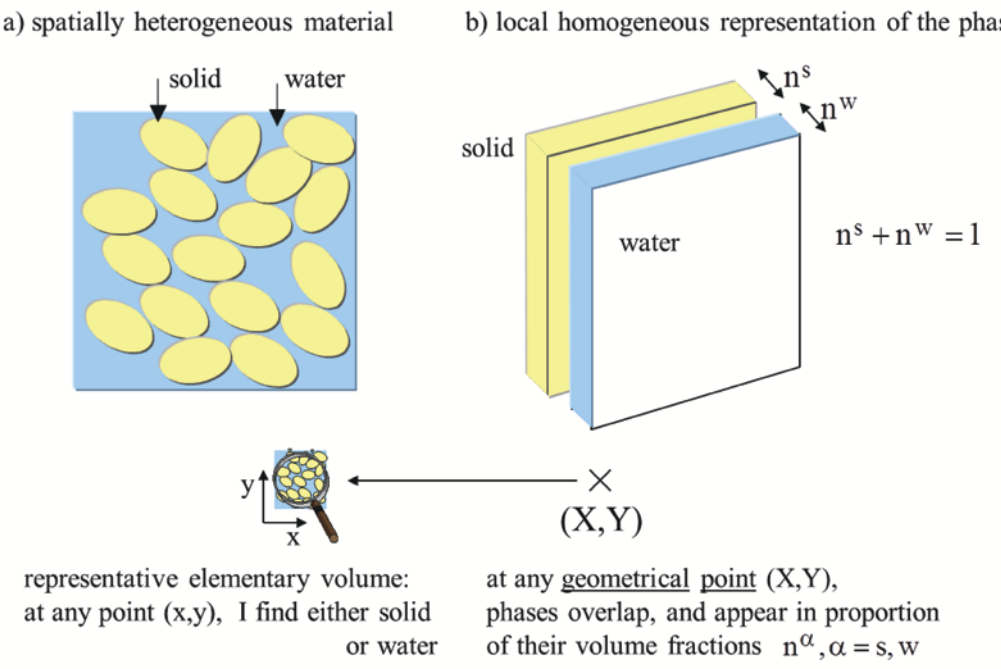

Fig. 7.1.1: While, in an actual material, a single species exists at any geometrical point, the mixture theory considers that all species are present at any point but in proportion with their volume fractions.

approximation to (4.5.7), the diffusive part of the total stress is neglected, and the total stress $\boldsymbol{\sigma}$ is then equal to the spatial (or areal) average of the intrinsic stresses, namely

$$\boldsymbol{\sigma} = \left\{ \begin{array}{rcl} n^{\rm s}\,\boldsymbol{\sigma}_{\rm s} + \displaystyle\sum_{k\in\mathcal{K}^{**}} n^k\,\boldsymbol{\sigma}_k & = & n^{\rm s}\,\boldsymbol{\sigma}_{\rm s} - \displaystyle\sum_{k\in\mathcal{K}^{**}} n^k\,p_k\,\mathbf{I}, \\ \boldsymbol{\sigma}^{\rm s} + \displaystyle\sum_{k\in\mathcal{K}^{**}} \boldsymbol{\sigma}^k & = & \boldsymbol{\sigma}^{\rm s} - \displaystyle\sum_{k\in\mathcal{K}^{**}} p^k\,\mathbf{I}\,. \end{array} \right. \tag{7.1.2}$$

The infinitesimal apparent strains are defined as the symmetrized gradients of the displacement fields $\mathbf{u}_k$,

$$\boldsymbol{\epsilon} = \boldsymbol{\epsilon}^{\rm s} = \frac{1}{2}\,(\mathbf{u}_{\rm s}\,\overleftarrow{\boldsymbol{\nabla}} + \overrightarrow{\boldsymbol{\nabla}}\,\mathbf{u}_{\rm s})\,; \quad \boldsymbol{\epsilon}^k = \frac{1}{2}\,(\mathbf{u}_k\,\overleftarrow{\boldsymbol{\nabla}} + \overrightarrow{\boldsymbol{\nabla}}\,\mathbf{u}_k), \quad k \in \mathcal{K}^{**}\,. \tag{7.1.3}$$

The apparent strain of the solid $\boldsymbol{\epsilon}^{\rm s}$ is also the strain of the solid skeleton $\boldsymbol{\epsilon}$, or mixture as a whole. Apparent strains and intrinsic strains of the species serve different purposes:

- the apparent strain $\boldsymbol{\epsilon} = \boldsymbol{\epsilon}^{\rm s}$ can be measured by observing, at the macroscopic scale, the deformation of a grid painted on the *solid skeleton*, with nodes moving at velocity $\mathbf{v}_{\rm s}$;
- intrinsic strains are attached to the *species*; no displacement field is defined to follow these microscopic motions.

The intrinsic strains of the solid constituent and of the fluid species are not treated on the same footing. For example, in absence of mass transfer and in an isothermal context, the incompressibility of the solid constituent implies a zero volumetric strain $\mathrm{tr}\,\boldsymbol{\epsilon}_{\rm s}$. The same cannot be said for fluid species: the volume changes because of the fluid compressibility, and because the fluid diffuses through the solid skeleton. Under these circumstances, the mass change vanishes only if the fluid remains attached to the solid skeleton, so-called *undrained condition*, which implies zero volume change only if the fluid is incompressible and thermally not dilatable.

Upscaling of the intrinsic strains results in

Proposition 7.1 The strain averaging relation.

The strain of the mixture, or solid skeleton, is obtained by spatial integration of the intrinsic strains of the constituents over a representative volume,

$$n^{\rm s}\,\mathrm{tr}\,\boldsymbol{\epsilon}_{\rm s} + \sum_{k\in\mathcal{K}^{**}} n^k\,\mathrm{tr}\,\boldsymbol{\epsilon}_k = \mathrm{tr}\,\boldsymbol{\epsilon}\,, \quad n^{\rm s}\,\mathrm{dev}\,\boldsymbol{\epsilon}_{\rm s} + \sum_{k\in\mathcal{K}^{**}} n^k\,\mathrm{dev}\,\boldsymbol{\epsilon}_k = \mathrm{dev}\,\boldsymbol{\epsilon}\,. \tag{7.1.4}$$

Consider a process where the solid skeleton undergoes a deformation of gradient $\mathbf{F}$. Then the intrinsic volumetric strain and variation of volume content (2.6.25) of each species are linked by the relation,

$$\det \mathbf{F}^{-1}\, \Delta v^k = n^k \operatorname{tr} \boldsymbol{\epsilon}_k, \quad k \in \mathcal{K}\,. \tag{7.1.5}$$

7.2 Elements of mixture theory: the level/scale of the species

The spatial and directional organizations at various length scales of the species constituting the mixture are of paramount significance for the overall response of the mixture. Still the physical properties of the species themselves are an important ingredient to this response. Table 7.2.1 serves to appreciate the typical orders of magnitude of the elastic moduli of the species and of the mixture of a few materials.

Table 7.2.1: Typical mechanical properties of some materials at room temperature and atmospheric pressure. t tensile; c: compressive; r: radial; or: orthoradial

Material	Volume Fraction of Water [-]	Modulus of Main Constituent [GPa]	Overall Bulk Modulus [MPa]	Shear Modulus [MPa]
Water	-	2.2	-	0
Articular cartilages	0.7 - 0.9	t: 0.1	t: 10; c: 0.2	0.1
Cornea	0.8 - 0.9	t: 0.1	or: 1; r: 10^{-3}	or: 10^{-2} ; r: 10^{-3}
Interstitium	0.2	-	0.1 - 0.5	10^{-2}
Sand	0 - 0.5	40	100	100
Marine Clay [(a)]	0.71	50	20	0.072
Halite (salt) [(a)]	0.001	23.5	20.7×10^3	12.4×10^3

[(a)] McTigue [1986]

7.2.1 Intrinsic properties of species

Let Δ denote the variation of any time dependent quantity $a = a(t)$ from its value $a_0 = a(0)$ in the initial state denoted by a subscript or superscript 0: $\Delta a \equiv a(t) - a_0$. In a linearized analysis about an unstressed and unstrained initial state, then simply $\Delta\boldsymbol{\sigma} = \boldsymbol{\sigma}$, $\Delta p_{\mathrm{w}} = p_{\mathrm{w}}$, $\Delta\boldsymbol{\epsilon} = \boldsymbol{\epsilon}$.

The mass transfers may be viewed as introducing a formal modification of the strain of the species,

$$\tilde{\boldsymbol{\epsilon}}^k = \Big(\operatorname{tr} \boldsymbol{\epsilon}^k - \int_0^t \frac{\hat{\rho}^k}{\rho^k}\, d\tau\Big)\, \frac{\mathbf{I}}{3} + \operatorname{dev} \boldsymbol{\epsilon}^k\,, \quad k \in \mathcal{K}\,. \tag{7.2.1}$$

Fluid mass transfers are governed by (electro)chemical potentials, as indicated by (4.7.31). To develop a constitutive equation of mass transfer for the solid, the notion of chemical potential tensor alluded for in Chapter 4 should be worked out. An alternative interpretation of the modified strains arises in the context of growth, addressed in Chapter 21: the rates of mass supply of the solid constituent are governed by growth laws.

The change of partial mass density can then be linearized to

$$\frac{\Delta\rho^k}{\rho_0^k} = -\operatorname{tr} \tilde{\boldsymbol{\epsilon}}^k\,, \quad k \in \mathcal{K}\,. \tag{7.2.2}$$

The incremental change of mass content results, namely

$$\zeta^k \equiv \frac{\Delta m^k}{\rho_k^0} = n^k\, (\operatorname{tr} \boldsymbol{\epsilon} - \operatorname{tr} \tilde{\boldsymbol{\epsilon}}^k), \quad k \in \mathcal{K}\,. \tag{7.2.3}$$

For the record, let us note several equivalent forms of the equation, emanating from the balance of mass of species (4.4.5), that governs the time evolution of the volume fraction n^k of a species $k \in \mathcal{K}$,

$$\begin{aligned}
&\frac{d^k n^k}{dt} + \frac{n^k}{\rho_k}\frac{d^k \rho_k}{dt} + n^k\big(\operatorname{div}\mathbf{v}_k - \frac{\hat\rho^k}{\rho^k}\big) = 0,\\
&\frac{d^k n^k}{dt} + \frac{n^k}{\rho_k}\frac{d^k \rho_k}{dt} + n^k \operatorname{tr}\frac{d\tilde{\boldsymbol{\epsilon}}^k}{dt} = 0,\\
&\frac{dn^k}{dt} + n^k \operatorname{div}\mathbf{v}_{\rm s} + \operatorname{div}\left(n^k\left(\mathbf{v}_k - \mathbf{v}_{\rm s}\right)\right) + \frac{n^k}{\rho_k}\frac{d^k \rho_k}{dt} - \frac{\hat\rho^k}{\rho_k} = 0,\\
&\frac{dn^k}{dt} + n^k \operatorname{div}\mathbf{v}_{\rm s} + \frac{n^k}{\rho_k}\frac{d\rho_k}{dt} - \frac{n^k}{m^k}\frac{dm^k}{dt} = 0\,.
\end{aligned} \tag{7.2.4}$$

If a constitutive equation governing the evolution of a volume fraction n need to be postulated, it should ensure that the volume fraction remains in the interval $[0,1]$. A simple way to satisfy this constraint is to set the rate dn/dt proportional to (some positive power of) $n\,(1-n)$.

7.2.1.1 Intrinsic properties of the fluid constituents

Fluid species are assumed to be a priori compressible and thermally dilatable. These properties are embedded in the relative change of the intrinsic mass density

$$\frac{\Delta\rho_k}{\rho_k^0} = \frac{\Delta p_k}{K_k} - c_{{\rm T}k}\,\Delta T_k\,, \quad k \in \mathcal{K}^{**}, \tag{7.2.5}$$

where

- K_k [unit : Pa] is the isothermal bulk modulus of the fluid k,

$$K_k = \rho_k^0 \frac{\Delta p_k}{\Delta\rho_k}_{|T_k}, \quad k \in \mathcal{K}^{**}\,; \tag{7.2.6}$$

- $c_{{\rm T}k}$ [unit : K^{-1}] its cubic coefficient of thermal expansion.

Fluid mass contents and volume-contents introduced in (2.6.25) are used as dependent or independent variables,

$$m^k = \rho^k \det\mathbf{F} = n^k\,\rho_k \det\mathbf{F} = \rho_k\,v^k, \quad v^k = n^k \det\mathbf{F}\,, \quad k \in \mathcal{K}^{**}, \tag{7.2.7}$$

from which follow the relations between rates,

$$\begin{aligned}
&\frac{1}{m^k}\frac{dm^k}{dt} = \frac{1}{\rho^k}\frac{d\rho^k}{dt} + \operatorname{div}\mathbf{v}_{\rm s} = \frac{1}{n^k}\frac{dn^k}{dt} + \frac{1}{\rho_k}\frac{d\rho_k}{dt} + \operatorname{div}\mathbf{v}_{\rm s} = \frac{1}{v^k}\frac{dv^k}{dt} + \frac{1}{\rho_k}\frac{d\rho_k}{dt},\\
&\frac{1}{v^k}\frac{dv^k}{dt} = \frac{1}{n^k}\frac{dn^k}{dt} + \operatorname{div}\mathbf{v}_{\rm s}\,, \quad k \in \mathcal{K}^{**}\,.
\end{aligned} \tag{7.2.8}$$

Therefore, since $dm^k/\rho_k = dv^k + v^k\,d\rho_k/\rho_k$, the (dimensionless) incremental change of the mass content of species k may be expressed in terms of the incremental changes of volume content, pressure and temperature of that species,

$$\begin{aligned}
\zeta^k \equiv \frac{\Delta m^k}{\rho_k^0} &= \Delta v^k + v^k\left(\frac{\Delta p_k}{K_k} - c_{{\rm T}k}\,\Delta T_k\right),\\
&\simeq \Delta v^k + n^k\left(\frac{\Delta p_k}{K_k} - c_{{\rm T}k}\,\Delta T_k\right), \quad k \in \mathcal{K}^{**}\,.
\end{aligned} \tag{7.2.9}$$

The basic thermodynamic functions, their inter-relations and differentials are listed in Table 7.2.2.
The expressions of the entropy, chemical potential, or free enthalpy, and internal energy of the compressible and thermally expansible fluid k are defined by (3.3.28), under mild restrictions on the thermomechanical coefficients. Upon linearization around a reference state (p_k^0, T_k^0), the incremental change of entropy is obtained from (3.3.30) and (7.2.5),

$$\rho_k^0\,(s_k - s_k^0) = -c_{{\rm T}k}\,(p_k - p_k^0) + \rho_k^0\,c_{{\rm p}k}\,\frac{T_k - T_k^0}{T_k^0}, \quad k \in \mathcal{K}^{**}\,. \tag{7.2.10}$$

Table 7.2.2: Thermodynamic measures of the state per unit mass [unit : J/kg = m^2/s^2] for the fluid constituent k endowed with temperature T_k, specific volume $1/\rho_k$ and pressure p_k.

Measure	Variables	Arbitrary Increment δ
Internal energy	$u_k = u_k(1/\rho_k, s_k)$	$\delta u_k = p_k\,\delta\rho_k/\rho_k^2 + T_k\,\delta s_k$
Free energy	$e_k = e_k(1/\rho_k, T_k) = u_k - T_k\,s_k$	$\delta e_k = p_k\,\delta\rho_k/\rho_k^2 - s_k\,\delta T_k$
Enthalpy	$h_k = h_k(p_k, s_k) = u_k + p_k/\rho_k$	$\delta h_k = \delta p_k/\rho_k + T_k\,\delta s_k$
Free enthalpy	$\mu_k = \mu_k(p_k, T_k) = h_k - T_k\,s_k$	$\delta\mu_k = \delta p_k/\rho_k - s_k\,\delta T_k$

In (7.2.10), c_{pk} [unit : J × kg^{-1} × K^{-1}] is the heat capacity at constant pressure per unit mass, linked to the heat capacity at constant volume per unit mass c_{vk} by $(3.3.18)_1$. This expression will be further approximated,

$$\begin{aligned} v_0^k\,\rho_k^0\,(s_k - s_k^0) &= -v_0^k\,c_{Tk}\,(p_k - p_k^0) + v_0^k\,\rho_k^0\,c_{pk}\,\frac{T_k - T_k^0}{T_k^0}, \\ S^k - S_0^k &= -n^k\,c_{Tk}\,(p_k - p_k^0) + C_p^k\,\frac{T_k - T_k^0}{T_k^0}\,, \end{aligned} \tag{7.2.11}$$

where

$$S^k = \rho^k s_k, \quad C_p^k = \rho^k c_{pk}\,, \tag{7.2.12}$$

are respectively the apparent entropy and apparent heat capacity of the fluid $k \in \mathcal{K}^{**}$ at constant pressure per unit (current) volume of mixture [unit : J × m^{-3} × K^{-1} =kg × m^{-1} × s^{-2} × K^{-1}].

Note also the rate relations between the internal energy and entropy, per unit mass and per unit volume, for any $k \in \mathcal{K}^{**}$,

$$\begin{aligned} \frac{du_k}{dt} &= T_k\,\frac{ds_k}{dt} - p_k\,\frac{d}{dt}(\frac{1}{\rho_k}), \\ \frac{dU^k}{dt} &= T_k\,\frac{dS^k}{dt} - E^k\,\mathrm{div}\,\mathbf{v}_s + \frac{\mu_k}{\det\mathbf{F}}\,\frac{dm^k}{dt} - \frac{p_k}{\det\mathbf{F}}\,\frac{dv^k}{dt}\,. \end{aligned} \tag{7.2.13}$$

Here E^k is the free energy per unit current volume of mixture, and μ_k the chemical potential, or free enthalpy, per unit current mass of the species k.

7.2.1.2 Intrinsic properties of the solid constituent

The solid constituent is endowed with the elastic tensor moduli $\mathbb{E}_s$ and with the tensor of thermal expansion $\mathbf{c}_{Ts}$. The constitutive equation,

$$\boldsymbol{\sigma}_s = \mathbb{E}_s : \boldsymbol{\epsilon}_s^e\,, \tag{7.2.14}$$

links the intrinsic stress $\boldsymbol{\sigma}_s$ to the 'effective' strain $\boldsymbol{\epsilon}_s^e$,

$$\boldsymbol{\epsilon}_s^e = \boldsymbol{\epsilon}_s - \mathbf{c}_{Ts}\,\Delta T_s - \Big(\int_0^t \frac{\hat{\rho}^s}{\rho^s}\Big)\,d\tau\,\frac{\mathbf{I}}{3}\,. \tag{7.2.15}$$

Since the intrinsic stress $\boldsymbol{\sigma}_s$ is related to the partial stress $\boldsymbol{\sigma}^s$ by $\boldsymbol{\sigma}^s = n^s\,\boldsymbol{\sigma}_s$, the change of volume content of the solid can be expressed in terms of total stress and pressures, namely using (7.1.2),

$$\begin{aligned} \det\mathbf{F}^{-1}\,\Delta\,v^s = n^s\,\mathrm{tr}\,\boldsymbol{\epsilon}_s &= n^s\,\mathbf{I} : \mathbb{E}_s^{-1} : \boldsymbol{\sigma}_s + n^s\,\mathrm{tr}\,\mathbf{c}_{Ts}\,\Delta T_s + n^s\int_0^t \frac{\hat{\rho}^s}{\rho^s}\,d\tau \\ &= \mathbf{I} : \mathbb{E}_s^{-1} : \boldsymbol{\sigma} + \frac{1}{K_s}\sum_{k\in\mathcal{K}^{**}} n^k\,p_k + n^s\,\mathrm{tr}\,\mathbf{c}_{Ts}\,\Delta T_s + n^s\int_0^t \frac{\hat{\rho}^s}{\rho^s}\,d\tau\,. \end{aligned} \tag{7.2.16}$$

Here K_s is the bulk modulus of the solid constituent,

$$\frac{1}{K_s} = \mathbf{I} : \mathbb{E}_s^{-1} : \mathbf{I}\,. \tag{7.2.17}$$

Note that the 'effective', or 'elastic', strain involved in the constitutive equations (7.2.14) is not the total strain of the solid constituent. The total strain is contributed additively by

- a mechanical strain, the isotropic part of which vanishes if the solid is elastically incompressible, namely $K_\mathrm{s} \to \infty$;
- a thermal strain, and
- a strain due to mass change.

The rate of change of the intrinsic mass density $\rho_\mathrm{s} = M_\mathrm{s}/V_\mathrm{s}$ of the solid constituent may be expressed in terms of the rate of change of the volume and of the rate of mass supply,

$$\begin{aligned} -\frac{1}{\rho_\mathrm{s}}\frac{d\rho_\mathrm{s}}{dt} &= \frac{1}{V_\mathrm{s}}\frac{dV_\mathrm{s}}{dt} - \frac{1}{M_\mathrm{s}}\frac{dM_\mathrm{s}}{dt} \\ &= \frac{d}{dt}\mathrm{tr}\,\boldsymbol{\epsilon}_\mathrm{s} - \frac{\hat{\rho}^\mathrm{s}}{\rho^\mathrm{s}}\,, \end{aligned} \tag{7.2.18}$$

where use has been made in differential form of the relation between the mass of the solid and the rate of mass supply,

$$\frac{M_\mathrm{s}(t)}{M_\mathrm{s}(0)} = \int_0^t \frac{\hat{\rho}^\mathrm{s}}{\rho^\mathrm{s}}\,d\tau\,. \tag{7.2.19}$$

Moreover

$$\begin{aligned} \frac{V_\mathrm{s}(t)}{V(0)} &= \frac{V_\mathrm{s}(0)}{V(0)}\,\det\mathbf{F}_\mathrm{s}(t) &&= n^\mathrm{s}(0)\,\det\mathbf{F}_\mathrm{s}(t) \\ &= \frac{V_\mathrm{s}(t)}{V(t)}\,\frac{V(t)}{V(0)} &&= n^\mathrm{s}(t)\,\det\mathbf{F}(t)\,, \end{aligned} \tag{7.2.20}$$

where $\mathbf{F}_\mathrm{s} = \mathbf{F}_\mathrm{s}(t)$ is the deformation gradient of the solid *species* giving rise to the infinitesimal strain $\boldsymbol{\epsilon}_\mathrm{s}$, as opposed to the deformation gradient $\mathbf{F} = \mathbf{F}(t)$ of the solid *skeleton* associated with the infinitesimal strain $\boldsymbol{\epsilon}$. Consequently, the volume fraction of the solid constituent varies according to the difference between the (macroscopic) strain of the solid skeleton and the (microscopic) strain of the solid constituent,

$$\frac{n^\mathrm{s}(t)}{n^\mathrm{s}(0)} = \frac{\det\mathbf{F}_\mathrm{s}}{\det\mathbf{F}} \simeq 1 + \mathrm{tr}\,\boldsymbol{\epsilon}_\mathrm{s} - \mathrm{tr}\,\boldsymbol{\epsilon}\,. \tag{7.2.21}$$

As a related result, an expression linking the change of the volume fraction of the fluid of a single porosity mixture to Terzaghi's effective stress is provided by Proposition 9.6, p. 295. Actual reports of measurements at the scale of the solid constituent are scarce. Moreover, the stiffness of the solid constituent is usually orders of magnitude larger than that of the porous medium. Therefore, the simplification below is sometimes adopted:

Proposition 7.2 The micro-isotropy assumption.

The solid particles are assumed to be randomly oriented and positioned in space so that the tensor of elastic moduli of the solid constituent is isotropic, with bulk modulus K_s and shear modulus μ_s, and so does the tensor of thermal expansion $\mathbf{c}_{\mathrm{T}\mathrm{s}} = \frac{1}{3}\,c_{\mathrm{T}\mathrm{s}}\,\mathbf{I}$,

$$\frac{1}{3}\,\mathrm{tr}\,\boldsymbol{\sigma}_\mathrm{s} = K_\mathrm{s}\,\mathrm{tr}\,\boldsymbol{\epsilon}_\mathrm{s}^\mathrm{e}\,, \quad \mathrm{dev}\,\boldsymbol{\sigma}_\mathrm{s} = 2\,\mu_\mathrm{s}\,\mathrm{dev}\,\boldsymbol{\epsilon}_\mathrm{s}\,. \tag{7.2.22}$$

Warning: linear and cubic coefficients of thermal expansion

The cubic or volumetric coefficient of thermal expansion is denoted by $c_{\mathrm{T}\mathrm{s}}$ for the solid constituent and by $c_{\mathrm{T}k}$ for the fluid k.

7.2.1.3 Incompressible and thermally not dilatable species

Mechanical incompressibility and absence of thermal expansion of one species[7.1], namely $\rho_k = \rho_k^0$, can be viewed as a special case. However, if all species are incompressible and thermally nondilatable, the velocity fields satisfy

[7.1] Actually, for a given fluid or elastic solid, the two properties are expected to be simultaneous. The case of fluids is considered in Section 3.3.2. Incompressibility $K = \infty$ is seen from (3.3.18) to imply a vanishing thermal dilatation coefficient c_T, in as far as the difference between heat capacities at constant pressure and constant volume is expected to remain finite. Still, the coefficient of thermal expansion of water changes sign at around 4 °C where the bulk modulus is finite, while the former becomes large and the latter small at the critical point as can be observed from Fig. 3.3.9.

Proposition 7.3 Constraint for incompressible and thermally nondilatable species.

$$\sum_{k\in\mathcal{K}} \operatorname{div}\left(n^k\,\mathbf{v}_k\right) = \operatorname{div}\mathbf{v}_{\rm s} + \sum_{k\in\mathcal{K}} \operatorname{div}\big(\underbrace{n^k\,(\mathbf{v}_k-\mathbf{v}_{\rm s})}_{\mathbf{J}_k}\big) = \sum_{k\in\mathcal{K}} \frac{\hat\rho^k}{\rho_k}\,. \tag{7.2.23}$$

This relation results from the summation of $(7.2.4)_3$ over species and use of the identity (7.1.1). It represents a kinematical constraint, which gives rise to a reaction stress (a pressure). The reaction stress is not defined by constitutive equations, but it is obtained in a boundary value problem, see Section 2.10.

An alternative linearized form, considering all time derivatives to be identical,

$$\sum_{k\in\mathcal{K}} n^k\,\operatorname{tr}\tilde{\boldsymbol{\epsilon}}^k = 0\,, \tag{7.2.24}$$

results from the summation of $(7.2.4)_2$ over species and use of the identity (7.1.1).

Quite generally, the volume change of the mixture may stem from

- the volume change of species themselves, due to mechanical or thermal loading;
- mass fluxes $\mathbf{J}_k$ crossing the boundary of the mixture;
- internal mass transfers, the change of volume being due to the fact that the densities of species are not identical;
- mass supplies from/towards the surroundings if the mixture is open.

For a solid saturated by a single fluid, the incremental change of fluid mass content is equal to,

$$\zeta^{\rm w} = \int_0^t \frac{\hat\rho^{\rm w}}{\rho_{\rm w}} - \operatorname{div}\mathbf{J}_{\rm w}\,d\tau = \operatorname{tr}\boldsymbol{\epsilon} - \int_0^t \frac{\hat\rho^{\rm s}}{\rho_{\rm s}}\,d\tau\,. \tag{7.2.25}$$

This relation is derived by introducing the constraint (7.2.23) in the balance of mass (4.4.9).

When mass transfers take place between species at identical intrinsic mass density, no overall volume change results. Then the right hand side of (7.2.23) vanishes, and (7.2.24) holds for the actual strains,

$$\sum_{k\in\mathcal{K}} n^k\,\operatorname{tr}\boldsymbol{\epsilon}^k = 0\,. \tag{7.2.26}$$

Consider again a solid saturated by a single fluid. Assume the solid skeleton to be endowed with the homogeneous velocity field $\mathbf{v}_{\rm s} = \mathbf{L}\cdot\mathbf{x}$, where the velocity gradient $\mathbf{L}$ is constant in space. The fluid flux $\mathbf{J}_{\rm w}$ is, to within a constant vector and a curl, equal to $-\mathbf{L}\cdot\mathbf{x}$.

7.2.2 Entropy production for a species

In order to structure the constitutive equations, we intend to derive first the contribution of a generic species $k\in\mathcal{K}$ to the entropy production. Although equivalent, the procedure is at variance with the derivation in Chapter 4 which concerned the mixture itself, that is, the contributions of all species were summed up directly.

The derivation uses the balance of mass in the forms (4.4.5) and (4.4.9), the balance of momentum (4.5.5), and of energy (4.6.11). Eliminating the heat term $\operatorname{div}\mathbf{Q}_k - \Theta_k$ with help of the energy equation, the entropy production (4.7.4) can be cast as the sum of three contributions,

$$\hat S^k_{\rm (i)} = \hat S^k_{\rm (i,1)} + \hat S^k_{\rm (i,2)} + \hat S^k_{\rm (i,3)}\,, \tag{7.2.27}$$

where

$$\begin{aligned}
\hat S^k_{\rm (i,1)} &= \frac{d}{dt}(\rho^k s_k) - \frac{1}{T_k}\frac{d}{dt}(\rho^k u_k) + \frac{1}{T_k}(\boldsymbol{\sigma}^k - \rho^k e_k\,\mathbf{I}) : \boldsymbol{\nabla}\mathbf{v}_{\rm s} + \frac{1}{\det\mathbf{F}}\frac{\mu_k}{T_k}\frac{dm^k}{dt};\\
\hat S^k_{\rm (i,2)} &= -\frac{\hat\rho^k}{T_k}\,(\mu_k + \frac{1}{2}(\mathbf{v}_k-\mathbf{v}_{\rm s})^2 - \frac{1}{2}\mathbf{v}_{\rm s}^2) - \frac{\hat{\mathbf{p}}^k}{T_k}\cdot\mathbf{v}_{\rm s} + \frac{\hat U^k}{T_k} - \hat S^k;\\
\hat S^k_{\rm (i,3)} &= -\Big(\frac{\mathbf{Q}_k}{T_k} + s_k\,\mathbf{M}_k\Big)\cdot\frac{\boldsymbol{\nabla}T_k}{T_k} - \frac{\mathbf{M}_k}{T_k}\cdot(\boldsymbol{\nabla}\mu_k + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k)\,.
\end{aligned} \tag{7.2.28}$$

Here $\hat\rho^k$, $\hat{\mathbf{p}}^k$, $\hat U^k$ and $\hat S^k$ are the total volume supply rates of mass, momentum, energy and entropy to the species k as defined by Eqns (4.4.2), (4.5.3), (4.6.9), and (4.7.3), respectively, namely

$$\begin{aligned}\hat{\mathbf{p}}^k &= \hat\rho^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol\pi}^k,\\ \hat U^k &= \hat\rho^k\,(\tilde u_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2) + \hat{\boldsymbol\pi}^k\cdot\mathbf{v}_k + \hat{\mathcal U}^k,\\ \hat S^k &= \hat\rho^k\,\tilde s_k + \hat{\mathcal S}^k\,.\end{aligned} \tag{7.2.29}$$

For a closed system, and in absence of surface supply rates, the volume supply rates of mass, momentum, energy and entropy sum to zero, Eqn (4.3.8),

$$\sum_{k\in\mathcal K}\hat\rho^k = 0,\quad \sum_{k\in\mathcal K}\hat{\mathbf{p}}^k = 0,\quad \sum_{k\in\mathcal K}\hat U^k = 0,\quad \sum_{k\in\mathcal K}\hat S^k = 0\,. \tag{7.2.30}$$

In (7.2.28), the terms involving the chemical potentials apply to the fluid species $k\in\mathcal K^{**}$ only, which actually have been assumed to be ideal fluids.

The superimposed tilde characterizes a property of the mass just before or at the time of transfer, while the superimposed hat denotes a supply rate in the form of mass, momentum or in other forms.

Remark on the rate of dissipation due to generalized diffusion:

Using the increment of chemical potential of fluid species, Table 7.2.2, namely

$$\delta\mu_k = \frac{\delta p_k}{\rho_k} - s_k\,\delta T_k\,, \tag{7.2.31}$$

and the volume flux $\mathbf{J}_k = \mathbf{M}_k/\rho_k$ instead of the mass flux $\mathbf{M}_k$, the contribution associated with diffusion of fluid species can be recast as,

$$\hat S^k_{(\mathrm{i},3)} = -\frac{\mathbf{Q}_k}{T_k}\cdot\frac{\boldsymbol\nabla T_k}{T_k} - \frac{\mathbf{J}_k}{T_k}\cdot\Big(\boldsymbol\nabla p_k + \rho_k\,(\frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k)\Big)\,. \tag{7.2.32}$$

Remark on the mechanical entropy production:

The mechanical entropy production is dealt with in two manners:

- either in the current configuration, as indicated on $(7.2.28)_1$. It then features Eshelby stress $\boldsymbol\sigma^{\mathrm{E}k} = \boldsymbol\sigma^k - \rho^k e_k\,\mathbf{I}$. However, most often, the distinction between Eshelby stress and Cauchy stress is neglected. Still, the issue is considered in Section 9.1.5;
- or in a reference configuration.

Upon multiplication of $(7.2.28)_1$ by $\det\mathbf{F}$, the entities that come into picture are

- mass contents $m^k = \det\mathbf{F}\,\rho^k$, $k\in\mathcal K^{**}$, rather than mass densities ρ^k, $k\in\mathcal K^{**}$;
- volume contents $v^k = \det\mathbf{F}\,n^k$, $k\in\mathcal K^{**}$ rather than volume fractions n^k, $k\in\mathcal K^{**}$;
- apparent pressures $v^k\,p_k = \det\mathbf{F}\,p^k$, $k\in\mathcal K^{**}$, rather than apparent pressures $n^k\,p_k = p^k$, $k\in\mathcal K^{**}$;
- Kirchhoff stresses $\boldsymbol\tau = \det\mathbf{F}\,\boldsymbol\sigma$ and $\boldsymbol\tau^k = \det\mathbf{F}\,\boldsymbol\sigma^k$, $k\in\mathcal K$, rather than Cauchy stresses $\boldsymbol\sigma$ and $\boldsymbol\sigma^k$, $k\in\mathcal K$;
- entropy per unit reference volume of mixture $\underline{S}^k = m^k\,s_k$, $k\in\mathcal K$, rather than entropy per unit current volume of mixture $S^k = \rho^k\,s_k$, $k\in\mathcal K$;
- entropy production per unit reference volume of mixture $\underline{\hat S}^k_{(\mathrm{i})}$, $k\in\mathcal K$, rather than entropy production per unit current volume of mixture $\hat S^k_{(\mathrm{i})}$, $k\in\mathcal K$;
- the free energy per reference volume $\underline{E}$ instead of the free energy per current volume E.

In particular, the relations (7.1.2) turn to,

$$\boldsymbol\tau = \boldsymbol\tau^{\mathrm{s}} + \sum_{k\in\mathcal K^{**}}\boldsymbol\tau^k = \boldsymbol\tau^{\mathrm{s}} - \sum_{k\in\mathcal K^{**}} v^k\,p_k\,\mathbf{I}\,. \tag{7.2.33}$$

In the theoretical developments, we adopt

Definition (ULC) *Updated Lagrangian configuration:*

When the current configuration is taken as reference, that is $\det\mathbf{F}$ is set equal to 1, these two families of entities are equal. However, their increments and rates are *not* identical.

Isothermal and nonisothermal mixtures in local thermal equilibrium or nonequilibrium, including a solid matrix and one or two fluids, are considered in Chapter 10 as particular cases of the framework described here.

Remark on the mechanical entropy production for a perfect fluid:

For a perfect fluid, the mechanical entropy production $\hat S_{(\mathrm{i},1)}$, Eqn $(7.2.28)_1$, simplifies to $p_k/T_k\,dn^k/dt$.

7.3 Anisotropic poroelasticity: a composite material format

7.3.1 Mechanical, viscous and inertial couplings

The mixture theory of fluid-saturated porous media involves three types of coupling between the fluids and the solid:

- mechanical coupling described in terms of stress-strain constitutive equations where the apparent stress of each phase (species) depends on the apparent strains of all phases (species);
- viscous coupling, described in terms of relative velocities of a fluid phase with respect to the solid, and defined through Darcy's law and other possible effects, and
- inertial coupling, described in terms of accelerations, Biot [1956].

Viscous coupling is not involved in the analysis of acceleration waves which yields information on the nature of the regime of the field equations. On the other hand, inertial coupling comes into the picture, changing not that much the wave-speeds themselves, rather the kinematics. The "raison d'être" of inertial coupling is the following: to accelerate a body in a fluid, one must exert a force as if the fluid would not provide resistance, plus the additional force to move part of the fluid. For a two phase porous medium, the balances of linear momentum can be cast in the following format, Eqn (4.5.5):

$$\begin{array}{ccccccccc} \overbrace{\operatorname{div}\boldsymbol{\sigma}^{\mathrm{s}}}^{\substack{\text{mechanical}\\ \text{coupling}}} & + & \overbrace{\hat{\rho}^{\mathrm{s}}\,(\tilde{\mathbf{v}}_{\mathrm{s}}-\mathbf{v}_{\mathrm{s}})+\hat{\boldsymbol{\pi}}^{\mathrm{s}}}^{\substack{\text{viscous}\\ \text{coupling}}} & + & \rho^{\mathrm{s}}\,\mathbf{b}_{\mathrm{s}} & = & \rho^{\mathrm{ss}}\,\mathbf{a}_{\mathrm{s}} & + & \overbrace{\rho^{\mathrm{sw}}\,\mathbf{a}_{\mathrm{w}}}^{\substack{\text{inertial}\\ \text{coupling}}} \\ \operatorname{div}\boldsymbol{\sigma}^{\mathrm{w}} & + & \hat{\rho}^{\mathrm{w}}\,(\tilde{\mathbf{v}}_{\mathrm{w}}-\mathbf{v}_{\mathrm{w}})+\hat{\boldsymbol{\pi}}^{\mathrm{w}} & + & \underbrace{\rho^{\mathrm{w}}\,\mathbf{b}_{\mathrm{w}}}_{\text{body force}} & = & \underbrace{\rho^{\mathrm{ww}}\,\mathbf{a}_{\mathrm{w}}}_{\text{acceleration}} & + & \rho^{\mathrm{ws}}\,\mathbf{a}_{\mathrm{s}} \end{array} \tag{7.3.1}$$

Here the **a**'s are the accelerations. For each phase, the viscous term represents the momentum supply to that phase by the rest of the mixture. It is provided through constitutive equations, Section 7.3.2. For a closed mixture, momentum supplies satisfy the constraint (4.5.2), namely,

$$\sum_{k=\mathrm{s,w}} \hat{\rho}^{k}\,\tilde{\mathbf{v}}_{k}+\hat{\boldsymbol{\pi}}^{k}=\mathbf{0}\,. \tag{7.3.2}$$

Inertial coupling is introduced through the out-of-diagonal coefficients ρ^{sw} and ρ^{ws}. Biot [1956] presents physical arguments that restrict the range of these coefficients, which are equal because the kinetic energy is assumed to be a symmetric quadratic function of the velocities. Consistency with a process with equal accelerations of the two phases requires,

$$\rho^{\mathrm{ss}}=\rho^{\mathrm{s}}-\rho^{\mathrm{sw}},\quad \rho^{\mathrm{ww}}=\rho^{\mathrm{w}}-\rho^{\mathrm{ws}}\,. \tag{7.3.3}$$

Moreover, if the solid was accelerated while the fluid was kept motionless, the force to be exerted on the fluid would be in opposite direction to the acceleration of the solid: hence

$$\rho^{\mathrm{sw}}=\rho^{\mathrm{ws}}\leq 0\,. \tag{7.3.4}$$

As a consequence,

$$\rho^{\mathrm{ss}}>0\,,\quad \rho^{\mathrm{ww}}>0\,,\quad \rho^{\mathrm{ss}}\rho^{\mathrm{ww}}-(\rho^{\mathrm{sw}})^{2}>0\,, \tag{7.3.5}$$

and the mass matrix $\mathbf{M}$, or equivalently the kinetic energy, is positive definite (P.D.):

$$\mathbf{M}=\begin{bmatrix} \rho^{\mathrm{ss}}\,\mathbf{I} & \rho^{\mathrm{sw}}\,\mathbf{I} \\ \rho^{\mathrm{ws}}\mathbf{I} & \rho^{\mathrm{ww}}\mathbf{I} \end{bmatrix}=\mathbf{M}^{\mathrm{T}}\quad \text{P.D.} \tag{7.3.6}$$

Notice that the above inequalities do not furnish a bound for the coupling coefficient $\rho^{\mathrm{sw}}=\rho^{\mathrm{ws}}$: they are actually implied by the negative sign of this coefficient.

There is no definitive method to estimate the coupling coefficient. It is usually related to a *structural factor* or *tortuosity factor* τ in the form,

$$\rho^{\mathrm{sw}}=-(\frac{1}{\tau}-1)\,\rho^{\mathrm{w}}\,. \tag{7.3.7}$$

When the porosity n^{w} is not too small, the tortuosity factor might be correlated to n^{w} through a power law, Sen et al. [1981], Johnson et al. [1982], Gajo [1996],

$$\tau=\sqrt{n^{\mathrm{w}}}\,. \tag{7.3.8}$$

7.3.2 Momentum supplies and Darcy's law

The approach followed in this work consists in trying to unveil the ingredients that allow to satisfy the entropy production. Generalized diffusion may be introduced through a diffusion matrix which should be positive (semi-)definite, but is otherwise arbitrary: the key equation is the entropy production associated with diffusion, Eqn (4.7.32). Examples, in presence of generalized diffusion, are worked out in Chapter 16. The momentum supplies are elusive in this approach, but they can be recovered once the constitutive equations governing mechanics, generalized diffusion, transfers and growth have been defined.

An alternative, pursued by Bowen in his papers, e.g., Bowen [1976], consists in

1. defining the primary variables,
2. expanding the dependent constitutive functions in terms of the latter;
3. restricting the ranges of the parameters by ensuring a positive entropy production.

To illustrate these two approaches, the ways Darcy's law is postulated by Bowen and in this work are contrasted.

In presence of body forces $\mathbf{b}_{\rm w}$, e.g., gravity $\mathbf{b}_{\rm w} = \mathbf{g}$, the momentum balance for a fluid phase with intrinsic pressure $p_{\rm w}$ and volume fraction $n^{\rm w}$, is expressed in the format, Eqn (4.5.5),

$$-\boldsymbol{\nabla}(n^{\rm w}\, p_{\rm w}) + \hat{\rho}^{\rm w}(\tilde{\mathbf{v}}_{\rm w} - \mathbf{v}_{\rm w}) + \hat{\boldsymbol{\pi}}^{\rm w} + \rho^{\rm w}\,(\mathbf{b}_{\rm w} - \frac{d^{\rm w}\mathbf{v}_{\rm w}}{dt}) = \mathbf{0}, \tag{7.3.9}$$

where the extended momentum supply $\hat{\rho}^{\rm w}(\tilde{\mathbf{v}}_{\rm w} - \mathbf{v}_{\rm w}) + \hat{\boldsymbol{\pi}}^{\rm w}$ is taken as the sum of a buoyancy term and of a Stokes' drag proportional to the velocity of the solid relative to the fluid $\mathbf{v}_{\rm s} - \mathbf{v}_{\rm w}$,

$$\hat{\rho}^{\rm w}\,(\tilde{\mathbf{v}}_{\rm w} - \mathbf{v}_{\rm w}) + \hat{\boldsymbol{\pi}}^{\rm w} = p_{\rm w}\boldsymbol{\nabla} n^{\rm w} + k_{\rm Sd}\,(\mathbf{v}_{\rm s} - \mathbf{v}_{\rm w})\,. \tag{7.3.10}$$

The momentum balance of the fluid becomes

$$-\,n^{\rm w}\boldsymbol{\nabla} p_{\rm w} + k_{\rm Sd}\,(\mathbf{v}_{\rm s} - \mathbf{v}_{\rm w}) + \rho^{\rm w}\,(\mathbf{b}_{\rm w} - \frac{d^{\rm w}\mathbf{v}_{\rm w}}{dt}) = \mathbf{0}\,, \tag{7.3.11}$$

which leads to the standard form of Darcy's law for the fluid flux,

$$\mathbf{J}_{\rm w} \equiv n^{\rm w}\,(\mathbf{v}_{\rm w} - \mathbf{v}_{\rm s}) = -k_{\rm H}\left(\boldsymbol{\nabla} p_{\rm w} + \rho_{\rm w}\,(\frac{d^{\rm w}\mathbf{v}_{\rm w}}{dt} - \mathbf{b}_{\rm w})\right). \tag{7.3.12}$$

In fact, Darcy's law may be expressed in various forms that are linked through the relations,

$$k_{\rm H} = \frac{K_{\rm H}}{\rho_{\rm w} g} = \frac{k_{\rm in}}{\eta_{\rm w}} = \frac{(n^{\rm w})^2}{k_{\rm Sd}}, \tag{7.3.13}$$

which involve

- the *intrinsic hydraulic permeability* $k_{\rm in}$ [unit : $\rm m^2$], a property of the porous medium architecture, also expressed in darcy, or millidarcy, 1 darcy=$0.987 \times 10^{-12}\,\rm m^2$;
- the *hydraulic conductivity* $K_{\rm H}$ [unit : $\rm m \times s^{-1}$];
- the *hydraulic permeability* $k_{\rm H}$ [unit : $\rm m^2 \times Pa^{-1} \times s^{-1} = kg^{-1} \times m^3 \times s$];
- the *coefficient of Stokes' drag* $k_{\rm Sd}$ [unit : $\rm kg \times m^{-3} \times s^{-1}$],

some properties of the fluid,

- the intrinsic density of water $\rho_{\rm w}$ [unit : $\rm kg/m^3$];
- the *dynamic viscosity* of water $\eta_{\rm w}$ [unit : Pa×s=kg/m/s=10^3 centipoise cP]. It is equal to 1 cP at ambient temperature, and decreases considerably as the temperature increases as shown in Table 3.3.1. The dynamic viscosity should be distinguished from the *kinematic viscosity* [unit : $\rm m^2/s$],

$$\nu_{\rm w} = \frac{\eta_{\rm w}}{\rho_{\rm w}}\,, \tag{7.3.14}$$

as well as the acceleration of gravity $g = 9.81\,\rm m/s^2$.

The time scale of seepage is quantified via the hydraulic diffusivity [unit : $\rm m^2/s$] which is defined as the product of the hydraulic permeability by an elastic modulus: a specific example is worked out in Section 9.5. Typical coefficients pertaining to seepage in porous media are displayed in Table 7.3.1.

Table 7.3.1: Indicative properties linked to seepage through some porous materials.

Material	Hydraulic Permeability [m^2/Pa/s]	Elastic Modulus [Pa]	Hydraulic Diffusivity [m^2/s]	Reference
Articular cartilages	10^{-15}	10^6	10^{-9}	Armstrong et al. [1984]
Tumor tissues	3×10^{-14}	10^5	3×10^{-9}	Netti et al. [1995]
Clay	2×10^{-13}	2×10^7	4×10^{-6}	McTigue [1986]
Clay liner	$10^{-18} - 10^{-17}$		$10^{-12} - 10^{-11}$	
Halite (salt)	10^{-18}	37×10^9	0.16×10^{-6}	McTigue [1986]

The dependence of the intrinsic permeability on the void geometry is worked out in Section 15.7. and values for soft tissues are provided in Chapters 14 and 19.

Remark on the gravity contribution:

Under static conditions, the flow is driven by the stimulus $\boldsymbol{\nabla} p_{\rm w} - \rho_{\rm w}\,\mathbf{g}$. Over small vertical distances, one may often neglect the gravity component with respect to the pressure gradient. Therefore, one may conclude that water flows from locations of large pressures to locations of low pressures. Now, consider a glass filled of water at rest. Even if the pressure increases downwards, water does not move up. In fact the reason is that the hydraulic head $p_{\rm w}/(\rho_{\rm w}\,g) + x_3$, with x_3 vertical coordinate counted positive upwards, vanishes. Therefore, one should actually be more accurate and refer to the hydraulic head, rather than to the pressure, as the driving gradient. See Section 15.7.3 for elaboration in the case of a compressible fluid.

7.3.3 Temperature dependence of the viscosity coefficient of liquids and gases

The dynamic viscosity of liquids decreases significantly as the temperature increases:

- as indicated in Table 3.3.1, the dynamic viscosity of *water* decreases from 1.791 cP at 0 °C to 0.282 cP at 100 °C. It can be approximated from the triple point to a neighborhood of the critical point through the expression ($\eta_{\rm w}$ in cP, T in K), Burger et al. [1985],

$$\eta_{\rm w} = 10^{247.8/(T-140)-1.62}\,; \tag{7.3.15}$$

- the dynamic viscosity of *blood* increases in an affine way with the hematocrit content, Stammers et al. [2003]. At 37 °C, it is about 3 to 4 cP. A decrease of temperature of 1 °C results in an increase of about 2%;
- the dynamic viscosity of *brine* departs from that of water in proportion of its salt content. It is a bit larger than that of pure water but it follows the same trend;
- the decrease of *bitumen* viscosity with temperature is considerable, from 10^7 cP at 10 °C to 10^1 cP at 200 °C.

As for *gases*, their viscosity increases as temperature increases. Mandel [1966], p. 297, refers to the approximate formula $\eta = A\sqrt{T}/(1 + B/T)$. For dry air: $A = 1.42 \times 10^{-3}$ cP, $B = 102.5$ K so that, at 100 °C, η=0.021 cP. These opposite trends for liquids and gases may be observed in Fig. 3.3.11 which displays the viscosity of liquid water and steam along the equilibrium curve.

The effect of pressure on the dynamic viscosity of liquids is significant at very high pressures only: for instance, the dynamic viscosity of oils is multiplied by 2 for a pressure change from 0 to 30 MPa and by 10 for a pressure change from 0 to 100 MPa.

7.3.4 Momentum supplies, the viscous fluid and Brinkman's law

The derivation of Darcy's law was concerned with a macroscopically inviscid fluid. Still, fluid viscosity is accounted for at a microscale to satisfy the boundary conditions of the flow. The more general case of a macroscopically viscous fluid is considered now.

The apparent fluid stress,

$$\boldsymbol{\sigma}^{\rm w} = -n^{\rm w}\,p_{\rm w}\,\mathbf{I} + 2\,n^{\rm w}\,\eta_{\rm w}\,\frac{d^{\rm w}\boldsymbol{\epsilon}^{\rm w}}{dt}\,, \tag{7.3.16}$$

expresses in terms of the intrinsic fluid pressure $p_{\rm w}$, coefficient of viscosity $\eta_{\rm w}$ and strain rate,

$$\frac{d^{\rm w}\boldsymbol{\epsilon}^{\rm w}}{dt} = \frac{1}{2}\left(\boldsymbol{\nabla}\mathbf{v}_{\rm w} + (\boldsymbol{\nabla}\mathbf{v}_{\rm w})^{\rm T}\right). \tag{7.3.17}$$

The balance of momentum,

$$\operatorname{div} \boldsymbol{\sigma}^{\mathrm{w}} + \hat{\rho}^{\mathrm{w}}(\tilde{\mathbf{v}}_{\mathrm{w}} - \mathbf{v}_{\mathrm{w}}) + \hat{\boldsymbol{\pi}}^{\mathrm{w}} + \rho^{\mathrm{w}} \left(\mathbf{b}_{\mathrm{w}} - \frac{d^{\mathrm{w}}\mathbf{v}_{\mathrm{w}}}{dt}\right) = \mathbf{0}\,, \tag{7.3.18}$$

becomes, neglecting the change of volume fraction in the viscous term,

$$-\,p_{\mathrm{w}}\boldsymbol{\nabla} n^{\mathrm{w}} - n^{\mathrm{w}}\boldsymbol{\nabla} p_{\mathrm{w}} + n^{\mathrm{w}}\,\eta_{\mathrm{w}}\left(\boldsymbol{\nabla}^2\,\mathbf{v}_{\mathrm{w}} + \boldsymbol{\nabla}\,(\operatorname{div}\mathbf{v}_{\mathrm{w}})\right) + \hat{\rho}^{\mathrm{w}}(\tilde{\mathbf{v}}_{\mathrm{w}} - \mathbf{v}_{\mathrm{w}}) + \hat{\boldsymbol{\pi}}^{\mathrm{w}} + \rho^{\mathrm{w}}\left(\mathbf{b}_{\mathrm{w}} - \frac{d^{\mathrm{w}}\mathbf{v}_{\mathrm{w}}}{dt}\right) = \mathbf{0}\,. \tag{7.3.19}$$

The momentum supply $\hat{\boldsymbol{\pi}}^{\mathrm{w}}$ is modified with respect to (7.3.10) due to the additional viscous term via the tortuosity factor $\tau < 1$,

$$\hat{\rho}^{\mathrm{w}}(\tilde{\mathbf{v}}_{\mathrm{w}} - \mathbf{v}_{\mathrm{w}}) + \hat{\boldsymbol{\pi}}^{\mathrm{w}} = p_{\mathrm{w}}\boldsymbol{\nabla} n^{\mathrm{w}} + k_{\mathrm{Sd}}\,(\mathbf{v}_{\mathrm{s}} - \mathbf{v}_{\mathrm{w}}) + (\frac{1}{\tau} - 1)\,n^{\mathrm{w}}\,\eta_{\mathrm{w}}\left(\boldsymbol{\nabla}^2\,\mathbf{v}_{\mathrm{w}} + \boldsymbol{\nabla}\,(\operatorname{div}\mathbf{v}_{\mathrm{w}})\right). \tag{7.3.20}$$

The balance of momentum of the fluid turns to,

$$-\,n^{\mathrm{w}}\boldsymbol{\nabla} p_{\mathrm{w}} + \frac{n^{\mathrm{w}}}{\tau}\,\eta_{\mathrm{w}}\big(\boldsymbol{\nabla}^2\,\mathbf{v}_{\mathrm{w}} + \boldsymbol{\nabla}\,(\operatorname{div}\mathbf{v}_{\mathrm{w}})\big) + k_{\mathrm{Sd}}\,(\mathbf{v}_{\mathrm{s}} - \mathbf{v}_{\mathrm{w}}) + \rho^{\mathrm{w}}\left(\mathbf{b}_{\mathrm{w}} - \frac{d^{\mathrm{w}}\mathbf{v}_{\mathrm{w}}}{dt}\right) = \mathbf{0}\,, \tag{7.3.21}$$

or, with the definitions (7.3.13),

$$n^{\mathrm{w}}\,(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) = -k_{\mathrm{H}}\left(\boldsymbol{\nabla} p_{\mathrm{w}} + \rho_{\mathrm{w}}\,(\frac{d^{\mathrm{w}}\mathbf{v}_{\mathrm{w}}}{dt} - \mathbf{b}_{\mathrm{w}})\right) + \frac{k_{\mathrm{in}}}{\tau}\left(\boldsymbol{\nabla}^2\,\mathbf{v}_{\mathrm{w}} + \boldsymbol{\nabla}\,(\operatorname{div}\mathbf{v}_{\mathrm{w}})\right). \tag{7.3.22}$$

Analyses accounting for this macroscopic viscosity usually consider a rigid solid skeleton $\operatorname{div}\mathbf{v}_{\mathrm{s}} = 0$ and an incompressible fluid $\operatorname{div}\mathbf{v}_{\mathrm{w}} = 0$, which simplifies somehow the modification with respect to Darcy's law. The resulting expression of the fluid flux is referred to as Brinkman's law or Brinkman's modification of Darcy's law. This terminology is in fact misleading because the formula merely introduces a viscous fluid. Besides, the paper of Brinkman [1947] actually targeted the dependence of the intrinsic permeability with respect to the fluid volume fraction as indicated by (15.7.40).

7.3.5 Derivation of the momentum equations via Hamilton's principle

An alternative derivation of the equations of momentum balance (7.3.1) may be obtained via the Hamilton's principle, or directly via the resulting Lagrange equations. The energies which come into picture should first be listed, namely,

- the kinetic energy of the body V,

$$\mathbb{C} = \sum_{k,l}^{\mathrm{s,w}} \int_V \frac{1}{2}\,\rho^{kl}\,\mathbf{v}_l^2\,dV\,; \tag{7.3.23}$$

- the total potential energy, equal to the elastic energy minus the potential of the external conservative forces, namely body force $\mathbf{b}_k$ and traction $\overline{\mathbf{t}}^k$ over the surface $\partial V_{\overline{t}}$,

$$\begin{aligned}\mathbb{W} &= \sum_{k}^{\mathrm{s,w}} \int_V \boldsymbol{\sigma}^k : \boldsymbol{\epsilon}^k - \rho^k\,\mathbf{b}_k\cdot\mathbf{u}_k\,dV - \int_{\partial V_{\overline{t}}} \overline{\mathbf{t}}^k\cdot\mathbf{u}_k\,dS \\ &= \sum_{k}^{\mathrm{s,w}} \int_V -\operatorname{div}\boldsymbol{\sigma}^k\cdot\mathbf{u}_k - \rho^k\,\mathbf{b}_k\cdot\mathbf{u}_k\,dV + \int_{\partial V} \mathbf{t}^k\cdot\mathbf{u}_k\,dS - \int_{\partial V_{\overline{t}}} \overline{\mathbf{t}}^k\cdot\mathbf{u}_k\,dS\,;\end{aligned} \tag{7.3.24}$$

- since $\boldsymbol{\nabla}\mu_{\mathrm{w}} = \boldsymbol{\nabla} p_{\mathrm{w}}/\rho_{\mathrm{w}}$ according to Table 7.2.2, the pointwise dissipation $T\hat{S}_{(\mathrm{i},3)}$ due to seepage (4.7.32) simplifies to

$$T\hat{S}_{(\mathrm{i},3)} = -\mathbf{M}_k\cdot\Big(\frac{\boldsymbol{\nabla} p_{\mathrm{w}}}{\rho_{\mathrm{w}}} + \frac{d^{\mathrm{w}}\mathbf{v}_{\mathrm{w}}}{dt} - \mathbf{b}_{\mathrm{w}}\Big), \tag{7.3.25}$$

and the dissipation potential $\mathbb{D}$ becomes in view of (7.3.11).

$$\mathbb{D} = \int_V \frac{1}{2}\,k_{\mathrm{Sd}}\,(\mathbf{v}_{\mathrm{s}} - \mathbf{v}_{\mathrm{w}})^2\,dV\,. \tag{7.3.26}$$

With $\mathbf{q} = [\mathbf{u}_{\mathrm{s}}\,\mathbf{u}_{\mathrm{w}}]^{\mathrm{T}}$ the generalized coordinate vector, and $\dot{\mathbf{q}} = [\mathbf{v}_{\mathrm{s}}\,\mathbf{v}_{\mathrm{w}}]^{\mathrm{T}}$ its derivative following the solid, the Lagrange equations,

$$\frac{d}{dt}\frac{\partial\mathbb{C}}{\partial\dot{\mathbf{q}}} - \frac{\partial\mathbb{C}}{\partial\mathbf{q}} + \frac{\partial\mathbb{W}}{\partial\mathbf{q}} = -\frac{\partial\mathbb{D}}{\partial\dot{\mathbf{q}}}\,, \tag{7.3.27}$$

yield, besides traction boundary conditions, a simplified form of the pointwise momentum equations (7.3.1), where the convective contributions to the acceleration terms and the spatial heterogeneity of the volume fraction have been neglected, Biot [1962].

7.3.6 Anisotropic poroelasticity in terms of apparent stresses and strains

There are several ways to introduce linear poroelasticity. One method, following Bowen [1976], consists in choosing apparent stresses $(\boldsymbol{\sigma}^{\rm s}, \boldsymbol{\sigma}^{\rm w})$ and strains $(\boldsymbol{\epsilon}^{\rm s}, \boldsymbol{\epsilon}^{\rm w})$ as work-conjugate variables. Let us recall that apparent (or partial) stresses $\boldsymbol{\sigma}^k$ are linked to the intrinsic stresses $\boldsymbol{\sigma}_k$ through the volume fractions n^k, namely $\boldsymbol{\sigma}^k = n^k\,\boldsymbol{\sigma}_k$, and similarly for the apparent fluid pressure $p^k = n^k\,p_k$ and the intrinsic fluid pressure p_k. Such an approach is appropriate when the velocities and balances of momentum of all species are required in explicit form. For example, when the inertial terms of both solid and fluid matter, e.g., for the analysis of the propagation of second order waves, Loret and Prévost [1991], or of first order waves, Radi and Loret [2007] [2008].

Another method, usually referred to as Biot's approach, uses the total stress $\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\rm s} + \boldsymbol{\sigma}^{\rm w}$ and intrinsic fluid pressure $p_{\rm w}$ which are work-conjugate to the strain of the solid skeleton $\boldsymbol{\epsilon}$ and fluid volume content $v^{\rm w}$, respectively. The field equations which are usually solved in this context are the balance of momentum of the mixture and the balance of mass of the fluid.

The differences between the two approaches are more formal than fundamental, at least in the linear static case. Biot's approach is presented in Section 7.4. The first approach is superior when inertial terms can not be neglected. The analysis below follows Bowen's approach, it is isothermal and assumes the mass supplies to vanish.

7.3.6.1 Work-conjugate apparent stresses and strains

The constitutive relations for the elastic mixture with an anisotropic solid phase, also referred to as solid skeleton, are postulated in a form which enjoys the major symmetry property so that they may be derived from a quadratic strain energy function $\mathcal{W}(\boldsymbol{\epsilon}^{\rm s}, \boldsymbol{\epsilon}^{\rm w})$:

$$\begin{bmatrix} \boldsymbol{\sigma}^{\rm s} \\ \\ \boldsymbol{\sigma}^{\rm w} \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\rm ss} & \mathbb{E}^{\rm sw} \\ \\ \mathbb{E}^{\rm ws} & \mathbb{E}^{\rm ww} \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon}^{\rm s} \\ \\ \boldsymbol{\epsilon}^{\rm w} \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\rm ss} & \lambda^{\rm sw}\,\boldsymbol{\lambda}_{\rm w} \otimes \mathbf{I} \\ \\ \mathbf{I} \otimes \lambda^{\rm sw}\,\boldsymbol{\lambda}_{\rm w} & \lambda^{\rm ww}\,\mathbf{I} \otimes \mathbf{I} \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon}^{\rm s} \\ \\ \boldsymbol{\epsilon}^{\rm w} \end{bmatrix} . \tag{7.3.28}$$

Note that the apparent strain of the solid $\boldsymbol{\epsilon}^{\rm s}$ is also the strain of the solid skeleton $\boldsymbol{\epsilon}$. However, the notations in this section are kept distinct so as to highlight the fact that the work-conjugate pairs are apparent quantities, that refer to the volume of the mixture.

The symmetry of the overall tensor moduli is ensured by the major symmetry of the diagonal moduli $\mathbb{E}^{\rm ss}$ and $\mathbb{E}^{\rm ww} = \lambda^{\rm ww}\mathbf{I}\otimes\mathbf{I}$ and by the fact that the coupling moduli are the transpose of one another: $\mathbb{E}^{\rm sw}{=}\lambda^{\rm sw}\boldsymbol{\lambda}_{\rm w}\otimes\mathbf{I}{=}(\mathbb{E}^{\rm sw})^{\rm T}$. The diagonal moduli $\mathbb{E}^{\rm ss}$ display the minor symmetry on the two first indices by necessity and on the two last indices by choice. The second order tensor $\boldsymbol{\lambda}_{\rm w}$ is symmetric by necessity as well.

The apparent constitutive parameters introduced in Eqns (7.3.28), namely the symmetric fourth order tensor $\mathbb{E}^{\rm ss}$, the (dimensionless) symmetric second order tensor $\boldsymbol{\lambda}_{\rm w}$, normalized to $\|\,\boldsymbol{\lambda}_{\rm w}\,\|{=}\sqrt{3}$, and the scalars $\lambda^{\rm sw}$, $\lambda^{\rm ww}$ are unspecified at the present stage but they may be identified from intrinsic material parameters measured in appropriate experimental tests as shown in Section 7.3.6.4.

7.3.6.2 The underlying drained solid and the strain energy function

The *underlying drained elastic solid* corresponds to the mixture where the fluid stress $\boldsymbol{\sigma}^{\rm w}$, or fluid pressure $p_{\rm w}$, vanishes. In an incremental process, it can also be defined by a constant intrinsic fluid pressure $p_{\rm w}$. Elimination of the fluid strain $\mathbf{I}:\boldsymbol{\epsilon}^{\rm w}$ from the second elastic constitutive equation (7.3.28) yields the drained moduli $\mathbb{E}$,

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\rm s} = \mathbb{E} : \boldsymbol{\epsilon}^{\rm s} \quad \text{where} \quad \mathbb{E} = \mathbb{E}^{\rm ss} - \frac{\lambda^{\rm sw}\,\boldsymbol{\lambda}_{\rm w}\otimes\lambda^{\rm sw}\,\boldsymbol{\lambda}_{\rm w}}{\lambda^{\rm ww}} . \tag{7.3.29}$$

For

$$\mathbb{E} \text{ positive definite} \quad \text{and} \quad \lambda^{\rm ww} > 0\,, \tag{7.3.30}$$

the strain energy function $\mathcal{W}(\boldsymbol{\epsilon}^{\rm s}, \boldsymbol{\epsilon}^{\rm w})$

$$\begin{aligned} \mathcal{W}(\boldsymbol{\epsilon}^{\rm s}, \boldsymbol{\epsilon}^{\rm w}) &= \frac{1}{2}\,\boldsymbol{\sigma}^{\rm s} : \boldsymbol{\epsilon}^{\rm s} + \frac{1}{2}\,\boldsymbol{\sigma}^{\rm w} : \boldsymbol{\epsilon}^{\rm w} \\ &= \frac{1}{2}\,\boldsymbol{\epsilon}^{\rm s} : \mathbb{E} : \boldsymbol{\epsilon}^{\rm s} + \frac{1}{2\lambda^{\rm ww}}\,(\lambda^{\rm sw}\,\boldsymbol{\lambda}_{\rm w} : \boldsymbol{\epsilon}^{\rm s} + \lambda^{\rm ww}\,\mathbf{I} : \boldsymbol{\epsilon}^{\rm w})^2\,, \end{aligned} \tag{7.3.31}$$

is positive definite so that the stress-strain relation is invertible. Incidentally note another work-conjugate pair,

$$\mathcal{W}(\boldsymbol{\epsilon}^{\rm s}, \boldsymbol{\epsilon}^{\rm w}) = \frac{1}{2}\,\boldsymbol{\sigma} : \boldsymbol{\epsilon}^{\rm s} + \frac{1}{2}\,p_{\rm w}\,n^{\rm w}\,(\mathbf{I} : \boldsymbol{\epsilon}^{\rm s} - \mathbf{I} : \boldsymbol{\epsilon}^{\rm w})\,. \tag{7.3.32}$$

7.3.6.3 The elastic effective stress of Biot or Nur-Byerlee

With any (dimensionless) symmetric second order tensor $\boldsymbol{\alpha}$, we associate a generalized elastic effective stress through the following formula (in the framework of a continuum mechanics approach, tensile stresses are positive):

$$\boldsymbol{\sigma}' \equiv \boldsymbol{\sigma} + p_{\rm w}\, \boldsymbol{\alpha}\ . \tag{7.3.33}$$

For a specific choice of tensor $\boldsymbol{\alpha}$, which allows *decoupling* of the elastic response, $\boldsymbol{\sigma}'$ is referred to as the effective stress of Biot or Nur-Byerlee. It is said to be effective in the sense that it characterizes completely the elastic response of the solid skeleton. The physical concepts associated with the notions of partial, total and effective stresses are illustrated in Fig. 7.3.1.

The effective stress expresses in terms of the apparent strains via the constitutive equations (7.3.28),

$$\begin{aligned} \boldsymbol{\sigma}' &= \boldsymbol{\sigma}^{\rm s} - n^{\rm w}\, p_{\rm w} \left(\mathbf{I} - \frac{\boldsymbol{\alpha}}{n^{\rm w}}\right) \\ &= \left(\mathbb{E}^{\rm ss} + (\mathbf{I} - \frac{\boldsymbol{\alpha}}{n^{\rm w}}) \otimes \lambda^{\rm sw}\, \boldsymbol{\lambda}_{\rm w}\right) : \boldsymbol{\epsilon}^{\rm s} + \left(\lambda^{\rm sw}\, \boldsymbol{\lambda}_{\rm w} + \lambda^{\rm ww}\, (\mathbf{I} - \frac{\boldsymbol{\alpha}}{n^{\rm w}})\, (\mathbf{I} : \boldsymbol{\epsilon}^{\rm w})\right) . \end{aligned} \tag{7.3.34}$$

Decoupling takes place for the specific choice,

$$\mathbf{I} - \frac{\boldsymbol{\alpha}}{n^{\rm w}} = -\frac{\lambda^{\rm sw}}{\lambda^{\rm ww}}\, \boldsymbol{\lambda}_{\rm w}\ , \tag{7.3.35}$$

that is for

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}_{\rm w} \equiv n^{\rm w} \left(\mathbf{I} + \frac{\lambda^{\rm sw}}{\lambda^{\rm ww}}\, \boldsymbol{\lambda}_{\rm w}\right)\ , \tag{7.3.36}$$

and then the effective tensor moduli turn out to be the drained moduli,

$$\boldsymbol{\sigma}' = \mathbb{E} : \boldsymbol{\epsilon}^{\rm s}\ . \tag{7.3.37}$$

7.3.6.4 Identification of the apparent coefficients

The material properties introduced in the constitutive equations may be deduced from

- the drained moduli $\mathbb{E}$;
- the bulk moduli of the fluid $K_{\rm w}$, Eqn (7.2.5), and of the solid constituent $K_{\rm s} = 1/\mathbf{I} : \mathbb{E}_{\rm s}^{-1} : \mathbf{I}$, Eqn (7.2.17);
- a volume fraction, $n^{\rm s}$ or $n^{\rm w}$.

Various procedures may be followed, e.g., Biot and Willis [1957] and Nur and Byerlee [1971] for isotropic mixtures and Carroll [1979] and Thompson and Willis [1991] for anisotropic solid skeletons. Here, the volumetric strain of the solid constituent is obtained in terms of the strain $\boldsymbol{\epsilon}^{\rm s}$ and fluid pressure, using the relation $n^{\rm s}\, \boldsymbol{\sigma}_{\rm s} = \boldsymbol{\sigma}^{\rm s}$, and Eqns (7.2.14), $(7.3.34)_1$ and (7.3.37). The volume change of the fluid is obtained in terms of the apparent strains and fluid pressure through (7.2.3) and (7.2.9).

Spatial averaging of the intrinsic strains yields the apparent strain of the solid, Eqn (7.1.4). The fluid pressure is provided in terms of the apparent strains by the constitutive equation $(7.3.28)_2$. Therefore, we have two equations to be satisfied by three quantities, namely the apparent strains and the fluid pressure,

$$\begin{aligned} (\mathbf{I} : \mathbb{E}_{\rm s}^{-1} : \mathbb{E} - n^{\rm s}\, \mathbf{I}) : \boldsymbol{\epsilon}^{\rm s} - n^{\rm w}\, \mathbf{I} : \boldsymbol{\epsilon}^{\rm w} + \left(\mathbf{I} : \mathbb{E}_{\rm s}^{-1} : (\mathbf{I} - \frac{\boldsymbol{\alpha}}{n^{\rm w}}) - \frac{1}{K_{\rm w}}\right) n^{\rm w}\, p_{\rm w} &= 0, \\ -\lambda^{\rm ww} (\mathbf{I} - \frac{\boldsymbol{\alpha}}{n^{\rm w}}) : \boldsymbol{\epsilon}^{\rm s} + \lambda^{\rm ww} \mathbf{I} : \boldsymbol{\epsilon}^{\rm w} &= -n^{\rm w}\, p_{\rm w}\ , \end{aligned} \tag{7.3.38}$$

or, equivalently, one equation to be satisfied by two arbitrary quantities. Two relations result,

$$\begin{aligned} \boldsymbol{\alpha}_{\rm w} &= \mathbf{I} - \mathbb{E} : \mathbb{E}_{\rm s}^{-1} : \mathbf{I}, \\ \frac{(n^{\rm w})^2}{\lambda^{\rm ww}} &= \frac{n^{\rm s}}{K_{\rm s}} + \frac{n^{\rm w}}{K_{\rm w}} - (\mathbf{I} : \mathbb{E}_{\rm s}^{-1}) : \mathbb{E} : (\mathbb{E}_{\rm s}^{-1} : \mathbf{I})\, . \end{aligned} \tag{7.3.39}$$

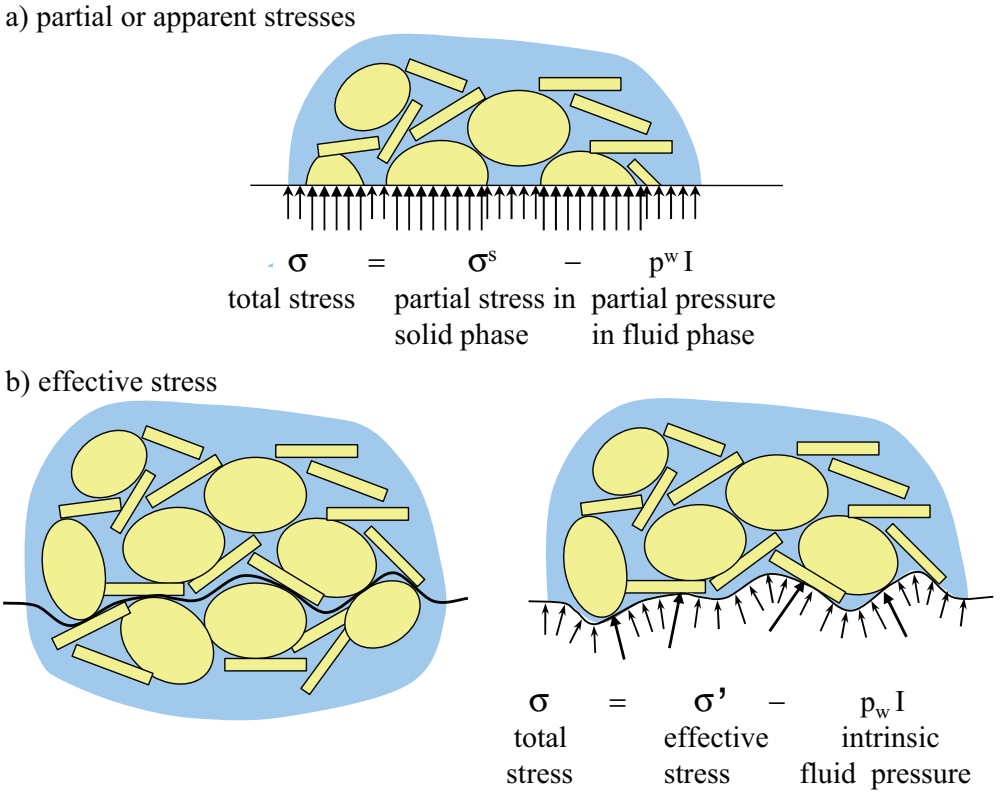

Fig. 7.3.1: (a) The sum of the forces exerted by a species over a plane surface divided by the total area of this surface provides the apparent stress of that species; (b) consider a granular material with pointwise contacts between rigid grains. A path in the water phase gives access to the intrinsic water pressure. The intergranular stress obtained by summing the forces at the contacts between grains is understood to govern the deformation of the solid skeleton. Reprinted with permission from Loret et al. [2004]a.

In turn,

$$\begin{aligned} \lambda^{\mathrm{sw}}\,\boldsymbol{\lambda}_{\mathrm{w}} &= \frac{\lambda^{\mathrm{ww}}}{n^{\mathrm{w}}}\,\left(n^{\mathrm{s}}\,\mathbf{I}-\mathbf{I}:\mathbb{E}_{\mathrm{s}}^{-1}:\mathbb{E}\right), \\ \mathbb{E}^{\mathrm{ss}} &= \mathbb{E}+\frac{\lambda^{\mathrm{sw}}\,\boldsymbol{\lambda}_{\mathrm{w}}\otimes\lambda^{\mathrm{sw}}\,\boldsymbol{\lambda}_{\mathrm{w}}}{\lambda^{\mathrm{ww}}}\,. \end{aligned} \tag{7.3.40}$$

Under undrained conditions, namely constant mass content, that is $\mathrm{tr}\,\boldsymbol{\epsilon}^{\mathrm{s}}-\mathrm{tr}\,\boldsymbol{\epsilon}^{\mathrm{w}}=0$, the fluid pressure and total stress are linked by the Skempton tensor $\mathbf{S}$,

$$p_{\mathrm{w}}=-\mathbf{S}:\boldsymbol{\sigma}\,, \tag{7.3.41}$$

whose expression is deduced from the constitutive equations,

$$\mathbf{S}=\frac{\lambda^{\mathrm{ww}}}{(n^{\mathrm{w}})^2}\,\boldsymbol{\alpha}_{\mathrm{w}}:\left(\mathbb{E}+\frac{\lambda^{\mathrm{ww}}}{(n^{\mathrm{w}})^2}\,\boldsymbol{\alpha}_{\mathrm{w}}\otimes\boldsymbol{\alpha}_{\mathrm{w}}\right)^{-1}. \tag{7.3.42}$$

7.3.6.5 Isotropic mixture

In the present framework, the anisotropic properties of the solid constituent and of the solid skeleton are formally independent of one another.

For a porous medium defined by the isotropic solid constituent tensor moduli $\mathbb{E}_{\mathrm{s}}$, with bulk modulus $1/K_{\mathrm{s}}=\mathbf{I}:\mathbb{E}_{\mathrm{s}}^{-1}:\mathbf{I}$, and the isotropic drained tensor moduli $\mathbb{E}$, with bulk modulus $1/K=\mathbf{I}:(\mathbb{E})^{-1}:\mathbf{I}$ and shear modulus μ, all tensor properties are isotropic, in particular,

$$\boldsymbol{\alpha}_{\mathrm{w}}=\overbrace{\left(1-\frac{K}{K_{\mathrm{s}}}\right)}^{\alpha_{\mathrm{w}}=}\mathbf{I},\quad \frac{1}{S}=\frac{1}{\mathrm{tr}\,\mathbf{S}}=1+\frac{n^{\mathrm{w}}}{\alpha_{\mathrm{w}}}\left(\frac{K}{K_{\mathrm{w}}}-\frac{K}{K_{\mathrm{s}}}\right). \tag{7.3.43}$$

Let $(\lambda = K - \frac{2}{3}\mu,\ \mu)$ be the Lamé moduli associated with the drained tensor moduli $\mathbb{E}$, and $(\lambda^{\rm ss},\ \mu^{\rm ss})$ be the Lamé moduli associated with the tensor moduli $\mathbb{E}^{\rm ss}$. Then the coefficients in the format (7.3.28) can be identified in the order below,

$$\begin{aligned}
&\lambda^{\rm ww} = \frac{(n^{\rm w})^2}{\alpha_{\rm w}}\,\frac{K\,S}{1-\alpha_{\rm w}\,S} = \frac{(n^{\rm w})^2\,K_{\rm s}^2}{\Big(\dfrac{1-n^{\rm w}}{K_{\rm s}} + \dfrac{n^{\rm w}}{K_{\rm w}}\Big)\,K_{\rm s}^2 - K}, \quad \boldsymbol{\lambda}_{\rm w} = \mathbf{I},\\
&\frac{\lambda^{\rm sw}}{\lambda^{\rm ww}} = \frac{\alpha_{\rm w}}{n^{\rm w}} - 1,\\
&\lambda^{\rm ss} = \lambda + \frac{(\lambda^{\rm sw})^2}{\lambda^{\rm ww}}, \quad \mu^{\rm ss} = \mu,\\
&S = \frac{\alpha_{\rm w}\,\lambda^{\rm ww}}{(n^{\rm w})^2 K + \alpha_{\rm w}^2\,\lambda^{\rm ww}} = \frac{1}{n^{\rm w}}\,\frac{\lambda^{\rm ww}+\lambda^{\rm sw}}{\lambda^{\rm ss}+\lambda^{\rm ww}+2\lambda^{\rm sw}+\dfrac{2}{3}\,\mu}\,.
\end{aligned} \tag{7.3.44}$$

Relations between the coefficients λ's and undrained moduli are considered in Section 11.5.2.3.

The positive definiteness of the strain energy function, Eqn (7.3.30), takes the usual explicit form in terms of the drained properties K and μ and of the representative water bulk modulus $\lambda^{\rm ww}$,

$$K = \lambda + \frac{2}{3}\,\mu = \lambda^{\rm ss} - \frac{(\lambda^{\rm sw})^2}{\lambda^{\rm ww}} + \frac{2}{3}\,\mu > 0, \quad \mu > 0, \quad \lambda^{\rm ww} > 0\,. \tag{7.3.45}$$

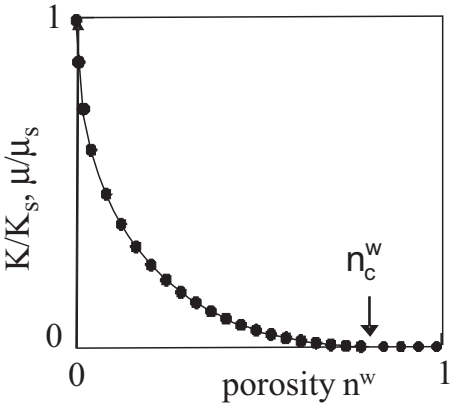

Fig. 7.3.2: Expected dependence of drained bulk and shear moduli in terms of porosity. The moduli may vanish at porosity smaller than 1, as if it was possible to define a path through the material entirely within the air constituent. For cancellous bones, the critical porosity $n_c^{\rm w}$ can reach 1.

7.3.6.6 Recovering the solid limit as $n^{\rm w} \to 0$

Although the analysis addresses primarily fluid-saturated porous media, one might think to establish contact with elastic solids, for which $n^{\rm w} = 0$. For that purpose the bulk modulus and shear modulus of the drained material are assumed to depend on the porosity $n^{\rm w}$ as sketched by Fig. 7.3.2. A wide range of data displaying the dependence in porosity of both dry moduli and dry wave-speeds of several cemented materials are reported by Knackstedt et al. [2005]. These data are approximated according to the simple, but realistic relation,

$$\frac{K}{K_{\rm s}} = \frac{\mu}{\mu_{\rm s}} = \langle 1 + \frac{1}{1-q}\,\Big(q\,\frac{n^{\rm w}}{n_c^{\rm w}} - (\frac{n^{\rm w}}{n_c^{\rm w}})^q\Big)\rangle\,, \tag{7.3.46}$$

where $\langle\cdot\rangle$ denotes the positive part of its argument. Thus the moduli $K_{\rm s}$ and $\mu_{\rm s}$ of the solid constituent are recovered as the porosity vanishes, and Poisson's ratio ν of the drained material remains equal to Poisson's ratio $\nu_{\rm s}$ of the solid constituent, irrespective of the porosity, namely

$$\nu = \frac{3\,K - 2\,\mu}{6\,K + 2\,\mu} = \nu_{\rm s} = \frac{3\,K_{\rm s} - 2\,\mu_{\rm s}}{6\,K_{\rm s} + 2\,\mu_{\rm s}}\,. \tag{7.3.47}$$

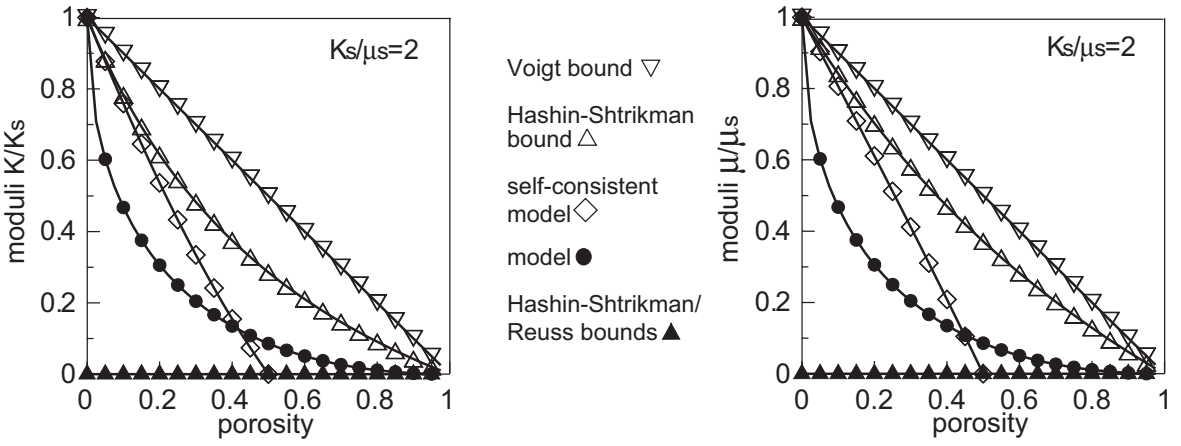

Fig. 7.3.3: Drained bulk and shear moduli in terms of porosity for the model (7.3.48), self-consistent model, Voigt and Reuss bounds, and Hashin-Shtrikman bounds. In presence of air constituent, the Reuss and lower Hashin-Shtrikman bounds vanish, Voigt bound is linear in terms of porosity, the self consistent model fails for porosities larger than 0.5.

Moreover, the drained moduli vanish smoothly at the upper limit $n^{\rm w} = n_c^{\rm w} \leq 1$. The slopes of the function that relate the moduli to the porosity are enforced to vanish at $n^{\rm w} = n_c^{\rm w}$, whatever the value of the exponent $q \in]0, 1[$. This empirical relation for the shear modulus remains below the upper bound of Voigt $\mu/\mu_{\rm s} = 1 - n^{\rm w}$ defined by Proposition 7.4.

The experimental value of the upper limit porosity $n_c^{\rm w}$ may be as low as 0.5. The consequences of this dependence in porosity for the body wave-speeds are analyzed in Chapter 11.

Table 7.3.2 displays the moduli of typical constituents of geological materials. These values may be contrasted to the bulk modulus of de-aired water, namely 2.2 GPa.

Table 7.3.2: Approximative bulk and shear moduli of quartz, dolomite, calcite and clay.

	$K_{\rm s}$ (GPa)	$\mu_{\rm s}$ (GPa)	$K_{\rm s}/\mu_{\rm s}$
Quartz	36.0	40.0	0.9
Dolomite	76.4	49.7	1.5
Calcite	74.8	36.0	2.1
Clay	20.8	6.9	3.0

As another consequence of this relation, the coefficient of Biot $\alpha_{\rm w}$ defined by (7.3.43) tends continuously to zero with the porosity. As an example illustrated by Fig. 7.3.3, consider the parameter $q = 1/2$ and a limit porosity $n_c^{\rm w} = 1$ so that the bulk and shear moduli, and the coefficient of Biot vary with porosity along the simple form,

$$\frac{K}{K_{\rm s}} = \frac{\mu}{\mu_{\rm s}} = (1 - \sqrt{n^{\rm w}})^2, \quad \alpha_{\rm w} = 1 - (1 - \sqrt{n^{\rm w}})^2 \,. \tag{7.3.48}$$

Moreover, by inserting the above relation for $\alpha_{\rm w}$ in (7.3.44), this dependence implies the modulus of elastic coupling to be positive, or zero for $n^{\rm w} = 0$,

$$\frac{\lambda^{\rm sw}}{\lambda^{\rm ww}} = \frac{2}{\sqrt{n^{\rm w}}} (1 - \sqrt{n^{\rm w}}) \geq 0 \,. \tag{7.3.49}$$

7.3.6.7 Incompressible constituents

If only the solid constituent is incompressible, namely

$$K_{\rm s} \to \infty \,, \tag{7.3.50}$$

then (7.3.40) implies the asymptotic relation,

$$\frac{\lambda^{\rm sw}}{\lambda^{\rm ww}} \boldsymbol{\lambda}_{\rm w} \to \frac{n^{\rm s}}{n^{\rm w}} \mathbf{I} \,. \tag{7.3.51}$$

If both solid and fluid constituents become incompressible, namely

$$K_{\rm s} \to \infty, \quad K_{\rm w} \to \infty\,, \tag{7.3.52}$$

the apparent strains are subjected to the constraint (7.2.26), namely,

$$n^{\rm s}\,\mathrm{tr}\,\boldsymbol{\epsilon}^{\rm s} + n^{\rm w}\,\mathrm{tr}\,\boldsymbol{\epsilon}^{\rm w} = 0\,. \tag{7.3.53}$$

The following asymptotic conditions should be satisfied,

$$\lambda^{\rm ww} \to \infty\,, \quad \lambda^{\rm sw} \to \infty\,, \quad \frac{\lambda^{\rm sw}}{\lambda^{\rm ww}}\,\boldsymbol{\lambda}_{\rm w} \to \frac{n^{\rm s}}{n^{\rm w}}\,\mathbf{I}\,. \tag{7.3.54}$$

The fluid pressure becomes indeterminate and the constitutive equations provide only the effective stress, Eqn (7.3.37). Since then $\boldsymbol{\alpha}_{\rm w} = \mathbf{I}$, the effective stress of Nur-Byerlee boils down to Terzaghi's effective stress, Terzaghi [1936].

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\rm w}\,\left(\mathbf{I} - \mathbb{E} : \mathbb{E}_{\rm s}^{-1} : \mathbf{I}\right) \quad \to \quad \boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\rm w}\,\mathbf{I}\,. \tag{7.3.55}$$

Skempton tensor tends to $\mathbf{I}/3$, and Skempton coefficient to one, and therefore, according to (7.3.41), $p_{\rm w} = -\mathbf{I} : \boldsymbol{\sigma}/3$. This relation is checked in laboratory experiments to verify that specimens tested are saturated by water. Any significant departure of the Skempton coefficient from 1 would signal the presence of a gas.

7.4 Anisotropic poroelasticity: drained and undrained properties

A general isothermal theory for anisotropic elastic porous solids saturated by a fluid has been exposed by Biot [1955]. Although many fluid infiltrated biological and geological porous solids display anisotropic mechanical properties, applications are scant. An analytical solution of Mandel's consolidation problem for a material with transverse isotropy under plane strain condition has been presented by Abousleiman et al. [1996]. Satisfaction of particular boundary conditions may require the development of an out-of-plane strain: this situation, referred to as generalized plane strain, has been analyzed analytically by Cheng [1998] on specific examples.

One reason that has delayed the application of the anisotropic poroelastic theory might come from the difficulties in measuring the material coefficients which characterize the mechanical behavior. Macroscopic homogeneity conditions that allow for space averaging have been examined by Carroll [1979] and Thompson and Willis [1991]. The identification of the material parameters uses generally, following Biot and Willis [1957], information from different scales, namely coefficients identifying the mechanical properties of the species (microscale) and coefficients defining the mechanical properties of the solid skeleton (macroscale). However, accurate information at the microscale may not be easily accessible. Therefore another route has been proposed, e.g., by Rice and Cleary [1976], which consists in using only information gathered at the macroscale along particular loadings, for instance drained paths corresponding to a constant pore pressure and undrained paths corresponding to a constant fluid mass content.

The number of material coefficients defining the most general form of anisotropy is 28, Biot [1955], Biot and Willis [1957], Cheng [1997], corresponding to a fourth order tensor with minor and major symmetries (21 coefficients), a symmetric second order tensor (6 coefficients) and a scalar (1 coefficient). The number of parameters follows also from a brute force count: the linear elastic relations involve $n = 6 + 1 = 7$ stress and strain components and so 49 material parameters, that, due to major symmetry, reduce to $\frac{1}{2}\,n\,(n+1) = 28$. Clearly, for the identification of these 28 parameters, the information provided together by the drained and undrained tensor moduli (42 coefficients) is overabundant. The above triplet of coefficients is (9,3,1) for orthotropy, amounting to 13 coefficients, (5,2,1) for transverse isotropy, amounting to 8 coefficients, and (2,1,1) for isotropy, that is 4 coefficients. Assuming the drained tensor moduli and the scalar referred to, in the isotropic case, as the Skempton coefficient to be known, it is important to assess, for specific classes of anisotropy, *which undrained parameters need to be measured and which need not*. Conversely, due to the symmetric roles played by the drained and undrained moduli in the following analysis, a simple switch of the results is feasible if the undrained moduli are known instead of the drained moduli.

Section 7.4 is based on Loret et al. [2001]. The micro-isotropy assumption is not used in this section. Still its implications are scrutinized in Section 7.4.5.2.

7.4.1 Constitutive equations in terms of drained properties

A basic issue in establishing constitutive equations is to choose the primary (or independent) variables. While the issue may be thought to be pointless for linear constitutive equations, the identification of coefficients might be easier in terms of a specific choice of variables. As for nonlinear constitutive equations, the decision has consequences, because the inversion of the equations, namely obtaining the independent variables in terms of the dependent variables, may be algebraically a burden if not impossible.

7.4.1.1 Generalized strains as primary variables

Constitutive equations are established using the free energy per unit reference volume $\underline{E}$, which can be expressed in terms of the work conjugate pairs $(\boldsymbol{\tau}, \cup_{k\in\mathcal{K}^{**}}\, \mu_k)$ and $(\boldsymbol{\epsilon}, \cup_{k\in\mathcal{K}^{**}}\, m^k)$. Here $\boldsymbol{\epsilon}$ is the infinitesimal strain of the solid skeleton, $\boldsymbol{\tau}$ is the Kirchhoff stress of the mixture, m^k is the fluid mass content per unit reference volume of fluid k, and $\mu_k = \int_0^{p_k} dp'_k/\rho_k(p'_k)$ its chemical potential which, in an isothermal context and in absence of solutes, reduces to the 'pressure function', Biot [1973] and Table 7.2.2.

We proceed as follows. Upon multiplication by $T \det \mathbf{F}$, the mechanical entropy production $(7.2.28)_1$ of the fluid k is modified to

$$T\, \underline{\hat{S}}^k_{(\mathrm{i},1)} = -\frac{d}{dt}(m^k e_k) + \boldsymbol{\tau}^k : \boldsymbol{\nabla}\mathbf{v}_\mathrm{s} + \mu_k \frac{dm^k}{dt}, \quad k \in \mathcal{K}^{**}\,. \tag{7.4.1}$$

The mechanical entropy production of the solid constituent has the form (7.4.1) but it does not involve the chemical potential term. Therefore, the mechanical entropy production of the wole mixture,

$$T\, \underline{\hat{S}}_{(\mathrm{i},1)} = T \sum_{k\in\mathcal{K}} \underline{\hat{S}}^k_{(\mathrm{i},1)} = -\frac{d\underline{E}}{dt} + \boldsymbol{\tau} : \boldsymbol{\nabla}\mathbf{v}_\mathrm{s} + \sum_{k\in\mathcal{K}^{**}} \mu_k \frac{dm^k}{dt} = 0\,, \tag{7.4.2}$$

expressed in terms of the free energy per reference volume of the mixture,

$$\underline{E} = \underline{E}(\boldsymbol{\epsilon},\ \cup_{k\,\in\,\mathcal{K}^{**}}\ m^k) = \sum_{k\,\in\,\mathcal{K}}\ m^k\, e_k\,, \tag{7.4.3}$$

is set to zero. Constitutive equations result for the following entities,

$$\boldsymbol{\tau} = \boldsymbol{\tau}^\mathrm{s} + \sum_{k\in\mathcal{K}^{**}} \boldsymbol{\tau}^k = \frac{\partial \underline{E}}{\partial \boldsymbol{\epsilon}}; \quad \mu_k = \frac{\partial \underline{E}}{\partial m^k}, \quad k \in \mathcal{K}^{**}\,. \tag{7.4.4}$$

7.4.1.2 Generalized stresses as primary variables

As an alternative, we can recover the stress and fluid pressures as primary variables, with an appropriate Legendre transform, namely,

$$\underline{E} \longrightarrow \underline{\mathcal{W}}(\boldsymbol{\tau},\ \cup_{k\,\in\,\mathcal{K}^{**}}\ p_k) = -\underline{E} + \sum_{k\in\mathcal{K}} \boldsymbol{\tau}^k : \boldsymbol{\epsilon} + \sum_{k\in\mathcal{K}^{**}} \mu_k\, m^k\,. \tag{7.4.5}$$

Eqn (7.4.5) transforms to

$$T\, \underline{\hat{S}}_{(\mathrm{i},1)} = \frac{d\underline{\mathcal{W}}}{dt} - \frac{d\boldsymbol{\tau}}{dt} : \boldsymbol{\epsilon} - \sum_{k\in\mathcal{K}^{**}} v^k \frac{dp_k}{dt} = 0\,, \tag{7.4.6}$$

and provides constitutive equations in the format,

$$\boldsymbol{\epsilon} = \frac{\partial \underline{\mathcal{W}}}{\partial \boldsymbol{\tau}}; \quad v^k = \frac{\partial \underline{\mathcal{W}}}{\partial p_k}, \quad k \in \mathcal{K}^{**}\,. \tag{7.4.7}$$

7.4.1.3 Linear poroelasticity with a single fluid constituent

The analysis is now restricted to linear poroelasticity, and the current configuration is taken as reference. The generalized strain $(\boldsymbol{\epsilon},\ \cup_{k\in\mathcal{K}^{**}} v^k)$ is obtained in terms of the generalized stress $(\boldsymbol{\sigma},\ \cup_{k\in\mathcal{K}^{**}} p_k)$ in a form which enjoys the major symmetry property. Moreover, the linearized relation $m^k = \rho_k\, v^k$, Eqn (7.2.9), simplifies in the isothermal case to,

$$\zeta^{\mathrm{k}} \equiv \frac{\Delta m^k}{\rho_k^0} = \Delta v^k + n^k \frac{p_k}{K_k}\,. \tag{7.4.8}$$

Consequently, the major symmetry property is conserved when the constitutive equations express the generalized strain $(\boldsymbol{\epsilon},\ \cup_{k\in\mathcal{K}^{**}} \zeta^k)$ in terms of the generalized stress $(\boldsymbol{\tau},\ \cup_{k\in\mathcal{K}^{**}} p_k)$, *even if these pairs are not work-conjugate.* Actually, we would like to write the constitutive equations in the matrix form,

$$[\mathbf{E}-\mathbf{E}_0] = [\mathbb{C}]\ ([\boldsymbol{\Sigma}-\boldsymbol{\Sigma}_0])\,, \tag{7.4.9}$$

where $[\mathbf{E}]$ and $[\boldsymbol{\Sigma}]$ are the generalized strain and stress, respectively, $[\mathbb{C}]$ is the poroelastic compliance matrix, and the subscript 0 indicates a reference value. Therefore the stress potential $\underline{\mathcal{W}}$ should include both linear and quadratic terms,

$$\underline{\mathcal{W}}\,([\boldsymbol{\Sigma}-\boldsymbol{\Sigma}_0]) = ([\boldsymbol{\Sigma}-\boldsymbol{\Sigma}_0])^{\mathrm{T}}[\mathbf{E}_0] + \frac{1}{2}([\boldsymbol{\Sigma}-\boldsymbol{\Sigma}_0])^{\mathrm{T}}\ [\mathbb{C}]\ [\boldsymbol{\Sigma}-\boldsymbol{\Sigma}_0])\,. \tag{7.4.10}$$

For a mixture with a single fluid constituent, the matrix form of the constitutive equations adopts the format,

$$\begin{bmatrix} \boldsymbol{\epsilon} \\ \\ \zeta^{\mathrm{w}} \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{-1} & \mathbb{E}^{-1}\!:\boldsymbol{\alpha}_{\mathrm{w}} \\ \\ \boldsymbol{\alpha}_{\mathrm{w}} : \mathbb{E}^{-1} & \mathbf{I} : \dfrac{\mathbb{E}^{-1}}{S} \!: \boldsymbol{\alpha}_{\mathrm{w}} \end{bmatrix} \begin{bmatrix} \boldsymbol{\sigma} \\ \\ p_{\mathrm{w}} \end{bmatrix}. \tag{7.4.11}$$

The constitutive equations (7.4.11) involve a fourth order tensor moduli $\mathbb{E}$ endowed with minor and major symmetries, a symmetric second order tensor $\boldsymbol{\alpha}_{\mathrm{w}}$ and the dimensionless Skempton coefficient S, for a total of $21+6+1=28$ parameters. The format and notations used to cast these equations are now justified.

When full drainage is allowed, that is $p_{\mathrm{w}}=0$, then $\boldsymbol{\sigma}^{\mathrm{s}}=\mathbb{E}:\boldsymbol{\epsilon}$, which shows that the tensor moduli $\mathbb{E}$ are the elastic moduli of the *Drained Solid*. These tensor moduli, which inherit the major symmetry property from the existence of the potential $\underline{\mathcal{W}}$, are accessible to macroscopic measurements at the scale of the porous medium. Eqn $(7.4.11)_1$ introduces implicitly a Nur-Byerlee or Biot *effective stress* $\boldsymbol{\sigma}'$,

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\mathrm{w}}\,\boldsymbol{\alpha}_{\mathrm{w}}\,. \tag{7.4.12}$$

The effective stress $\boldsymbol{\sigma}'$ and the strain of the solid skeleton $\boldsymbol{\epsilon}$ are linked through the drained stiffness,

$$\boldsymbol{\sigma}' = \mathbb{E} : \boldsymbol{\epsilon}, \quad \boldsymbol{\epsilon} = \mathbb{E}^{-1} : \boldsymbol{\sigma}'\,. \tag{7.4.13}$$

The tensor $\boldsymbol{\alpha}_{\mathrm{w}}$ can be defined in terms of the macroscopic moduli $\mathbb{E}$ and of the moduli of the solid constituent $\mathbb{E}_{\mathrm{s}}$; indeed

$$\boldsymbol{\alpha}_{\mathrm{w}} = \mathbf{I} - \mathbb{E} : \mathbb{E}_{\mathrm{s}}^{-1} : \mathbf{I}\,. \tag{7.4.14}$$

The material identification procedure is sketched in Fig. 7.4.1. In fact, let us assume the intrinsic stresses in the solid constituent $\boldsymbol{\sigma}_{\mathrm{s}}$ and in the fluid constituent $\boldsymbol{\sigma}_{\mathrm{w}}$ to be equal, say $\boldsymbol{\sigma}_{\mathrm{s}} = \boldsymbol{\sigma}_{\mathrm{w}} = -p\ \mathbf{I}$; then if we assume the porous medium to behave homogeneously at the scale of the solid constituent, its strain will be $\boldsymbol{\epsilon} = \mathbb{E}_{\mathrm{s}}^{-1} : (-p\,\mathbf{I})$ as if there was no porosity; equating this expression with Eqn $(7.4.11)_1$, and accounting for the fact that the total stress $\boldsymbol{\sigma}$ is now equal to $-p\,\mathbf{I}$ as well, yields the above identification, Eqn (7.4.14).

For the above loading, the assumption of a homogeneous response is equivalent to proportional volume changes Δv and $\Delta v^{\mathrm{w}} = n^{\mathrm{w}}\Delta v$, where $\Delta v \equiv \Delta V/V_0 = \mathrm{tr}\,\boldsymbol{\epsilon}$, now equal to $\mathbf{I}:\mathbb{E}_{\mathrm{s}}^{-1}:(-p\ \mathbf{I})$, is the relative volume change of the solid skeleton. Then Eqns (7.4.8) and $(7.4.11)_2$ together with Eqn (7.4.14) yield the Skempton coefficient S, e.g., Bishop and Hight [1977], Eqn (23),

$$\frac{1}{S} = 1 + n^{\mathrm{w}} \left(\frac{1}{K_{\mathrm{w}}} - \frac{1}{K_{\mathrm{s}}}\right)\left(\frac{1}{K} - \frac{1}{K_{\mathrm{s}}}\right)^{-1}, \tag{7.4.15}$$

in terms of the porosity n^{w}, of the bulk moduli of the fluid and solid constituents, respectively K_{w} and K_{s}, and of the macroscopic bulk modulus K,

$$\frac{1}{K_{\mathrm{s}}} \equiv \mathbf{I} : \mathbb{E}_{\mathrm{s}}^{-1} : \mathbf{I}\,, \quad \frac{1}{K} \equiv \mathbf{I} : \mathbb{E}^{-1} : \mathbf{I}\,. \tag{7.4.16}$$

The formalism (7.4.11) is intended for visual purposes. A more operational expression of the coefficients can now be deduced,

$$\mathbf{A} \equiv \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\mathrm{w}} = \mathbb{E}^{-1} : \mathbf{I} - \mathbb{E}_{\mathrm{s}}^{-1} : \mathbf{I}, \quad \mathbf{I} : \frac{\mathbb{E}^{-1}}{S} \!: \boldsymbol{\alpha}_{\mathrm{w}} = \frac{1}{K} - \frac{1+n^{\mathrm{w}}}{K_{\mathrm{s}}} + \frac{n^{\mathrm{w}}}{K_{\mathrm{w}}}\,. \tag{7.4.17}$$

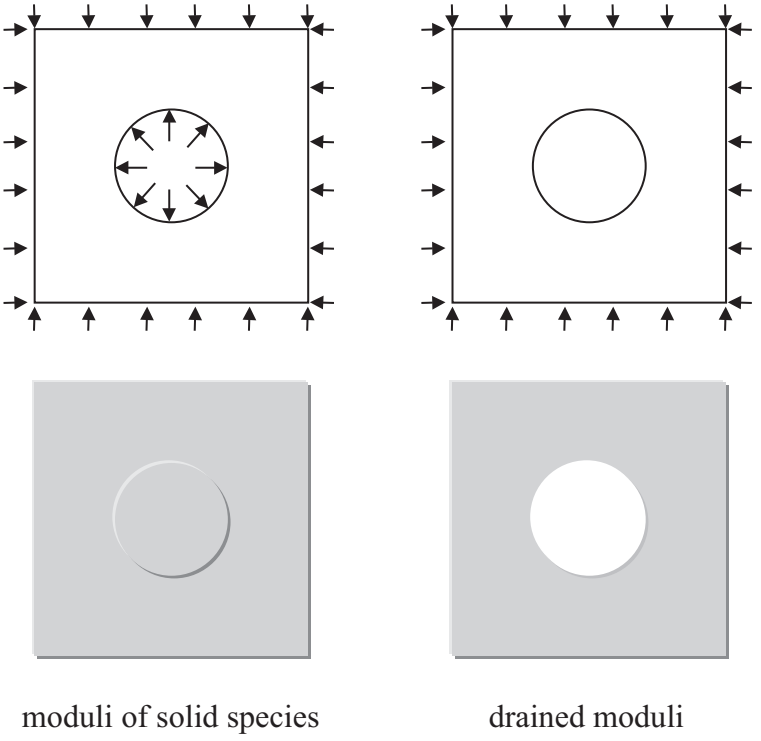

Fig. 7.4.1: Elastic constants are accessible to measurements by appropriate loadings of the pores and of the solid.

7.4.2 Constitutive equations in terms of undrained properties

A potential difficulty inherent in the above expressions of $\boldsymbol{\alpha}_{\rm w}$ and S comes from the fact that they involve material properties of the species which may not be accurately accessible, due for example to an imperfect homogeneity at the corresponding scale. To alleviate this problem, it might be more appropriate to use moduli all measured at the same scale. Following Rice and Cleary [1976], a good candidate is the *Undrained tensor moduli* $\mathbb{E}^{\rm U}$ corresponding to a constant fluid mass content, namely $\zeta^{\rm w}$=0. Indeed, inverting the constitutive relations (7.4.11), we get the generalized stresses $(\boldsymbol{\sigma}, p_{\rm w})$ in terms of the generalized strains $(\boldsymbol{\epsilon}, \zeta^{\rm w})$,

$$\left[\begin{array}{c} \boldsymbol{\sigma} \\ p_{\rm w} \end{array}\right] = \left[\begin{array}{cc} \mathbb{E}^{\rm U} & -M\,\boldsymbol{\alpha}_{\rm w} \\ -M\,\boldsymbol{\alpha}_{\rm w} & M \end{array}\right] \left[\begin{array}{c} \boldsymbol{\epsilon} \\ \zeta^{\rm w} \end{array}\right], \tag{7.4.18}$$

where

$$\begin{aligned} \frac{1}{M} &= \frac{1}{S}\,\mathbf{I} : \mathbb{E}^{-1} \colon \boldsymbol{\alpha}_{\rm w} - \boldsymbol{\alpha}_{\rm w} : \mathbb{E}^{-1} \colon \boldsymbol{\alpha}_{\rm w} \\ &= \frac{1-n^{\rm w}}{K_{\rm s}} + \frac{n^{\rm w}}{K_{\rm w}} - (\mathbf{I} : \mathbb{E}_{\rm s}^{-1}) : \mathbb{E} : (\mathbb{E}_{\rm s}^{-1} : \mathbf{I})\,. \end{aligned} \tag{7.4.19}$$

Then, the undrained stress-strain relationships can be recast in the format

$$\boldsymbol{\epsilon} = (\mathbb{E}^{\rm U})^{-1} : \boldsymbol{\sigma}\,, \quad p_{\rm w} = -\,\mathbf{S} : \boldsymbol{\sigma}\,. \tag{7.4.20}$$

Here $\mathbf{S} = M\,(\mathbb{E}^{\rm U})^{-1} : \boldsymbol{\alpha}_{\rm w}$ is the *Skempton tensor* (see Thompson and Willis [1991], Eqn (16), and, up to a factor 1/3, Cheng [1997], Eqn (17)),

$$\frac{\mathbf{S}}{\operatorname{tr}\mathbf{S}} = \frac{\mathbf{A}}{\operatorname{tr}\mathbf{A}}\,, \quad S = \operatorname{tr}\mathbf{S}\,, \tag{7.4.21}$$

which generalizes to the anisotropic case the Skempton pore pressure parameter $B = S$, Skempton [1954]. For isotropy, $\mathbf{S}$ reduces to $S\,\mathbf{I}/3$ and (7.4.20) becomes $p_{\rm w} = -\,S\operatorname{tr}\boldsymbol{\sigma}/3$. Moreover

Property 1: The drained and undrained compliance tensors and the drained and undrained tensor moduli differ by a rank one term:

$$(\mathbb{E}^{\rm U})^{-1} \equiv \mathbb{E}^{-1} - S\,\frac{\mathbf{A}\otimes\mathbf{A}}{\operatorname{tr}\mathbf{A}} \quad \Leftrightarrow \quad \mathbb{E}^{\rm U} = \mathbb{E} + M\,\boldsymbol{\alpha}_{\rm w}\otimes\boldsymbol{\alpha}_{\rm w}\,. \tag{7.4.22}$$

The strain energy function $\underline{\mathcal{W}}(\boldsymbol{\epsilon},\boldsymbol{\epsilon}^{\mathrm{w}})$ obtained from the free energy $\underline{E}(\boldsymbol{\epsilon},\zeta^{\mathrm{w}})$ through the change of strain variables (7.4.8),

$$\underline{E}\,(\boldsymbol{\epsilon},\zeta^{\mathrm{w}}) = \frac{1}{2}\,\boldsymbol{\sigma}:\boldsymbol{\epsilon} + \frac{1}{2}\,p_{\mathrm{w}}\,\zeta^{\mathrm{w}} = \underline{\mathcal{W}}\,(\boldsymbol{\epsilon},\boldsymbol{\epsilon}^{\mathrm{w}})\,, \tag{7.4.23}$$

can be recast in the following alternative formats:

$$\underline{\mathcal{W}}\,(\boldsymbol{\epsilon},\boldsymbol{\epsilon}^{\mathrm{w}}) = \begin{cases} \dfrac{1}{2}\,\boldsymbol{\epsilon}:\mathbb{E}:\boldsymbol{\epsilon} + \dfrac{1}{2}\,M\left((\boldsymbol{\alpha}_{\mathrm{w}} - n^{\mathrm{w}}\,\mathbf{I}):\boldsymbol{\epsilon} + n^{\mathrm{w}}\,\mathbf{I}:\boldsymbol{\epsilon}^{\mathrm{w}}\right)^2, \\ \dfrac{1}{2}\,(\boldsymbol{\epsilon} - \zeta^{\mathrm{w}}\,\mathbf{S}):\mathbb{E}^{\mathrm{U}}:(\boldsymbol{\epsilon} - \zeta^{\mathrm{w}}\,\mathbf{S}) + \dfrac{1}{2}\,(M - \mathbf{S}:\mathbb{E}^{\mathrm{U}}:\mathbf{S})\,(\zeta^{\mathrm{w}})^2\,. \end{cases} \tag{7.4.24}$$

Therefore, we have reached

Property 2: Positive definiteness (PD) of the strain energy function takes one of the following equivalent forms:

$$\underline{\mathcal{W}}(\boldsymbol{\epsilon},\boldsymbol{\epsilon}^{\mathrm{w}}) \quad \text{PD} \quad \Leftrightarrow \quad \mathbb{E} \text{ PD and } M > 0 \quad \Leftrightarrow \quad \mathbb{E}^{\mathrm{U}} \text{ PD and } \frac{\operatorname{tr}\mathbf{A}}{S} = \frac{1}{M - \mathbf{S}:\mathbb{E}^{\mathrm{U}}:\mathbf{S}} > 0\,. \tag{7.4.25}$$

Notice that Eqns (7.4.14), (7.4.19) and (7.4.25) are consistent with the inequalities,

$$\operatorname{tr}\mathbf{A} > 0 \quad \text{and} \quad \operatorname{tr}\mathbf{S} = S > 0\,, \tag{7.4.26}$$

the latter result being expected on physical grounds as it will be seen below in relation with Eqn $(7.4.20)_2$. In view of Eqns $(7.4.22)_{1,2}$, since $M > 0$ and $\operatorname{tr}\mathbf{A}/S > 0$, the undrained response appears to be *stiffer* than the drained response.

Later, it will be convenient to rewrite relation (7.4.22) in terms of the second order tensor $\mathbf{E}$ of unit norm ($\|\mathbf{E}\| = \sqrt{\mathbf{E}:\mathbf{E}} = 1$) proportional to $\mathbf{A}$ and $\mathbf{S}$ and defined implicitly through the following formulas,

$$\mathbf{A} = \frac{\Lambda}{S}\,(\operatorname{tr}\mathbf{E})\,\mathbf{E}\,, \quad \Lambda > 0\,, \quad \frac{\mathbf{S}}{\operatorname{tr}\mathbf{S}} = \frac{\mathbf{A}}{\operatorname{tr}\mathbf{A}} = \frac{\mathbf{E}}{\operatorname{tr}\mathbf{E}}\,. \tag{7.4.27}$$

The sign of Λ is implied by $\operatorname{tr}\mathbf{A}/S > 0$. Then *Property 1* can be viewed in a slightly different perspective:

Property 3: The difference $\mathbb{C}$ of compliance tensors, Eqn $(7.4.22)_1$,

$$\mathbb{C} \equiv \mathbb{E}^{-1} - (\mathbb{E}^{\mathrm{U}})^{-1} = \Lambda\,\mathbf{E}\otimes\mathbf{E} \tag{7.4.28}$$

has a single nonzero eigentensor $\mathbf{E}$ which is parallel to $\mathbf{A}$ and $\mathbf{S}$. Since $\operatorname{tr}\mathbf{A}$ is strictly positive, this eigentensor is non-isochoric.

Another slightly different form of Eqn $(7.4.22)_1$ is also recorded for later use:

Property 4: Assuming the triplet $(\mathbb{E}^{\mathrm{U}},\mathbf{S},M)$ corresponding to the undrained moduli $\mathbb{E}^{\mathrm{U}}$, the Skempton tensor $\mathbf{S}$ and the scalar M to be known, the drained compliance tensor is obtained explicitly as

$$\mathbb{E}^{-1} = (\mathbb{E}^{\mathrm{U}})^{-1} + \frac{1}{M - \mathbf{S}:\mathbb{E}^{\mathrm{U}}:\mathbf{S}}\,\mathbf{S}\otimes\mathbf{S}\,. \tag{7.4.29}$$

To prove this relation, observe first that $\boldsymbol{\alpha}_{\mathrm{w}}$ can be expressed in terms of the above triplet, using Eqns (7.4.18) and (7.4.20),

$$\boldsymbol{\alpha}_{\mathrm{w}} = \frac{1}{M}\,\mathbf{S}:\mathbb{E}^{\mathrm{U}}\,. \tag{7.4.30}$$

Further, Eqns (7.4.17), (7.4.19), (7.4.21) and (7.4.30) provide

$$\mathbf{A} = \frac{1}{M - \mathbf{S}:\mathbb{E}^{\mathrm{U}}:\mathbf{S}}\,\mathbf{S}\,, \tag{7.4.31}$$

which, introduced in Eqn $(7.4.22)_1$, yields the announced result, Eqn (7.4.29). Combining (7.4.19) and (7.4.17) with (7.4.31) yields in turn,

$$M = \frac{\mathbf{S}:\mathbb{E}^{\mathrm{U}}:\mathbf{S}}{\boldsymbol{\alpha}_{\mathrm{w}}:\mathbf{S}}\,. \tag{7.4.32}$$

The constitutive relations (7.4.18) can then be recast in a format,

$$\begin{bmatrix} \boldsymbol{\sigma} \\ p_{\mathrm{w}} \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\mathrm{U}} & -\mathbb{E}^{\mathrm{U}} : \mathbf{S} \\ -\mathbf{S} : \mathbb{E}^{\mathrm{U}} & M \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ \zeta^{\mathrm{w}} \end{bmatrix} . \tag{7.4.33}$$

Therefore, at zero total stress,

$$\boldsymbol{\epsilon} = \zeta^{\mathrm{w}}\, \mathbf{S}, \quad p_{\mathrm{w}} = \zeta^{\mathrm{w}} \left(\frac{1}{\boldsymbol{\alpha}_{\mathrm{w}} : \mathbf{S}} - 1\right) \mathbf{S} : \mathbb{E}^{\mathrm{U}} : \mathbf{S} . \tag{7.4.34}$$

Given the positive definiteness of the undrained moduli $\mathbb{E}^{\mathrm{U}}$, the positive definiteness of the strain energy function Eqn (7.4.25) is ensured by the inequality,

$$M > M_{\mathrm{PD}} = \mathbf{S} : \mathbb{E}^{\mathrm{U}} : \mathbf{S} . \tag{7.4.35}$$

So, since the scalar coefficient in the denominator of Eqn (7.4.29) is strictly positive, this relation is another manifestation that the undrained response is *stiffer* than the drained response.

Let K^{U} be the undrained bulk modulus, namely

$$\frac{1}{K^{\mathrm{U}}} = \mathbf{I} : (\mathbb{E}^{\mathrm{U}})^{-1} : \mathbf{I} . \tag{7.4.36}$$

In view of the definition of $\mathbf{A}$, Eqn (7.4.14), and using the expression of K in terms of the triplet $(\mathbb{E}^{\mathrm{U}}, \mathbf{S}, M)$ provided by (7.4.29), namely

$$\frac{1}{K} = \frac{1}{K^{\mathrm{U}}} + \frac{(\mathrm{tr}\, \mathbf{S})^2}{M - \mathbf{S} : \mathbb{E}^{\mathrm{U}} : \mathbf{S}} , \tag{7.4.37}$$

the bulk modulus of the solid constituent K_{s} follows in terms of this triplet,

$$\frac{1}{K_{\mathrm{s}}} = \frac{1}{K^{\mathrm{U}}} + \frac{(\mathrm{tr}\, \mathbf{S})^2 - \mathrm{tr}\, \mathbf{S}}{M - \mathbf{S} : \mathbb{E}^{\mathrm{U}} : \mathbf{S}} . \tag{7.4.38}$$

Since, as noted below, it is expected that $0 < S = \mathrm{tr}\, \mathbf{S} < 1$, we have a more stringent requirement than Eqn (7.4.35); indeed

Property 5: The positiveness of K_{s} requires a higher lower bound for M, namely,

$$M > M_{\mathrm{inf}} = \mathbf{S} : \mathbb{E}^{\mathrm{U}} : \mathbf{S} + (\mathrm{tr}\, \mathbf{S} - (\mathrm{tr}\, \mathbf{S})^2)\, K^{\mathrm{U}} , \tag{7.4.39}$$

than that required by the mere positive definiteness of the strain energy function (7.4.35).

7.4.3 Independent measurements

Henceforth we assume the drained moduli $\mathbb{E}$ (or the undrained moduli $\mathbb{E}^{\mathrm{U}}$) and the Skempton coefficient S to be known and measurable through macroscopic experiments. To measure S, one may perform an experiment with an isotropic total stress $\boldsymbol{\sigma} = -p\, \mathbf{I}$: relations $(7.4.20)_2$ and $(7.4.21)_2$ yield the Skempton coefficient $S = p_{\mathrm{w}}/p$, which is expected to be strictly positive. Moreover, according to the identification (7.4.15), since $K_{\mathrm{s}} > K$, the inequality $S < 1$ is equivalent to $K_{\mathrm{s}} > K_{\mathrm{w}}$: the latter inequality holds for example for all the geological materials listed by Cheng and Detournay [1993]. In that context, discovering the *compatibility relations* between drained and undrained material parameters in view of *Properties 1 to 5* is an issue. The knowledge of these compatibility relations is crucial to define, not the number of measurements that we need to perform (this we already know) but which measurements are *independent*, in a sense that will become clear through examples. Of course, we have already some knowledge of $\mathbb{E}^{\mathrm{U}}$ (or of $\mathbb{E}$): since water can not sustain shear stresses, the undrained shear moduli should be equal to the drained shear moduli. This information can also be read directly from Eqns (7.4.22) and (7.4.28),(7.4.29). The existence of other relations is less intuitive, especially in the presence of anisotropy.

A general and systematic approach has been adopted in Loret et al. [2001], where materials endowed with isotropy, general transverse isotropy and general orthotropy are examined in turn. These authors also consider the situation where the Skempton tensor $\mathbf{S}$ is known and then define which information should be extracted from the undrained (or drained) properties.

To discover the compatibility relations that link the drained and undrained stiffness and compliance tensors, the point of view delivered by *Property 1* is adopted for orthotropic materials and the perspective contained in *Property 3* is envisaged for isotropic and transversely isotropic materials. In all cases, the drained and undrained tensor stiffness and compliance tensors are assumed from the start to belong to the same class of anisotropy and to be endowed with the same directions of orthotropy.

7.4.4 Compatibility conditions for isotropic porous media

The drained and undrained isotropic compliance tensors are defined by their respective pairs of Young's moduli and Poisson's ratios $(E,\ \nu)$ and $(E^{\mathrm{U}},\ \nu^{\mathrm{U}})$:

$$\begin{aligned} \mathbb{E}^{-1} &= \frac{1+\nu}{E}\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I} - \frac{\nu}{E}\,\mathbf{I}\otimes\mathbf{I}\,, \\ (\mathbb{E}^{\mathrm{U}})^{-1} &= \frac{1+\nu^{\mathrm{U}}}{E^{\mathrm{U}}}\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I} - \frac{\nu^{\mathrm{U}}}{E^{\mathrm{U}}}\,\mathbf{I}\otimes\mathbf{I}\,. \end{aligned} \tag{7.4.40}$$

The meaning of the operator $\underline{\overline{\otimes}}$ is read from (2.1.24). The tensor $\mathbf{A}$ defined by (7.4.17) can be obtained by a simple direct calculation. However, the derivation is less straightforward for anisotropic materials and recourse to a spectral decomposition of the elasticity tensors is an alternative. This method can also be used in the present context. Indeed, for isotropy as indicated in Section 5.3.1, the difference $\mathbb{C}$, Eqn (7.4.28), has a single non-isochoric eigenmode $\mathbf{E}{=}\mathbf{I}/\sqrt{3}$ associated with the eigenvalue $1/3K - 1/3K^{\mathrm{U}}$, while the five other eigenmodes are isochoric and associated with the eigenvalue $1/2\,\mu - 1/2\,\mu^{\mathrm{U}}$: in terms of Young's moduli and Poisson's ratios, drained and undrained bulk and shear moduli are equal to $K{=}E/3\,(1-2\,\nu)$, $K^{\mathrm{U}}{=}E^{\mathrm{U}}/3\,(1-2\,\nu^{\mathrm{U}})$, and $\mu = E/2(1+\nu)$, $\mu^{\mathrm{U}} = E^{\mathrm{U}}/2(1+\nu^{\mathrm{U}})$, respectively. Then Eqn $(7.4.27)_1$ implies, as expected, that $\mathbf{A}$ is isotropic. As a further consequence of Eqn (7.4.22), the drained and undrained shear moduli are equal as expected as well, $\mu = \mu^{\mathrm{U}}$. Therefore, together with the drained Young's modulus and Poissons' ratio, a *single undrained parameter needs to be measured*, say Poisson's ratio ν^{U}. Then,

$$E^{\mathrm{U}} = E\,\frac{1+\nu^{\mathrm{U}}}{1+\nu} = 2\,\mu\,(1+\nu^{\mathrm{U}}), \quad K^{\mathrm{U}} = 2\,\mu\,\frac{1+\nu^{\mathrm{U}}}{3\,(1-2\,\nu^{\mathrm{U}})}\,, \tag{7.4.41}$$

and Eqn $(7.4.27)_1$ yields, e.g., Rice and Cleary [1976],

$$\boldsymbol{\alpha}_{\mathrm{w}} = \frac{3}{S}\,\frac{\nu^{\mathrm{U}}-\nu}{(1+\nu^{\mathrm{U}})(1-2\nu)}\,\mathbf{I}\,, \quad \mathbf{A} = \mathbb{E}^{-1}\colon\boldsymbol{\alpha}_{\mathrm{w}} = \frac{3}{S\,E}\,\frac{\nu^{\mathrm{U}}-\nu}{1+\nu^{\mathrm{U}}}\,\mathbf{I}\,. \tag{7.4.42}$$

The positive definiteness of the strain energy $\underline{\mathcal{W}}$, Eqn (7.4.25), restricts the ranges of E^{U} and ν^{U}, indeed

$$-1 < \nu < \nu^{\mathrm{U}} < \frac{1}{2} \quad \text{and} \quad 0 < E < E^{\mathrm{U}} < \frac{3}{2}\,\frac{E}{1+\nu}\,, \tag{7.4.43}$$

and therefore $K^{\mathrm{U}} > 0$. Indeed, the undrained Poisson's ratio can also be cast in the following forms:

$$\nu^{\mathrm{U}} = \nu + \frac{\alpha_{\mathrm{w}}\,S\,(1-2\,\nu)(1+\nu)}{3-\alpha_{\mathrm{w}}\,S\,(1-2\,\nu)} = \frac{1}{2} - \frac{3}{2}\,\frac{(1-\alpha_{\mathrm{w}}\,S)\,(1-2\,\nu)}{3-\alpha_{\mathrm{w}}\,S\,(1-2\,\nu)}\,. \tag{7.4.44}$$

It is worth recording the particular form of some constitutive relations for an isotropic solid skeleton. Indeed then $\boldsymbol{\alpha}_{\mathrm{w}}$ simplifies to the classical expressions, Nur and Byerlee [1971], Rice and Cleary [1976],

$$\boldsymbol{\alpha}_{\mathrm{w}} = \alpha_{\mathrm{w}}\,\mathbf{I}\,, \quad \alpha_{\mathrm{w}} = 1 - \frac{K}{K_{\mathrm{s}}}\,. \tag{7.4.45}$$

The constitutive equations (7.4.11) take the form,

$$\begin{bmatrix} \operatorname{tr}\boldsymbol{\epsilon} \\ \zeta^{\mathrm{w}} \end{bmatrix} = \frac{1}{K}\begin{bmatrix} 1 & \alpha_{\mathrm{w}} \\ \alpha_{\mathrm{w}} & \alpha_{\mathrm{w}}/S \end{bmatrix}\begin{bmatrix} \frac{1}{3}\operatorname{tr}\boldsymbol{\sigma} \\ p_{\mathrm{w}} \end{bmatrix}, \quad \operatorname{dev}\boldsymbol{\epsilon} = \frac{1}{2\,\mu}\operatorname{dev}\boldsymbol{\sigma}\,, \tag{7.4.46}$$

where μ is the (drained) shear modulus of the solid skeleton. The inverse form (7.4.18),

$$\begin{bmatrix} \frac{1}{3}\operatorname{tr}\boldsymbol{\sigma} \\ p_{\mathrm{w}} \end{bmatrix} = \begin{bmatrix} K^{\mathrm{U}} & -M\,\alpha_{\mathrm{w}} \\ -M\,\alpha_{\mathrm{w}} & M \end{bmatrix}\begin{bmatrix} \operatorname{tr}\boldsymbol{\epsilon} \\ \zeta^{\mathrm{w}} \end{bmatrix}, \quad \operatorname{dev}\boldsymbol{\sigma} = 2\,\mu\operatorname{dev}\boldsymbol{\epsilon}\,, \tag{7.4.47}$$

features the undrained bulk modulus K^{U} that can be expressed in terms of the drained bulk modulus K, and of the coefficients α_{w} and S,

$$K^{\mathrm{U}} = \frac{K}{1-\alpha_{\mathrm{w}}\,S} = \frac{M\,\alpha_{\mathrm{w}}}{S}\,. \tag{7.4.48}$$

Another form of the elastic relations may be recorded,

$$\begin{bmatrix} \frac{1}{3}\,\mathrm{tr}\,\boldsymbol{\sigma} \\ \zeta^{\mathrm{w}} \end{bmatrix} = \begin{bmatrix} K & -\alpha_{\mathrm{w}} \\ \alpha_{\mathrm{w}} & 1/M \end{bmatrix} \begin{bmatrix} \mathrm{tr}\,\boldsymbol{\epsilon} \\ p_{\mathrm{w}} \end{bmatrix}, \quad \mathrm{dev}\,\boldsymbol{\sigma} = 2\,\mu\,\mathrm{dev}\,\boldsymbol{\epsilon}\,, \tag{7.4.49}$$

which provides a further mixed expression of the energy,

$$\frac{1}{2}\,\boldsymbol{\sigma} : \boldsymbol{\epsilon} + p_{\mathrm{w}}\,\zeta^{\mathrm{w}} = \frac{1}{2}\,\boldsymbol{\sigma}' : \boldsymbol{\epsilon} + \frac{1}{2}\,\frac{p_{\mathrm{w}}^2}{M} = \frac{1}{2}\,K\,(\mathrm{tr}\,\boldsymbol{\epsilon})^2 + \mu\,(\mathrm{dev}\,\boldsymbol{\epsilon})^2 + \frac{1}{2}\,\frac{p_{\mathrm{w}}^2}{M}\,. \tag{7.4.50}$$

in terms of strain and pore pressure, since $\boldsymbol{\sigma}' = \boldsymbol{\sigma} + \alpha_{\mathrm{w}}\,\mathbf{I} = K\,\mathrm{tr}\,\boldsymbol{\epsilon}\,\mathbf{I} + 2\,\mu\,\mathrm{dev}\,\boldsymbol{\epsilon}$.

Finally, since water does not resist shear stresses, note

Proposition 7.4 Voigt bound for the shear modulus.

For an isotropic solid skeleton, the estimation of the shear modulus of the solid skeleton in terms of the shear modulus of the solid constituent and its volume fraction,

$$\mu = n^{\mathrm{s}}\,\mu_{\mathrm{s}}\,, \tag{7.4.51}$$

represents an upper bound known as Voigt bound, Fig. 7.3.3.

Indeed, the deviatoric parts of the constitutive laws at the scale of the solid constituent and porous medium write respectively, $\mathrm{dev}\,\boldsymbol{\sigma}_{\mathrm{s}} = 2\,\mu_{\mathrm{s}}\,\mathrm{dev}\,\boldsymbol{\epsilon}_{\mathrm{s}}$, Eqn (7.2.22), and $\mathrm{dev}\,\boldsymbol{\sigma} = 2\,\mu\,\mathrm{dev}\,\boldsymbol{\epsilon}$, Eqn (7.4.47). Moreover $\mathrm{dev}\,\boldsymbol{\sigma} = n^{\mathrm{s}}\mathrm{dev}\,\boldsymbol{\sigma}_{\mathrm{s}}$, Eqn (7.1.2), since the fluid does not resist shear. The relation follows if the deviatoric strain is assumed to be uniform over constituents, namely $\mathrm{dev}\,\boldsymbol{\epsilon} = \mathrm{dev}\,\boldsymbol{\epsilon}_{\mathrm{s}}$.

7.4.5 Compatibility conditions for transversely isotropic porous media

We consider now a transversely isotropic elastic porous medium with rotational symmetry about the unit vector $\mathbf{b}$, and we make use of a cartesian material frame $(\mathbf{b}^{(1)}, \mathbf{b}^{(2)}, \mathbf{b}^{(3)}{=}\mathbf{b})$. The drained elastic compliance tensor $\mathbb{E}^{-1}$ are expressed in terms of five independent parameters, namely longitudinal Young's modulus E_{L} and Poisson's ratio ν_{L} (contraction in transverse direction due to traction in longitudinal direction), transverse Young's modulus E_{T} and Poisson's ratio ν_{T}, and longitudinal shear modulus μ_{L}, the transverse shear modulus μ_{T} being equal to $E_{\mathrm{T}}/2(1+\nu_{\mathrm{T}})$.

In order to perform the spectral analysis of the drained elastic compliance tensor $\mathbb{E}^{-1}$, it is convenient to use the matrix representation in the format (5.2.52). Positive definiteness of $\mathbb{E}^{-1}$ is ensured by the inequalities (5.2.56). A similar representation in terms of undrained moduli and Poisson's ratios is available for the undrained compliance tensor $(\mathbb{E}^{\mathrm{U}})^{-1}$ which are also assumed to be positive definite.

The spectral analysis of the elastic stiffness $\mathbb{E}$ of a transversely isotropic material is reported in Section 5.3.2.1. This information can be used for the difference $\mathbb{C}$ of elastic compliance tensors, Eqn (7.4.28). $\mathbb{C}$ has in general four distinct eigenvalues, namely $\Lambda^{(1,2)} = 1/2\,\mu_{\mathrm{L}} - 1/2\,\mu_{\mathrm{L}}^{\mathrm{U}}$ and $\Lambda^{(3,4)} = 1/2\,\mu_{\mathrm{T}} - 1/2\,\mu_{\mathrm{T}}^{\mathrm{U}}$ each of multiplicity two, and two eigenvalues $\Lambda^{(5)}$ and $\Lambda^{(6)}$ of single multiplicity. Since from *Property 3*, the difference $\mathbb{C}$ should have a single non zero eigenvalue of multiplicity one associated with a dilatational eigenmode, the following four cases are available:

$$\begin{array}{lllllll} \text{1) either} & \mu_{\mathrm{L}} - \mu_{\mathrm{L}}^{\mathrm{U}} \neq 0 & \text{while} & \mu_{\mathrm{T}} - \mu_{\mathrm{T}}^{\mathrm{U}} = 0, & \Lambda^{(5,6)} = 0\,, & & \\ \text{2) or} & \mu_{\mathrm{T}} - \mu_{\mathrm{T}}^{\mathrm{U}} \neq 0 & \text{while} & \mu_{\mathrm{L}} - \mu_{\mathrm{L}}^{\mathrm{U}} = 0, & \Lambda^{(5,6)} = 0\,, & & \\ \text{3) or} & \Lambda^{(5)} \neq 0 & \text{while} & \mu_{\mathrm{L}} - \mu_{\mathrm{L}}^{\mathrm{U}} = 0, & \mu_{\mathrm{T}} - \mu_{\mathrm{T}}^{\mathrm{U}} = 0, & \Lambda^{(6)} = 0\,, & \\ \text{4) or} & \Lambda^{(6)} \neq 0 & \text{while} & \mu_{\mathrm{L}} - \mu_{\mathrm{L}}^{\mathrm{U}} = 0, & \mu_{\mathrm{T}} - \mu_{\mathrm{T}}^{\mathrm{U}} = 0, & \Lambda^{(5)} = 0\,. & \end{array} \tag{7.4.52}$$

However, $\Lambda^{(1,2)}$ and $\Lambda^{(3,4)}$ are of double multiplicity and, moreover, their associated eigenmodes are isochoric: therefore, cases 1) and 2) above are excluded. Using Eqn (5.3.9), one may show that cases 3) and 4) yield formally similar constraints. Consequently, there are three compatibility relations to be satisfied by the drained and undrained coefficients for the difference $\mathbb{E}^{-1} - (\mathbb{E}^{\mathrm{U}})^{-1}$ to be dyadic, namely,

$$\mu_{\mathrm{L}}^{\mathrm{U}} = \mu_{\mathrm{L}}\,, \quad \mu_{\mathrm{T}}^{\mathrm{U}} = \frac{E_{\mathrm{T}}^{\mathrm{U}}}{2\,(1+\nu_{\mathrm{T}}^{\mathrm{U}})} = \mu_{\mathrm{T}} = \frac{E_{\mathrm{T}}}{2\,(1+\nu_{\mathrm{T}})}\,, \quad C_{11}C_{33} - C_{13}^2 = 0\,, \tag{7.4.53}$$

with

$$C_{11} = \frac{1}{E_{\rm T}} - \frac{1}{E^{\rm U}_{\rm T}}\,, \quad C_{33} = \frac{1}{E_{\rm L}} - \frac{1}{E^{\rm U}_{\rm L}}\,, \quad C_{13} = -\frac{\nu_{\rm L}}{E_{\rm L}} + \frac{\nu^{\rm U}_{\rm L}}{E^{\rm U}_{\rm L}}\,. \tag{7.4.54}$$

Cases 3) and 4) differ only by the sign of C_{11} and C_{33}: for case 3), both these scalars are negative while they are positive for case 4). In both cases, the eigenvalue Λ and unit eigentensor $\mathbf{E}$ of $\mathbb{C}$ are equal to,

$$\Lambda = 2\,C_{11} + C_{33}\,, \quad \mathbf{E} = \frac{\mathbf{diag}\,[C_{11}, C_{11}, C_{13}]}{\sqrt{2\,C_{11}^2 + C_{13}^2}}\,. \tag{7.4.55}$$

In view of Eqns $(7.4.53)_3$ and $(7.4.55)_1$, C_{11} and C_{33} should be of the same sign as Λ, that is, according to $(7.4.27)_1$, positive,

$$C_{11} > 0\,, \qquad C_{33} > 0\,. \tag{7.4.56}$$

Also, the constraints (7.4.53) and (7.4.54) and the positive definiteness of the strain energy function (7.4.25) imply the inequality

$$1 + \frac{(\nu^{\rm U}_{\rm L} - \nu_{\rm L})^2}{\dfrac{1-\nu_{\rm T}}{2}\dfrac{E_{\rm L}}{E_{\rm T}} - (\nu_{\rm L})^2} < \frac{E^{\rm U}_{\rm L}}{E_{\rm L}}\,, \tag{7.4.57}$$

and, as a further consequence of (7.4.53) and (7.4.57), the following inequalities hold as well:

$$-1 < \nu_{\rm T} < \nu^{\rm U}_{\rm T} < 1 \quad \text{and} \quad 0 < E_{\rm T} < E^{\rm U}_{\rm T} < \frac{2\,E_{\rm T}}{1+\nu_{\rm T}}\,. \tag{7.4.58}$$

Since there are three constraints, Eqns (7.4.53), on the five undrained parameters $E^{\rm U}_{\rm L}$, $\nu^{\rm U}_{\rm L}$, $E^{\rm U}_{\rm T}$, $\nu^{\rm U}_{\rm T}$, $\mu^{\rm U}_{\rm L}$, *two independent undrained measurements* are, as expected, still required to define completely the eight constitutive parameters.

The question of which measurements are the most satisfactory is discussed further in Loret et al. [2001]. The notion of *independent* measurements can now be illustrated: for example, due to $(7.4.53)_2$, the measurements of the undrained Poisson's ratio $\nu^{\rm U}_{\rm T}$ and undrained Young's modulus $E^{\rm U}_{\rm T}$ are not independent.

7.4.5.1 Further applications to incomplete data sets

The above compatibility analysis is useful to estimate lacking data. An incomplete data set of material constants is provided by Aoki et al. [1993] for a transversely isotropic shale. They give values for only seven of the eight material coefficients, namely the undrained moduli $\mathbb{E}^{\rm U}$ and the Skempton tensor $\mathbf{S}$, Table 7.4.1.

Table 7.4.1: Data set of Aoki et al. [1993] for a transversely isotropic shale.

$E^{\rm U}_{\rm L}$	$E^{\rm U}_{\rm T}$	$G^{\rm U}_{L}$	$\nu^{\rm U}_{\rm L}$	$\nu^{\rm U}_{\rm T}$	$S_{\rm L}$	$S_{\rm T}$
18.8 GPa	22.0 GPa	7.23 GPa	0.34	0.27	0.21	0.17

With one lacking measurement, bounds to the poroelastic constants are obtained by choosing the coefficient M, Eqn (7.4.19), as the missing parameter. This coefficient is left to take values at least larger than the lower bound ensuring positive definiteness of the tensor moduli, namely $M > M_{\rm PD} = 6.41\,$GPa, Eqn (7.4.35). At the upper bound of the interval, namely for $M \to \infty$, the drained and undrained elastic compliance tensors are identical, Eqn (7.4.29). Actually, since $\mathrm{tr}\,\mathbf{S} = 2\,S_{\rm T} + S_{\rm L} = 0.55 < 1$, the positiveness of the tensor moduli $\mathbb{E}_{\rm s}$ of the solid constituent requires the higher lower bound $M > M_{\rm inf} = 11.65\,$GPa, which is obtained from (7.4.39) by substituting the undrained bulk modulus,

$$K^{\rm U} = \frac{E^{\rm U}_{\rm L}\,E^{\rm U}_{\rm T}}{2\,(1-\nu^{\rm U}_{\rm T})\,E^{\rm U}_{\rm L} + (1-4\,\nu^{\rm U}_{\rm L})\,E^{\rm U}_{\rm T}} = 21.18\,\text{GPa}\,. \tag{7.4.59}$$

For any value of $M > M_{\rm inf}$, the drained compliance tensor is obtained explicitly from Eqn (7.4.29), the second order tensor $\mathbf{A}$ from Eqn (7.4.31) and the bulk moduli K and $K_{\rm s}$ from Eqns (7.4.37) and (7.4.38), respectively. Notice that, as it appears from Eqns (7.4.29) and (7.4.38), for $M \to \infty$, $(\mathbb{E})^{-1} \to (\mathbb{E}^{\rm U})^{-1}$ and K, $K_{\rm s} \to K^{\rm U}$, while, from Eqn (7.4.31), $\mathbf{A} \to \mathbf{0}$.

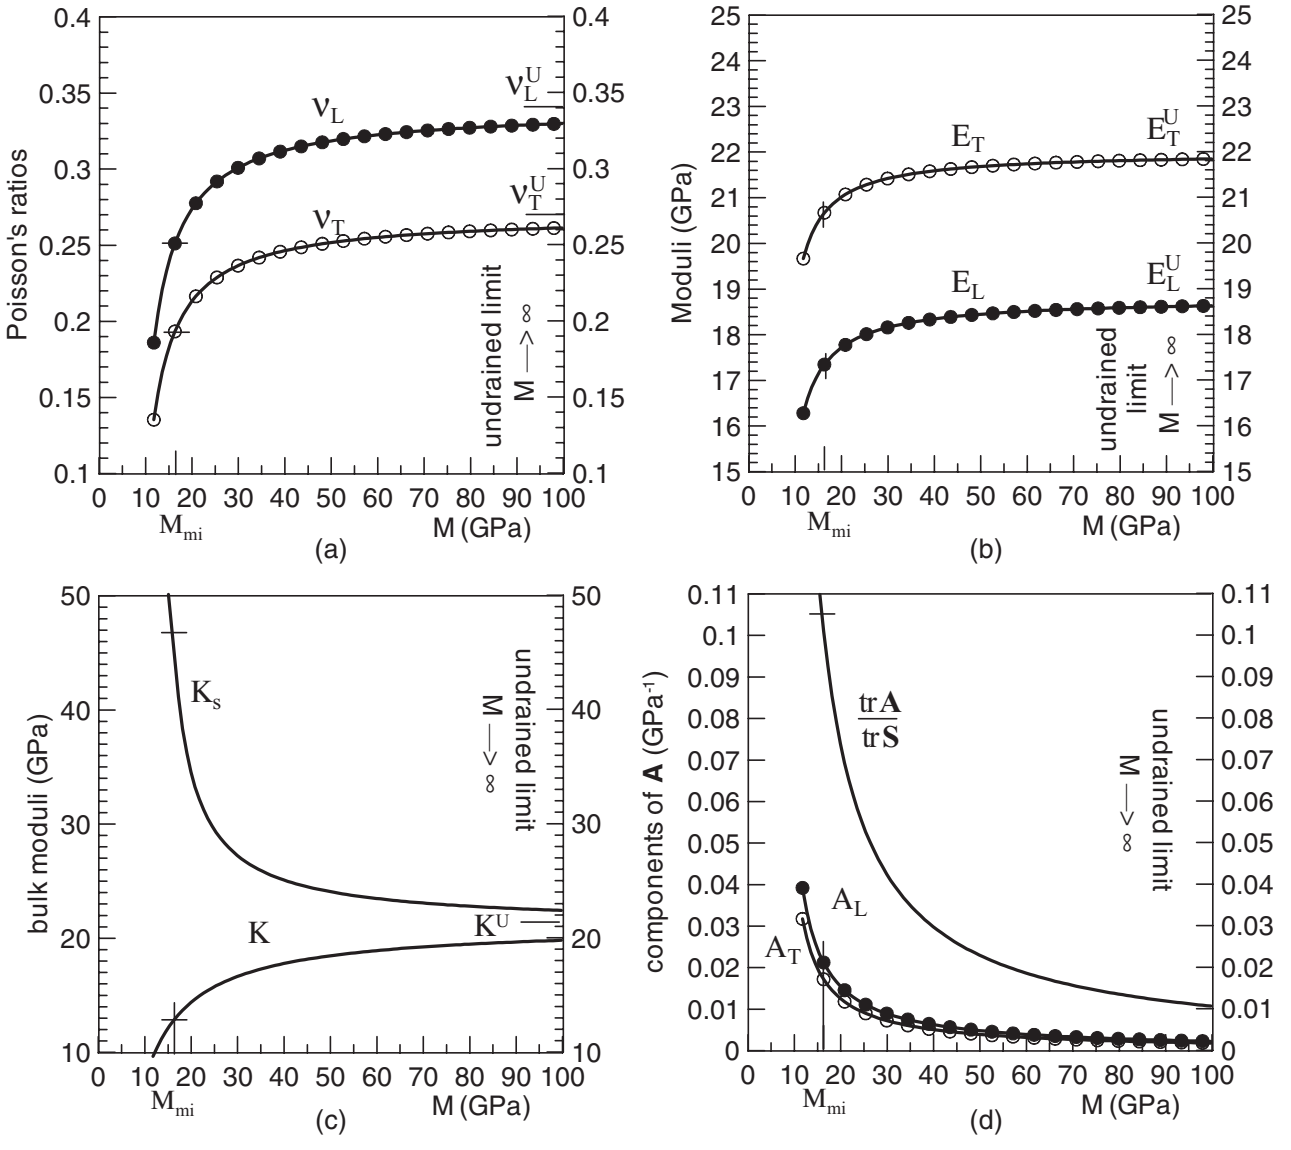

Fig. 7.4.2: Transverse isotropic shale whose undrained coefficients and Skempton tensor have been measured by Aoki et al. [1993] as indicated by Table 7.4.1. (a) Drained longitudinal and transverse Poisson's ratios ν_{L} and ν_{T} as a function of the unknown modulus M varying in the admissible range $]M_{\mathrm{inf}}, +\infty[$. The lower bound M_{inf}=11.65 GPa ensures positiveness of the bulk modulus $K_{\mathrm{s}}>0$ of the solid constituent, and is oversufficient to ensure the positive definiteness of the tensor of drained moduli. The value $M = M_{\mathrm{mi}}$ reported by Cheng [1997] for an isotropic solid constituent is equal to 15.76 GPa. (b) Drained longitudinal and transverse Young's moduli E_{L} and E_{T}. (c) Drained bulk modulus K and bulk modulus K_{s} of the solid constituent. (d) Longitudinal and transverse components A_{L}, A_{T} of the second order tensor $\mathbf{A}$ and coefficient $\mathrm{tr}\,\mathbf{A}/S$. Redrawn with permission from Loret et al. [2001].

The poroelastic constants involved in the constitutive Eqns (7.4.11), namely the drained compliance tensor $\mathbb{L}^{-1}$, given in terms of ν_{L}, ν_{T}, E_{L}, E_{T}, and μ_{L}, the second order tensor $\mathbf{A}$ and the scalar $\mathrm{tr}\,\mathbf{A}/S$, together with the bulk moduli K and K_{s}, are plotted in Fig. 7.4.2. As shown in Fig. 7.4.2(b), the ranges of variation of the drained moduli E_{L} and E_{T} are quite narrow and, as implied by inequalities (7.4.57) and (7.4.58), E_{L} and E_{T} are smaller than their undrained counterparts. On the other hand, the ranges of the other parameters are wider. Fig. 7.4.2(a) shows that the Poisson's ratios vary more significantly than the Young's moduli and, consistently with Eqn (7.4.58), $\nu_{\mathrm{T}} < \nu_{\mathrm{T}}^{\mathrm{U}}$. The range of the bulk modulus K_{s} shown in Fig. 7.4.2(c) is very wide, starting from $+\infty$ for $M \to M_{\mathrm{inf}}$, to K^{U} for $M \to \infty$, while the variation of K, which also converges to K^{U} for $M \to \infty$, is less pronounced, since $K \to (1-S)\,K^{\mathrm{U}}$ for $M \to M_{\mathrm{inf}}$. Finally, Fig. 7.4.2(d) shows how the Skempton coefficient S amplifies the interval of variation of the scalar $\mathrm{tr}\,\mathbf{A}/S$ with respect to the ranges of the two components A_{L}, A_{T}, which are rather close

to each other; as expected from Eqn (7.4.31), the components of $\mathbf{A}$ tend to zero for $M \to \infty$, while they increase rapidly when $M \to M_{\rm inf}$ even if this value is still larger than $M_{\rm PD}$, Eqns (7.4.31) and (7.4.35).

A different solution procedure is also proposed in Loret et al. [2001]: all material coefficients may be solved explicitly in terms of one of the drained parameters $E_{\rm L}$, $E_{\rm T}$, $\nu_{\rm L}$ and $\nu_{\rm T}$, ranging between the bounds ensuring positiveness of the strain energy and of $K_{\rm s}$.

While this approach only bounds the elastic parameters, the two alternatives below allow to recover some definite value of the missing datum.

7.4.5.2 Micro-isotropy

Cheng [1997] assumes the microscale elastic response to be isotropic: macroscale anisotropy emanates from non-random directional and spatial distributions of structural members.

This micro-isotropy assumption results in a reduced number of independent coefficients. For example, for transverse isotropy, we know that the constitutive equations are defined by 8 independent constants, e.g., from Eqns (7.4.18) and (7.4.30), by $\mathbb{E}^{\rm U}$ (5 constants), $\boldsymbol{\alpha}_{\rm w}$ or $\mathbf{S}$ (2 constants) and M. However, for micro-isotropy, $\mathbb{E}_{\rm s}^{-1} : \mathbf{I} = \mathbf{I}/3K_{\rm s}^{\rm mi}$, and $K_{\rm s}^{\rm mi}$ and $M_{\rm mi}$ can be expressed in terms of $\mathbb{E}^{\rm U}$ and $\mathbf{S}$. Therefore only 7 independent measurements are required. In fact using Eqns (7.4.14), $(7.4.22)_2$, and (7.4.30) yields the (Biot) tensor,

$$\boldsymbol{\alpha}_{\rm w}^{\rm mi} = \frac{1}{1 - \dfrac{1}{3K_{\rm s}^{\rm mi}}\,\mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{I}} \left(\mathbf{I} - \frac{1}{3K_{\rm s}^{\rm mi}}\,\mathbb{E}^{\rm U} : \mathbf{I}\right), \tag{7.4.60}$$

which, again with (7.4.30), provides $K_{\rm s}^{\rm mi}$ and $M_{\rm mi}$ in terms of $\mathbb{E}^{\rm U}$ and $\mathbf{S}$:

$$\frac{1}{3K_{\rm s}^{\rm mi}} = \frac{3}{X}\,\mathrm{dev}\,\mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{S}\,, \qquad \frac{1}{M_{\rm mi} - \mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{S}} = \frac{3}{X}\,\frac{\mathrm{dev}\,\mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{I}}{\mathrm{tr}\,\mathbf{S} - 1}\,, \tag{7.4.61}$$

where $\mathrm{dev}\,\mathbf{S}$ is the deviatoric part of $\mathbf{S}$, namely $\mathrm{dev}\,\mathbf{S} = \mathbf{S} - (\mathrm{tr}\,\mathbf{S}/3)\,\mathbf{I}$, which is expected to be non zero for true anisotropy, and then

$$X = (\mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{S})\,(\mathbf{I} : \mathbb{E}^{\rm U} : \mathbf{I}) - (\mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{I})^2\,, \tag{7.4.62}$$

is positive as a consequence of the Cauchy-Schwarz inequality.

7.4.5.3 On the Saint-Venant's relations for transverse isotropy

In place of the micro-isotropy assumption, one might have thought to use the so-called Saint-Venant's relations, Section 5.2.10, to obtain the missing coefficient M. For arbitrary anisotropy, Eqn (7.4.29) yields M in the following format,

$$\frac{1}{M - \mathbf{S} : \mathbb{E}^{\rm U} : \mathbf{S}} = \frac{f_{\rm SV}(\mathbb{E}^{\rm U}) - f_{\rm SV}(\mathbb{E})}{(S_{\rm T} - S_{\rm L})^2}\,, \tag{7.4.63}$$

where $f_{\rm SV}(\mathbb{E})$, Eqn (5.2.68), is the Saint-Venant's function associated with the drained moduli,

$$f_{\rm SV}(\mathbb{E}) \equiv \frac{1}{\mu_{\rm L}} - \frac{1}{E_L} - \frac{1}{E_T} - 2\,\frac{\nu_{\rm L}}{E_L}\,, \tag{7.4.64}$$

and similarly for $f_{\rm SV}(\mathbb{E}^{\rm U})$. Consequently, the Saint-Venant's relation $f_{\rm SV} = 0$ can not hold *strictly* for *both* the drained and undrained coefficients, if these two sets of coefficients are to be different and to correspond to a positive definite strain energy function.

7.4.6 Compatibility conditions for orthotropic porous media

Let us consider an orthotropic porous medium with axes of elastic orthotropy denoted by $(\mathbf{b}^{(1)}, \mathbf{b}^{(2)}, \mathbf{b}^{(3)})$. The matrix representation in these axes of the drained elastic compliance tensor $\mathbb{E}^{-1}$ is displayed on Eqn (5.2.46). It expresses in terms of three drained Young's moduli E_1, E_2, E_3, three shear moduli μ_{12}, μ_{13}, μ_{23} and three Poisson's ratios ν_{12}, ν_{13}, ν_{23}. The conditions of positive definiteness are provided by (5.E.25).

By the principle of equipresence, the symmetric second order tensor $\mathbf{E}$, Eqns (7.4.27)$_1$ and (7.4.28), expresses along the orthotropy axes,

$$\mathbf{E} = \sum_{i=1}^{3} \gamma_i \, \mathbf{b}^{(i)} \otimes \mathbf{b}^{(i)} \quad \text{with} \quad \sum_{i=1}^{3} \gamma_i^2 = 1 \,. \tag{7.4.65}$$

Consequently the lower principal 3×3 minor of the matrix representation of the fourth order tensor $\mathbb{C}$ vanishes: the drained and undrained shear coefficients are equal as expected,

$$\mu_{12} = \mu_{12}^{\mathrm{U}} \,, \quad \mu_{23} = \mu_{23}^{\mathrm{U}} \,, \quad \mu_{13} = \mu_{13}^{\mathrm{U}} \,. \tag{7.4.66}$$

Let us now have a closer look at the upper principal minor of $\mathbb{C}$,

$$\mathbf{C} = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{12} & C_{22} & C_{23} \\ C_{13} & C_{23} & C_{33} \end{bmatrix} = \Lambda \begin{bmatrix} \gamma_1^2 & \gamma_1\gamma_2 & \gamma_1\gamma_3 \\ \gamma_1\gamma_2 & \gamma_2^2 & \gamma_2\gamma_3 \\ \gamma_1\gamma_3 & \gamma_2\gamma_3 & \gamma_3^2 \end{bmatrix} , \tag{7.4.67}$$

where

$$\begin{aligned} C_{11} &= \frac{1}{E_1} - \frac{1}{E_1^{\mathrm{U}}} \,, \quad C_{22} = \frac{1}{E_2} - \frac{1}{E_2^{\mathrm{U}}} \,, \quad C_{33} = \frac{1}{E_3} - \frac{1}{E_3^{\mathrm{U}}} \,, \\ C_{12} &= -\frac{\nu_{12}}{E_1} + \frac{\nu_{12}^{\mathrm{U}}}{E_1^{\mathrm{U}}} \,, \quad C_{13} = -\frac{\nu_{13}}{E_1} + \frac{\nu_{13}^{\mathrm{U}}}{E_1^{\mathrm{U}}} \,, \quad C_{23} = -\frac{\nu_{23}}{E_2} + \frac{\nu_{23}^{\mathrm{U}}}{E_2^{\mathrm{U}}} \,. \end{aligned} \tag{7.4.68}$$

Notice that if $\{\gamma_1, \gamma_2, \gamma_3\}$ is a solution set of (7.4.67), so is $\{-\gamma_1, -\gamma_2, -\gamma_3\}$; therefore, only one of these sets needs to be considered. Now, for solutions to (7.4.67) to exist, the coefficient matrix $\mathbf{C}$ should satisfy the following compatibility requirements, for $i \neq j \neq k$ (no sum over repeated indices):

$$\operatorname{sgn} C_{ii} = \operatorname{sgn} \Lambda = 1 \,; \quad C_{ii}\, C_{jj} - C_{ij}^2 = 0 \,; \quad \text{if } C_{ij}\, C_{jk}\, C_{ki} \neq 0 \,, \quad \text{then } \operatorname{sgn} C_{ij}\, C_{jk}\, C_{ki} = 1 \,. \tag{7.4.69}$$

Then, since $\gamma_i^2 = C_{ii}/\Lambda$, $i \in [1,3]$, (no sum over i), the signs of the γ's are defined according to the following rules:

$$\begin{aligned} &- \text{ if } \gamma_1 \neq 0, \text{ then } \operatorname{sgn} \gamma_1 = 1 \text{ and, for } j \neq 1 : \begin{cases} \text{if } C_{1j} \neq 0, & \text{then } \operatorname{sgn} \gamma_j = \operatorname{sgn} (C_{1j}/\Lambda), \\ \text{if } C_{1j} = 0, & \text{then } \gamma_j = 0; \end{cases} \\ &- \text{ if } \gamma_1 = 0, \text{ then } \begin{cases} \text{if } C_{23} \neq 0, & \text{then } \operatorname{sgn} \gamma_2 \operatorname{sgn} \gamma_3 = \operatorname{sgn} (C_{23}/\Lambda), \\ \text{if } C_{23} = 0, & \text{then } \gamma_2 = 0 \text{ or } \gamma_3 = 0 \,. \end{cases} \end{aligned} \tag{7.4.70}$$

In other words, the eigenmode $\mathbf{E}$ of the compliance difference $\mathbb{C}$, Eqn (7.4.28), may be defined by one of the following three equivalent forms:

$$\mathbf{E} = \mathbf{E}_{(1)} = \mathbf{E}_{(2)} = \mathbf{E}_{(3)} \quad \text{with} \quad \mathbf{E}_{(i)} = \frac{\mathbf{diag}\,[C_{1i}, C_{2i}, C_{3i}\,]}{\sqrt{C_{1i}^2 + C_{2i}^2 + C_{3i}^2}}, \quad i \in [1,3]. \tag{7.4.71}$$

Summarizing, notwithstanding the sign restrictions, there are six constraints, Eqns (7.4.66) and (7.4.69)$_2$, on the nine undrained coefficients E_1^{U}, E_2^{U}, E_3^{U}, μ_{12}^{U}, μ_{13}^{U}, μ_{23}^{U}, ν_{12}^{U}, ν_{13}^{U}, ν_{23}^{U}: *three independent undrained measurements* required to define the 13 constitutive parameters can be proposed, Loret et al. [2001]:

- three undrained coefficients may be measured directly;
- alternatively, the Skempton tensor $\mathbf{S}$ may be measured together with one undrained coefficient.

7.4.7 Porous media with fabric anisotropy

The particular form of anisotropic elasticity based on a symmetric second order fabric tensor $\mathbf{B}$ has been described in Section 5.2.11. The relations (7.4.13) linking the strain and the effective stress express through the drained stiffness (5.2.72) or its inverse (5.2.79). Positive definiteness of the drained stiffness expresses, through Eqn (5.2.30), like for isotropic elasticity, either in terms of the drained Lamé moduli or in terms of Young's modulus and Poisson's ratio.

When the eigenvalues $b_i > 0$, $i \in [1,3]$, of $\mathbf{B}$ are distinct, the material is orthotropic. When only two of the eigenvalues of $\mathbf{B}$ are equal, the material is endowed with transverse isotropy. Otherwise, the material is isotropic, since then $\mathbf{B} = \mathbf{I}$.

7.4.7.1 Compatibility between drained and undrained fabrics

A representation similar to that of the drained compliance (and stiffness) holds for its undrained counterpart: it expresses in terms of the undrained Young's modulus E^{U} and Poisson's ratio ν^{U}, and of the undrained fabric tensor $\mathbf{B}^{\mathrm{U}}$:

$$\begin{aligned}(\mathbb{E})^{-1} &= \frac{1+\nu}{E}\,(\mathbf{B})^{-1}\,\underline{\overline{\otimes}}\,(\mathbf{B})^{-1} - \frac{\nu}{E}\,(\mathbf{B})^{-1}\otimes(\mathbf{B})^{-1},\\ (\mathbb{E}^{\mathrm{U}})^{-1} &= \frac{1+\nu^{\mathrm{U}}}{E^{\mathrm{U}}}\,(\mathbf{B}^{\mathrm{U}})^{-1}\,\underline{\overline{\otimes}}\,(\mathbf{B}^{\mathrm{U}})^{-1} - \frac{\nu^{\mathrm{U}}}{E^{\mathrm{U}}}\,(\mathbf{B}^{\mathrm{U}})^{-1}\otimes(\mathbf{B}^{\mathrm{U}})^{-1}.\end{aligned} \tag{7.4.72}$$

The undrained fabric tensor $\mathbf{B}^{\mathrm{U}}$ should satisfy conditions analogous to (5.2.74). Also, since we have assumed the drained and undrained moduli to share the same directions of anisotropy, the undrained fabric tensor needs to be coaxial with $\mathbf{B}$. Indeed, more than that, the compatibility relations (7.4.22) and (7.4.28) require the two fabric tensors to be equal,

$$\mathbf{B}^{\mathrm{U}} = \mathbf{B}\,. \tag{7.4.73}$$

In fact, since the diagonal shear terms of the compliance difference $\mathbb{C}$ corresponding to the $\underline{\overline{\otimes}}$ products must vanish, from Eqn (7.4.72) we get:

$$\frac{1+\nu^{\mathrm{U}}}{E^{\mathrm{U}}}(\mathbf{B}^{\mathrm{U}})^{-1}\,\underline{\overline{\otimes}}\,(\mathbf{B}^{\mathrm{U}})^{-1} = \frac{1+\nu}{E}\mathbf{B}^{-1}\,\underline{\overline{\otimes}}\,\mathbf{B}^{-1}\,. \tag{7.4.74}$$

The inverse of $\mathbf{B}^{-1}\,\underline{\overline{\otimes}}\,\mathbf{B}^{-1}$ is $\mathbf{B}\,\underline{\overline{\otimes}}\,\mathbf{B}$, which has matrix components along the diagonal only, namely $[\,b_1^2, b_2^2, b_3^2, b_2\,b_3,\, b_1\,b_3,\, b_1\,b_2\,]$, and similarly for the undrained fabric. Then the normalization $(5.2.74)_2$ implies the same relation (7.4.41) which holds for isotropy, namely $E^{\mathrm{U}}/(1+\nu^{\mathrm{U}})=E/(1+\nu)$.

Finally, to satisfy the dyadic forms (7.4.22) and (7.4.28), the tensor $\mathbf{A}$, Eqn $(7.4.27)_1$, must be proportional to $\mathbf{B}^{-1}$ and can be cast in a form that generalizes its isotropic counterpart, Eqn (7.4.42):

$$\mathbf{A} = \mathbb{E}^{-1}\!:\boldsymbol{\alpha}_{\mathrm{w}} = \frac{1}{S\,E}\,\frac{\nu^{\mathrm{U}}-\nu}{1+\nu^{\mathrm{U}}}\,(\mathrm{tr}\,\mathbf{B}^{-1})\,\mathbf{B}^{-1}\,. \tag{7.4.75}$$

Consequently, together with the drained Young's modulus and Poisson's ratio, *a single undrained parameter needs to be measured, e.g.,* ν^{U}. The condition $M>0$, Eqns (7.4.19) and (7.4.25), implies the same restrictions on the measured coefficient ν^{U} and on E and E^{U} as in the isotropic case, Eqn (7.4.43). The general properties outlined here are confirmed below by separate derivations for the particular forms of transverse isotropy and orthotropy.

7.4.7.2 Compatibility between drained and undrained fabrics: transverse isotropy

Let us assume the axis of rotational symmetry to be the axis $\mathbf{b}=\mathbf{b}^{(3)}$, i.e., $b_1=b_2$, and hence $2\,b_1^2+b_3^2=3$. The drained compliance being expressed in the axes of anisotropy, the identification of the five drained coefficients in terms of, e.g., E, ν and b_1 (and b_3) yields, the indices T and L indicating the transverse and longitudinal directions, respectively,

$$E_T = E\,b_1^2\,,\ \nu_{\mathrm{T}}=\nu\,,\ E_L = E\,b_3^2\,,\ \nu_{\mathrm{L}}=\nu\,\frac{b_3}{b_1}\,,\ \mu_{\mathrm{L}}=\frac{E}{2(1+\nu)}\,b_1\,b_3\,. \tag{7.4.76}$$

Similar relations hold for the undrained coefficients:

$$E^{\mathrm{U}}_{\mathrm{T}} = E^{\mathrm{U}}\,(b_1^U)^2\,,\ \nu^{\mathrm{U}}_{\mathrm{T}}=\nu^{\mathrm{U}}\,,\ E^{\mathrm{U}}_{\mathrm{L}} = E^{\mathrm{U}}\,(b_3^U)^2\,,\ \nu^{\mathrm{U}}_{\mathrm{L}}=\nu^{\mathrm{U}}\,\frac{b_3^U}{b_1^U}\,,\ \mu^{\mathrm{U}}_{\mathrm{L}}=\frac{E^{\mathrm{U}}}{2\,(1+\nu^{\mathrm{U}})}b_1^U b_3^U\,. \tag{7.4.77}$$

Out of the three constraints in Eqn (7.4.53), only two are independent. As expected, they imply the tensors $\mathbf{B}$ and $\mathbf{B}^{\mathrm{U}}$ to be equal; also the undrained coefficients can be expressed in terms of E, ν, b_1 (and b_3) and of a single undrained parameter to be measured, say ν^{U}:

$$E^{\mathrm{U}}_{\mathrm{T}} = E\,\frac{1+\nu^{\mathrm{U}}}{1+\nu}\,b_1^2,\ \nu^{\mathrm{U}}_{\mathrm{T}}=\nu^{\mathrm{U}},\ E^{\mathrm{U}}_{\mathrm{L}} = E\,\frac{1+\nu^{\mathrm{U}}}{1+\nu}\,b_3^2,\ \nu^{\mathrm{U}}_{\mathrm{L}}=\nu^{\mathrm{U}}\,\frac{b_3}{b_1},\ \mu^{\mathrm{U}}_{\mathrm{L}}=\mu_{\mathrm{L}}=\frac{E}{2(1+\nu)}\,b_1 b_3. \tag{7.4.78}$$

Notice that positive definiteness of $\mathbb{E}^{\mathrm{U}}$ requires ν^{U} to belong to the interval $]-1,1/2[$. Then, using (7.4.55), it is an easy matter to calculate the eigenvalue Λ and eigenmode $\mathbf{E}$, from which the tensor $\mathbf{A}$, Eqn $(7.4.27)_1$, may be cast in the form (7.4.75).

In summary, elastic fluid-saturated porous media embedding this particular form of transverse isotropy based on a fabric tensor are characterized by five parameters, e.g., E, ν, b_1, ν^{U}, S, as opposed to eight for general transversely isotropic porous media.

7.4.7.3 Compatibility between drained and undrained fabrics: orthotropy

Proceeding as above, one may first identify the orthotropic drained parameters in terms of E, ν and the eigenvalues of $\mathbf{B}$:

$$E_i = E\, b_i^2 \quad \text{for } i = 1,2,3\,;$$
$$\nu_{ij} = \nu\, \frac{b_i}{b_j}, \quad \mu_{ij} = \mu\, b_i\, b_j \quad \text{for } (i,j) = (1,2),\ (1,3),\ (2,3)\,. \tag{7.4.79}$$

Similar relations hold for the undrained coefficients:

$$E_i^{\mathrm{U}} = E^{\mathrm{U}}\, (b_i^{\mathrm{U}})^2 \quad \text{for } i = 1,2,3\,;$$
$$\nu_{ij}^{\mathrm{U}} = \nu^{\mathrm{U}}\, \frac{b_i^{\mathrm{U}}}{b_j^{\mathrm{U}}}\,; \quad \mu_{ij}^{\mathrm{U}} = \mu^{\mathrm{U}}\, b_i^{\mathrm{U}}\, b_j^{\mathrm{U}} \quad \text{for} \quad (i,j) = (1,2),\ (1,3),\ (2,3)\,. \tag{7.4.80}$$

Positive definiteness of $\mathbb{E}^{\mathrm{U}}$ requires ν^{U} to belong to the interval $]-1, 1/2[$. As expected, the six constraints, Eqns (7.4.66) and $(7.4.69)_2$, imply $\mathbf{B}{=}\mathbf{B}^{\mathrm{U}}$; the remaining relations reduce to a single independent constraint which makes it possible to express the nine undrained parameters in terms of E, ν, b_1, b_2 (and b_3) and of a single undrained parameter to be measured, say ν^{U}:

$$E_i^{\mathrm{U}} = E\, \frac{1+\nu^{\mathrm{U}}}{1+\nu}\, b_i^2 \quad \text{for } i = 1,2,3\,;$$
$$\nu_{ij}^{\mathrm{U}} = \nu^{\mathrm{U}}\, \frac{b_i}{b_j}\,,\ \mu_{ij}^{\mathrm{U}} = \mu_{ij} = \frac{E}{2(1+\nu)}\, b_i\, b_j \ \text{ for } (i,j) = (1,2),\ (1,3),\ (2,3)\,. \tag{7.4.81}$$

The ensuing expression of $\mathbf{A}$ is still given by Eqn (7.4.75).

In summary, elastic fluid-saturated porous media embedding this particular form of orthotropy based on the fabric tensor are characterized by 6 parameters, e.g., E, ν, b_1, b_2, ν^{U}, S, as opposed to 13 for general orthotropic porous media.

7.5 Unconfined compression of a poroelastic cylinder

The unconfined compression of a poroelastic cylinder is analysed as an initial and boundary value problem. The constitutive equations, the field equations and boundary conditions, and the initial conditions that govern the problem in space and time are first highlighted. An analytical solution is next derived.

7.5.1 Poroelastic field and constitutive equations

The equations of standard poroelasticity with incompressible species are cast in the format,

$$\begin{aligned}
&\text{Balance of total mass} && \operatorname{div}\,(n^{\mathrm{s}}\,\mathbf{v}_{\mathrm{s}} + n^{\mathrm{w}}\,\mathbf{v}_{\mathrm{w}}) = 0,\\
&\text{Balance of momentum of solid phase} && \operatorname{div}\,\boldsymbol{\sigma}^{\mathrm{s}} + k_{\mathrm{Sd}}(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) - p_{\mathrm{w}}\,\boldsymbol{\nabla} n^{\mathrm{w}} = \mathbf{0}\,,\\
&\text{Balance of momentum of fluid phase} && \operatorname{div}\,\boldsymbol{\sigma}^{\mathrm{w}} - k_{\mathrm{Sd}}(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) + p_{\mathrm{w}}\,\boldsymbol{\nabla} n^{\mathrm{w}} = \mathbf{0}\,,\\
&\text{Elastic constitutive equation} && \boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\mathrm{w}}\,\mathbf{I} = \lambda\, e\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon}, \quad e \equiv \operatorname{tr}\boldsymbol{\epsilon}\,.
\end{aligned} \tag{7.5.1}$$

Several stresses come into picture: the partial stress in the fluid $\boldsymbol{\sigma}^{\mathrm{w}} = -n^{\mathrm{w}}\, p_{\mathrm{w}}\,\mathbf{I}$, p_{w} being the intrinsic fluid pressure; the total stress $\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\mathrm{s}} + \boldsymbol{\sigma}^{\mathrm{w}}$ which is the sum of the partial stresses in the solid and fluid phases; and the effective stress $\boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\mathrm{w}}\,\mathbf{I}$. The velocity of phase α is denoted by $\mathbf{v}_\alpha$, $\alpha = \mathrm{s}, \mathrm{w}$. The volume fractions n^α, $\alpha = \mathrm{s}, \mathrm{w}$, are tacitly assumed to remain fixed. The elastic constitutive equations feature the Lamé moduli λ and μ of the drained solid skeleton, or matrix, which can be expressed in terms of the drained Young's modulus and Poisson's ratio, E and ν respectively. The two balances of momentum are equivalent to the two equations,

$$\begin{aligned}
&\text{Balance of momentum of porous medium} && \operatorname{div}\,\boldsymbol{\sigma} = \mathbf{0}\,,\\
&\text{Darcy's law} && n^{\mathrm{w}}\,(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) = -k_{\mathrm{H}}\,\boldsymbol{\nabla} p_{\mathrm{w}},
\end{aligned} \tag{7.5.2}$$

where the hydraulic permeability $k_{\mathrm{H}} = (n^{\mathrm{w}})^2/k_{\mathrm{Sd}}$ [unit : $\mathrm{m}^2/\mathrm{Pa/s}$] is equal to the intrinsic permeability [unit : m^2] of the porous medium divided by the fluid viscosity [unit : Pa×s].

The field and constitutive equations should be complemented by appropriate initial and boundary conditions in order to obtain a well-posed problem.

7.5.2 Axisymmetric deformations independent of the axial coordinate

The analysis features a cylindrical specimen of radius a and the boundary conditions result in axisymmetric strains that depend on the radial position r but are independent of the axial z-coordinate as sketched in Fig. 7.5.1.

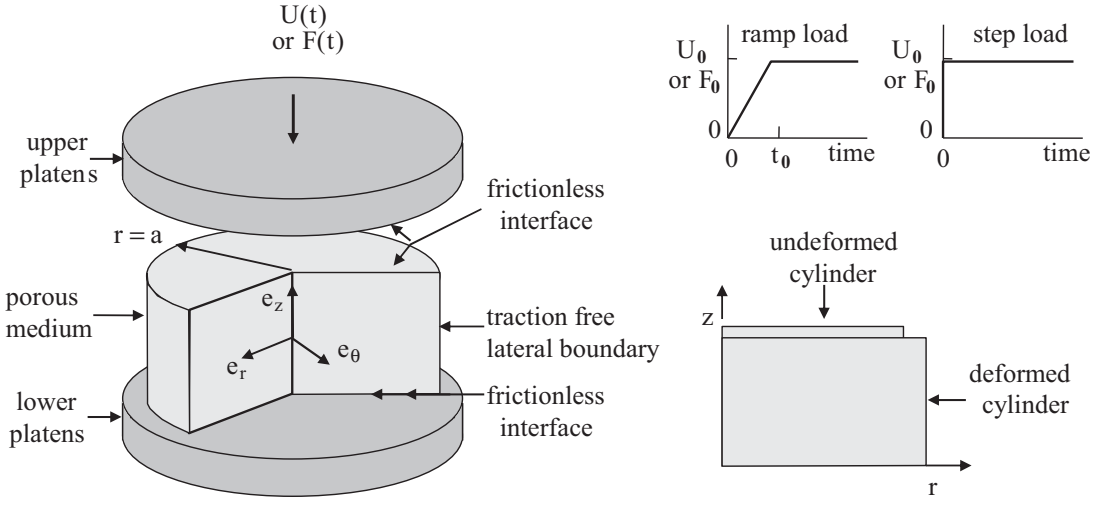

Fig. 7.5.1: A porous cylinder is squeezed between two frictionless platens, so that it keeps its cylindrical shape under application of either an axial force or an axial displacement, while the lateral boundary remains traction free, at atmospheric pressure.

The tests mimic unconfined compression, where the interface between the upper and lower platens and the specimen are frictionless. Therefore the radial, circumferential and axial components of the solid displacement in the cylindrical coordinates (r, θ, z) are of the form,

$$u_{sr} = u_{sr}(r,t), \quad u_{s\theta} = 0, \quad u_{sz} = z\,\epsilon(t)\,, \tag{7.5.3}$$

resulting in the nonzero strain components,

$$\epsilon_{rr} = \frac{\partial u_{sr}}{\partial r}\,, \quad \epsilon_{\theta\theta} = \frac{u_{sr}}{r}\,, \quad \epsilon_{zz} = \epsilon(t)\,, \tag{7.5.4}$$

and dilatation of the porous medium,

$$e = \frac{\partial u_{sr}}{\partial r} + \frac{u_{sr}}{r} + \epsilon(t)\,. \tag{7.5.5}$$

The displacement is reckoned from the configuration at time $t = 0$.

In view of the isotropic material behavior, both shear stresses and shear strains vanish in the whole specimen. The principal stresses depend on r and t due to the poroelastic equations.

There is no relative fluid flow along the axial direction, so that the components of the fluid velocity have the format,

$$v_{wr} = v_{wr}(r,t), \quad v_{w\theta} = 0, \quad v_{wz} = z\,\dot{\epsilon}\,. \tag{7.5.6}$$

The z-component of the pressure gradient $\boldsymbol{\nabla} p_w = (\partial p_w/\partial r, \partial p_w/r\partial\theta, \partial p_w/\partial z)$ vanishes in view of Darcy's law, and the fluid pressure depends only on r and t.

The lateral surface $r = a$ is traction free and the pore pressure vanishes (the fluid pressure being reckoned from the atmospheric pressure):

$$\sigma_{rr}(a,t) = 0, \quad p_w(a,t) = 0, \quad t \geq 0\,. \tag{7.5.7}$$

Of course, the radial solid displacement and fluid velocity vanish on the symmetry axis,

$$u_{sr}(r=0,t) = 0, \quad v_{wr}(r=0,t) = 0, \quad t \geq 0\,. \tag{7.5.8}$$

The field equations that are not satisfied automatically are the balance of mass $(7.5.1)_1$,

$$\frac{1}{r}\,\frac{\partial}{\partial r}\Big(r\,(n^w\,v_{wr} + n^s\,v_{sr})\Big) + \frac{\partial}{\partial z}(n^w\,v_{wz} + n^s\,v_{sz}) = 0\,, \tag{7.5.9}$$

and the balance of momentum $(7.5.2)_1$ in the r direction

$$\frac{\partial \sigma_{rr}}{\partial r} + \frac{1}{r}\,(\sigma_{rr} - \sigma_{\theta\theta}) = 0\,. \tag{7.5.10}$$

Since the axial solid and fluid velocities are equal, the equation of mass balance can be integrated in space with help of the condition (7.5.8) on the symmetry axis,

$$n^{\mathrm{w}}\, v_{\mathrm{w}r} = -n^{\mathrm{s}}\, v_{\mathrm{s}r} - \frac{r}{2}\,\dot{\epsilon}\,. \tag{7.5.11}$$

Thus Darcy's law $(7.5.2)_2$ yields the fluid pressure in terms of the radial solid velocity,

$$k_{\mathrm{H}}\,\frac{\partial p_{\mathrm{w}}}{\partial r} = v_{\mathrm{s}r} + \frac{r}{2}\,\dot{\epsilon}\,. \tag{7.5.12}$$

Introducing the elastic equation $(7.5.1)_4$ in the field equation (7.5.10), and making use of (7.5.12), yields the field equation satisfied by the radial displacement,

$$\frac{\partial^2 u_{\mathrm{s}r}}{\partial r^2} + \frac{1}{r}\,\frac{\partial u_{\mathrm{s}r}}{\partial r} - \frac{u_{\mathrm{s}r}}{r^2} = \frac{1}{H\,k_{\mathrm{H}}}\left(v_{\mathrm{s}r} + \frac{r}{2}\,\dot{\epsilon}\right), \tag{7.5.13}$$

where

$$H = \lambda + 2\,\mu = 2\,\mu\,\frac{1-\nu}{1-2\,\nu}\,, \tag{7.5.14}$$

is the drained confined compression modulus. Armstrong et al. [1984] provide an analytical solution for this problem that is detailed below.

7.5.3 Solution in the Laplace domain

The configuration at time $t = 0$ being taken as reference, the Laplace transform [7.2] $\overline{u}_{\mathrm{s}r}(r,s)$ of $u_{\mathrm{s}r}(r,t)$ satisfies the non homogeneous modified Bessel equation,

$$\frac{\partial^2 \overline{u}_{\mathrm{s}r}}{\partial R^2} + \frac{1}{R}\,\frac{\partial \overline{u}_{\mathrm{s}r}}{\partial R} - (1 + \frac{1}{R^2})\,\overline{u}_{\mathrm{s}r} = \frac{1}{2}\,b\,\overline{\epsilon}\,R\,, \tag{7.5.15}$$

with $R = r/b$, and

$$b = \sqrt{H\,k_{\mathrm{H}}/s}\,. \tag{7.5.16}$$

It is useful to introduce the characteristic seepage time t_{H} (note: the Darcy's seepage time is often defined as this quantity divided by π^2),

$$t_{\mathrm{H}} = \frac{a^2}{H\,k_{\mathrm{H}}}\,, \tag{7.5.17}$$

and then

$$\frac{a}{b} = \sqrt{t_{\mathrm{H}}\,s}\,. \tag{7.5.18}$$

The solution of the inhomogeneous differential equation is sought in the form,

$$\overline{u}_{\mathrm{s}r}(r,s) = A(R,s)\,I_1(R) + B(R,s)\,K_1(R)\,, \tag{7.5.19}$$

where the functions $A(R,s)$ and $B(R,s)$ are required to satisfy the condition

$$\frac{dA(R,s)}{dR}\,I_1(R) + \frac{dB(R,s)}{dR}\,K_1(R) = 0\,. \tag{7.5.20}$$

Here I_m and K_m are the modified Bessel functions of order m of the first and second kind respectively. For $m = 1$, they satisfy the homogeneous equation (7.5.15) defined by a zero rhs.

[7.2] The solution process based on the Laplace transform technique implicitly assumes that the transforms of the functions $f(t)$ that will be operated on are bounded, which, in practice, amounts to assume these functions to 1. vanish for a negative argument, $f(t) = 0$, $t < 0$; 2. have an finite number of points of discontinuity; 3. to be of exponential order, that is, to decay sufficiently fast towards infinity.

Backsubstitution of (7.5.19), of its derivative with respect to R and of (7.5.20) in (7.5.15), and use of the relation $(7.5.75)_2$ with $m = 1$ results in the system

$$\left[\begin{array}{cc} dI_1/dR & dK_1/dR \\ I_1 & K_1 \end{array}\right]\left[\begin{array}{c} dA/dR \\ dB/dR \end{array}\right] = \left[\begin{array}{c} b\,\overline{\epsilon}\,R/2 \\ 0 \end{array}\right] \Longrightarrow \left[\begin{array}{c} dA/dR \\ dB/dR \end{array}\right] = b\,\overline{\epsilon}/2\left[\begin{array}{c} R^2\,K_1 \\ -R^2\,I_1 \end{array}\right]. \tag{7.5.21}$$

Using in turn (7.5.71) with $m = 2$ yields,

$$A(R,s) = A_0(s) - b\,\frac{\overline{\epsilon}}{2}\,R^2\,K_2(R), \quad B(R,s) = B_0(s) - b\,\frac{\overline{\epsilon}}{2}\,R^2\,I_2(R)\,. \tag{7.5.22}$$

Reporting these expressions in (7.5.19) results in,

$$\overline{u}_{sr}(r,s) = A_0(s)\,I_1(R) + B_0(s)\,K_1(R) - b\,\frac{\overline{\epsilon}}{2}\,R^2\,(I_1(R)\,K_2(R) + I_2(R)\,K_1(R))\,, \tag{7.5.23}$$

which, via (7.5.76), simplifies to,

$$\overline{u}_{sr}(r,s) = A_0(s)\,I_1(R) + B_0(s)\,K_1(R) - b\,\frac{\overline{\epsilon}}{2}\,R\,. \tag{7.5.24}$$

Since $K_1(R)$ is unbounded at $R = 0$, the function $B_0(s)$ should vanish for the solution to remain bounded at $R = 0$. The function $A_0(s)$ is obtained via satisfaction of the boundary conditions $p_{\rm w} = 0$ and $\sigma_{rr} = -p_{\rm w} + \lambda\,e + 2\,\mu\,\epsilon_{rr} = 0$ at $r = a$, and use of $(7.5.73)_1$,

$$A_0(s) = \frac{\overline{\epsilon}(s)}{2}\,\frac{b}{D(s)}\,, \tag{7.5.25}$$

where

$$D(s) = \frac{H}{2\,\mu}\,I_0(\frac{a}{b}) - \frac{b}{a}\,I_1(\frac{a}{b})\,. \tag{7.5.26}$$

Backsubstitution in (7.5.24) provides the Laplace transform of the radial solid displacement,

$$\overline{u}_{\rm sr}(r,s) = \frac{\overline{\epsilon}(s)}{2}\,r\,\frac{\frac{b}{r}\,I_1(\frac{r}{b})}{D(s)} - \frac{\overline{\epsilon}(s)}{2}\,r\,. \tag{7.5.27}$$

The Laplace transform of the pressure results, upon integration in space of (7.5.12), accounting for the boundary condition $p_{\rm w}(a,t) = 0$, and using (7.5.72) with $m = 0$,

$$\frac{\overline{p_{\rm w}}}{\mu}(r,s) = \frac{H}{2\,\mu}\,\overline{\epsilon}(s)\frac{I_0(\frac{r}{b}) - I_0(\frac{a}{b})}{D(s)}\,. \tag{7.5.28}$$

Other Laplace transforms follow readily, namely the volume change and the radial flux,

$$\overline{e}(r,s) = \frac{\overline{\epsilon}(s)}{2}\,\frac{I_0(\frac{r}{b})}{D(s)}, \quad n^{\rm w}\,(\overline{v}_{\rm wr} - \overline{v}_{\rm sr})(r,s) = -\frac{\overline{\epsilon}(s)}{2}\,\frac{s\,\frac{b}{r}\,I_1(\frac{r}{b})}{D(s)}\,, \tag{7.5.29}$$

and the total radial and axial stress components,

$$\begin{aligned} \overline{\sigma}_{rr}(r,s) &= \frac{\mu\,\overline{\epsilon}(s)}{D(s)}\,\Big(\frac{H}{2\,\mu}\,I_0(\frac{a}{b}) - \frac{b}{r}\,I_1(\frac{r}{b})\Big) - \mu\,\overline{\epsilon}(s), \\ \overline{\sigma}_{zz}(r,s) &= \frac{\mu\,\overline{\epsilon}(s)}{D(s)}\,\Big(-I_0(\frac{r}{b}) + 3\,\frac{H}{2\,\mu}\,I_0(\frac{a}{b}) - 2\,\frac{b}{a}\,I_1(\frac{a}{b})\Big)\,. \end{aligned} \tag{7.5.30}$$

Therefore the Laplace transform of the axial load $F(t) = 2\,\pi\,\int_0^a\,\sigma_{zz}(r,t)\,r\,dr$ takes the form,

$$\frac{\overline{F}(s)}{\mu\,\pi\,a^2} = \frac{\overline{\epsilon}(s)}{D(s)}\,\Big(3\,\frac{H}{2\,\mu}\,I_0(\frac{a}{b}) - 4\,\frac{b}{a}\,I_1(\frac{a}{b})\Big)\,. \tag{7.5.31}$$

7.5.4 Relaxation tests: applied axial strain

The axial strain $\epsilon(t)$ is imposed either as a step load or as a ramp load,

$$\epsilon(t) = \begin{cases} -\epsilon_0\,\mathcal{H}(t) & \text{step load,} \\ -\dot\epsilon_0\left(t\,\mathcal{H}(t) - (t-t_0)\,\mathcal{H}(t-t_0)\right) & \text{ramp load,} \end{cases} \tag{7.5.32}$$

where $\mathcal{H}$ is the Heaviside step function, ϵ_0 is a positive reference strain, and $\dot\epsilon_0$ a positive strain rate. In practice, the primary entity which is controlled is not the strain, but the axial displacement.

7.5.4.1 Relaxation tests: step strain

Instantaneous response:

The instantaneous response is obtained by the initial value theorem: for any generic function g, $\lim_{t\to 0^+} g(t) = \lim_{s\to\infty} s\,\overline{g}(s)$. For that purpose, we use the asymptotic property (7.5.77) of Bessel functions, defining $\sqrt{s}$ such that $\mathrm{Re}\,\sqrt{s} > 0$.

The instantaneous strains result spatially uniform. Their values can be retrieved based on the basic assumption, consistent with application of the initial value theorem to (7.5.27), that the radial solid displacement is linear in r. Indeed

- seepage flow is not instantaneous, and it has not yet started at $t = 0^+$, thus $n^{\mathrm{w}}\,(v_{\mathrm{w}r} - v_{\mathrm{s}r})(r,\,0^+) = 0$. Moreover, since both the solid and fluid constituents are incompressible, the only way for the porous medium to change volume its by seepage. Thus $e(r,\,0^+) = 0$;
- admitting the radial displacement to be linear in r, the strains in the radial and circumferential directions are uniform and equal;
- gathering the two previous arguments implies $\epsilon_{rr}(r,\,0^+) = \epsilon_{\theta\theta}(r,\,0^+) = \epsilon_0/2$;
- equilibrium in the radial and circumferential directions yields $\sigma_{rr}(r,\,0^+) = \sigma_{\theta\theta}(r,\,0^+) = 0$. Thus the elastic equations in these directions, and the stress decomposition, yield $p_{\mathrm{w}}(r,\,0^+) = \mu\,\epsilon_0$;
- the strains being known, the elastic equations yield $\sigma'_{zz}(r,\,0^+) = -2\,\mu\,\epsilon_0$, $\sigma'_{rr}(r,\,0^+) = \sigma'_{\theta\theta}(r,\,0^+) = \mu\,\epsilon_0$. The total axial stress results from the effective stress and pressure as $\sigma_{zz}(r,\,0^+) = -3\,\mu\,\epsilon_0$. Consequently, the axial force is equal to $F(0^+)/(\mu\,\pi\,a^2) = -3\,\epsilon_0$.

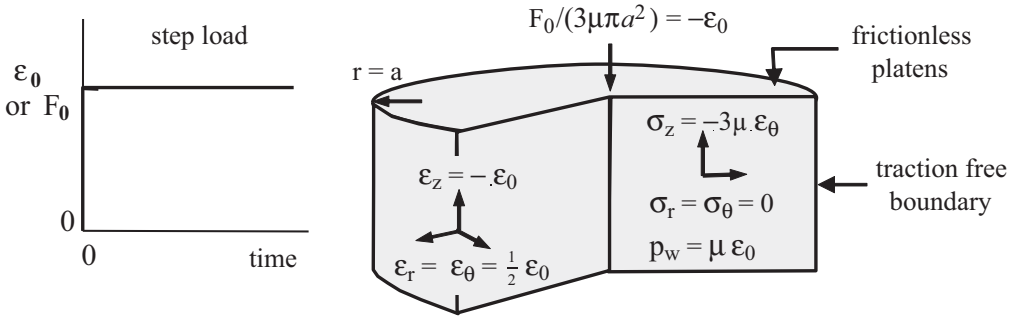

Fig. 7.5.2: Instantaneous response of the cylinder subjected to an axial step loading.

These results are sketched in Fig. 7.5.2 and summarized in Table 7.5.1 which displays the instantaneous response after an axial step load in terms of strain, $\epsilon(t) = -\epsilon_0\,\mathcal{H}(t)$, and the asymptotic (drained) response at large times.

A point is puzzling, still: the fact that the pressure at $t = 0^+$ is everywhere equal to a non zero value is in contradiction with the boundary condition at the lateral surface. In fact, the material will quickly manage to restore the boundary conditions, namely $\sigma_{rr}(r, 0^{++}) = 0$, $p_{\mathrm{w}}(r, 0^{++}) = 0$, so that $\sigma'_{rr}(r, 0^{++}) = 0$. If, following Berry et al. [2006], we admit that, close to the surface, $\epsilon_{\theta\theta}(r, 0^{++})$ remains equal to $\epsilon_0/2$, the elastic relation results in $\epsilon_{rr}(r, 0^{++})/\epsilon_0 = \nu/(2(1-\nu)) < \nu$. Thus immediately after loading, the strain close to the boundary drops to a value lower than the asymptotic value $\nu\,\epsilon_0$ corresponding to the drained response.

For plane strain, the same reasoning would provide $\epsilon_{xx}(x, 0^+)/\epsilon_0 = 1$, and $\epsilon_{xx}(x, 0^{++})/\epsilon_0 = \nu/(1-\nu)$, which again is the drained response.

Table 7.5.1: Porous cylinder loaded by frictionless platens with traction free lateral boundary subjected to an instantaneous axial strain $\epsilon(t) = -\epsilon_0\,\mathcal{H}(t)$. For a step force $F(t) = -F_0\,\mathcal{H}(t)$, these instantaneous and asymptotic responses hold when ϵ_0 is replaced respectively by $\epsilon_c^{0+} = F_0/(3\mu\,\pi\,a^2)$, and by $\epsilon_c = F_0/(E\,\pi\,a^2)$.

Transient response in the time domain

To calculate the inverse Laplace transforms through integration in the complex domain, the roots of the denominator $D(s)$ in (7.5.27) are needed. Note first that the functions in the complex domain of the Laplace variable s are uniform (in the sense of a function of the complex variable!), due to the parity of the modified Bessel functions I_0 and I_1. Using the relation between the Bessel and modified Bessel functions indicated in $(7.5.69)_2$, the roots of the equation below where $X = i\,a/b$,

$$\frac{1}{X}\,\frac{J_1(X)}{J_0(X)} = \frac{H}{2\,\mu}\,, \tag{7.5.33}$$

are requested. The roots with large magnitude can be sought by using the asymptotic expansion (7.5.77). Then

$$X_j = \frac{\pi}{4} + \tan^{-1}\left(\frac{H}{2\,\mu}\,X_j\right) + j\,\pi, \quad j \in]-\infty, +\infty[\,. \tag{7.5.34}$$

For X_j large, this formula simplifies further to

$$X_j = \frac{3}{4}\pi + j\,\pi, \quad j \in [0, +\infty[\,. \tag{7.5.35}$$

This approximation is quite correct, except for the first two or three roots. Indeed, for $\nu = 0.25$, the actual roots scaled by π are 0.658710, 1.71752, 2.72976, $\cdots$, 9.74436, $\cdots$ For $\nu = 0.0$, the above sequence becomes 0.586067, 1.69705, 2.71719, $\cdots$, 9.74089, $\cdots$ The accuracy increases as ν gets closer to 0.5.

Since Eqn (7.5.33) is even in X, it is sufficient to collect the positive roots. For each root,

$$\frac{a}{b} = \sqrt{t_{\rm H}\,s_j} = -i\,X_j\,, \tag{7.5.36}$$

so that

$$s_j = -\frac{X_j^2}{t_{\rm H}}, \quad j \in [0, +\infty[\,. \tag{7.5.37}$$

As just remarked, the roots $j = 0, 1, 2$ above are not accurate, but they can be used as a starting point to solve the nonlinear equation (7.5.33). The roots $j \geq 3$ can be verified to be quite accurate (the accuracy improves with $H/2\,\mu$, i.e., with Poisson's ratio ν), in the sense that the asymptotic expansion provides a quite acceptable estimation of the actual roots of (7.5.33). Moreover, it can also be verified numerically that the actual number of solutions is the same as the number of approximate roots.

The different functions whose inverse Laplace transforms are to be estimated can be expressed formally as $\overline{g}(s) = \overline{\epsilon}(s)\,N(s)/D(s)$, omitting the dependence in r for simplicity. For the step load, $\overline{\epsilon}(s) = -\epsilon_0/s$ and $s = 0$ is a pole of order 1, while it is a pole of order two for the ramp load. The other poles are simple. Thus, the Laplace inverse can be cast in the generic format,

$$\frac{g(t)}{-\epsilon_0} = \frac{N(0)}{D(0)} + \sum_j \frac{1}{s_j}\,\frac{N(s_j)}{D'(s_j)}\,e^{t\,s_j}\,. \tag{7.5.38}$$

The appropriate functions required to obtain the radial displacement have the following explicit expression,

$$D(s) = \frac{H}{2\,\mu}I_0(\sqrt{t_{\rm H}\,s}) - \frac{I_1(\sqrt{t_{\rm H}\,s})}{\sqrt{t_{\rm H}\,s}}, \quad N(s) = \frac{I_1((r/a)\sqrt{t_{\rm H}\,s})}{(r/a)\sqrt{t_{\rm H}\,s}}\,. \tag{7.5.39}$$

Using $(7.5.69)_2$, (7.5.72), (7.5.73), and the iterated fact that the s_j's are the roots of the denominator $D(s)$, Eqn (7.5.33), Eqn (7.5.39) yields for each root,

$$\frac{dD}{ds}(s_j) = \frac{t_{\rm H}}{2}\,\frac{(1-\nu)^2\,X_j^2 - (1-2\,\nu)}{(1-\nu)\,(1-2\,\nu)}\,\frac{J_1(X_j)}{X_j^3}, \quad N(s_j) = \frac{J_1((r/a)X_j)}{(r/a)X_j}\,. \tag{7.5.40}$$

Note, for small R, the approximations $I_0(R) \sim 1$ and $I_1(R)/R \sim 1/2$. Thus the radial displacement becomes

$$\frac{u_{sr}(r,t)}{a\,\epsilon_0} = \frac{r}{a}\,\nu + \sum_j \frac{(1-\nu)\,(1-2\,\nu)}{(1-\nu)^2\,X_j^2 - (1-2\,\nu)}\,\frac{J_1((r/a)\,X_j)}{J_1(X_j)}\,e^{-X_j^2\,t/t_{\rm H}}\,. \tag{7.5.41}$$

Thus $t_{\rm H}$ appears as *a time characterizing the seepage phenomenon* governed by Darcy's law. It is referred to as consolidation time in soil mechanics. Observe that it is proportional to the *square* of the seepage length and inversely proportional to the stiffness and permeability of the porous medium. Numerical results show that a large part of the seepage has taken place at $t = t_{\rm H}$. In fact, the smallest value of the X_j^2's, namely X_0^2, is about 4.5 for $\nu = 0.3$ and does not vary much with ν.

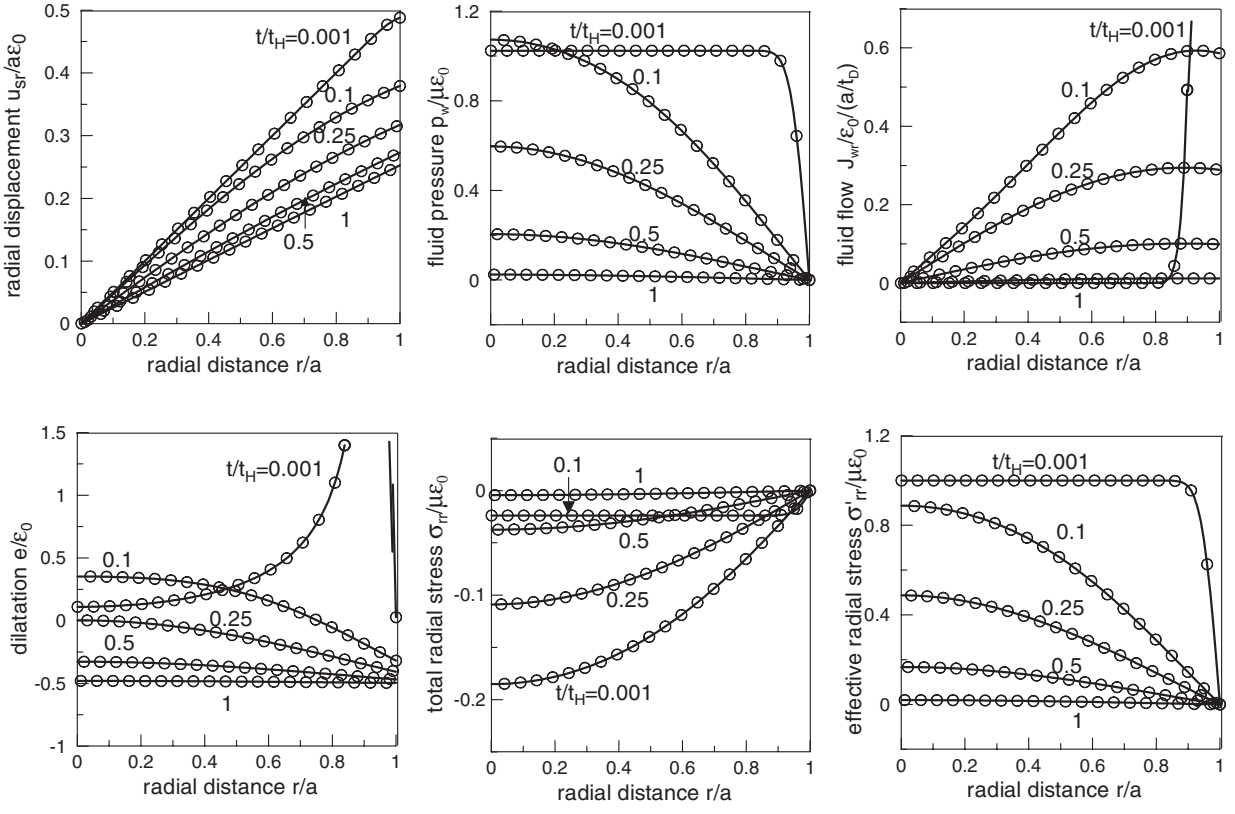

Fig. 7.5.3: Porous cylinder squeezed by a step strain $\boldsymbol{\epsilon}(t) = -\epsilon_0\,\mathcal{H}(t)$ between two frictionless platens, with traction free lateral boundary: Poisson's ratio $\nu = 0.25$, radius a=5 mm. For a shear modulus $\mu = 0.33$ MPa and a hydraulic permeability equal to $10^{-15}\,\mathrm{m}^2/\mathrm{Pa/s}$, Darcy's characteristic time $t_{\rm H}$ is equal to 25×10^3 s. The value of the fluid volume fraction $n^{\rm w}$ is elusive for all quantities plotted here. On the other hand, it comes into picture to obtain the particle fluid velocity, see Eqn (7.5.2). The temporary increase of fluid pressure in the center of the specimen is referred to as Mandel-Cryer effect.

Other quantities are derived similarly, e.g., the load,

$$\frac{F(t)}{\pi\mu\,a^2\,\epsilon_0} = -2\,(1+\nu) - \sum_j \frac{2\,(1-\nu)\,(1-2\,\nu)}{(1-\nu)^2\,X_j^2 - (1-2\,\nu)}\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.42}$$

the pressure,

$$\frac{p_{\rm w}(r,t)}{\mu\,\epsilon_0} = \sum_j \frac{2\,(1-\nu)\,(1-2\,\nu)}{(1-\nu)^2\,X_j^2-(1-2\,\nu)}\Big(\frac{J_0(\frac{r}{a}X_j)}{J_0(X_j)}-1\Big)\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.43}$$

the radial flux $J_{\rm wr} = n^{\rm w}\,(v_{\rm wr}-v_{\rm sr})$,

$$\frac{J_{\rm wr}(r,t)}{(a/t_{\rm H})\,\epsilon_0} = \sum_j \frac{(1-2\,\nu)^2\,X_j}{(1-\nu)^2\,X_j^2-(1-2\,\nu)}\,\frac{J_1(\frac{r}{a}X_j)}{J_0(X_j)}\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.44}$$

the dilatation,

$$\frac{e(r,t)}{\epsilon_0} = -(1-2\,\nu)+\sum_j \frac{(1-2\,\nu)^2}{(1-\nu)^2\,X_j^2-(1-2\,\nu)}\,\frac{J_0((r/a)\,X_j)}{J_0(X_j)}\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.45}$$

and the total radial stress,

$$\frac{\sigma_{rr}(r,t)}{\mu\,\epsilon_0} = \sum_j \frac{2\,(1-\nu)\,(1-2\,\nu)}{(1-\nu)^2\,X_j^2-(1-2\,\nu)}\Big(1-\frac{\frac{a}{r}J_1(\frac{r}{a}X_j)}{J_1(X_j)}\Big)\,e^{-X_j^2\,t/t_{\rm H}}\,. \tag{7.5.46}$$

Steady state:

At steady state, i.e., when the flow has practically vanished because the pressure homogenizes, the load is supported completely by the solid skeleton, i.e., the behavior is elastic and dictated by the shear modulus μ and drained Poisson's ratio ν. Thus $\epsilon_{zz}=-\epsilon_0$, $\epsilon_{rr}=\nu\,\epsilon_0$, $\sigma_{rr}=0$, $\sigma_{zz}=-E\,\epsilon_0$, with $E=2\,(1+\nu)\,\mu$ drained Young's modulus.

The plots shown in Fig. 7.5.3 display the transient response that covers the time interval between time $t=0^+$ where the material responds as if it was incompressible and the steady state where the material response is contributed entirely by the underlying drained solid skeleton. Steady state is nearly reached at time $t=t_{\rm H}$. The total radial stress is compressive while the effective radial stress is tensile due to the initial radial extension, which, later on, decreases as water is expelled from the sample. The flow begins close to the lateral boundary, it penetrates progressively the specimen, and finally dies out over time. Expulsion of water leads to a simultaneous decrease in radial strain and volume.

The calculations have been performed with double precision using the expressions of Bessel functions provided in Numerical Recipes, Press et al. [1992]. The number of poles used in the estimation of the inverse Laplace transforms should be larger than 20 to avoid oscillations at small times.

7.5.4.2 Relaxation tests: ramp strain

Since $s=0$ is a pole of order two, the inverse Laplace transforms can be expressed in terms of the generic function $g_1(s)=N(s)/D(s)$ in the format,

$$\begin{aligned}\frac{g_1(t)}{-\dot\epsilon_0} &= \frac{1}{1!}\frac{d}{ds}\Big(\frac{N(s)}{D(s)}\,e^{t\,s}\Big)_{|s=0}+\sum_j\frac{1}{s_j^2}\,\frac{N(s_j)}{D'(s_j)}\,e^{t\,s_j}\,,\\ &= \frac{d}{ds}\Big(\frac{N(s)}{D(s)}\Big)_{|s=0}+t\,\frac{N(0)}{D(0)}+\sum_j\frac{1}{s_j^2}\,\frac{N(s_j)}{D'(s_j)}\,e^{t\,s_j}\,.\end{aligned} \tag{7.5.47}$$

The generic inverse of $\overline{g}(s)=\overline{\epsilon}(s)\,g_1(s)/(-\dot\epsilon_0)$ is equal to $g(t)=g_1(t)\mathcal{H}(t)-g_1(t-t_0)\mathcal{H}(t-t_0)$. For instance, the function $F_1(t)$ associated with the axial load expresses as,

$$\frac{t_0}{t_{\rm H}}\,\frac{F_1(t)}{\mu\,\pi\,a^2\,\epsilon_0} = -\frac{1}{4}\,(1-\nu)\,(1-2\nu)-2\,(1+\nu)\,\frac{t}{t_{\rm H}}+\sum_j\frac{2\,(1-\nu)\,(1-2\,\nu)}{(1-\nu)^2\,X_j^2-(1-2\,\nu)}\,\frac{1}{X_j^2}\,e^{-X_j^2\,t/t_{\rm H}}\,. \tag{7.5.48}$$

To estimate the influence of the strain rate, simulations corresponding to different loading periods t_0, but to the same strain $\epsilon_0=\dot\epsilon_0\,t_0$, are displayed in Fig. 7.5.4. The maximum force increases with strain rate: the maximum scaled force $F/(\pi\,a^2)$ varies from $-2(1+\nu)\,\mu\,\epsilon_0$ for very low loading rate, or steady state, to $-3\,\mu\,\epsilon_0$ for step loading.

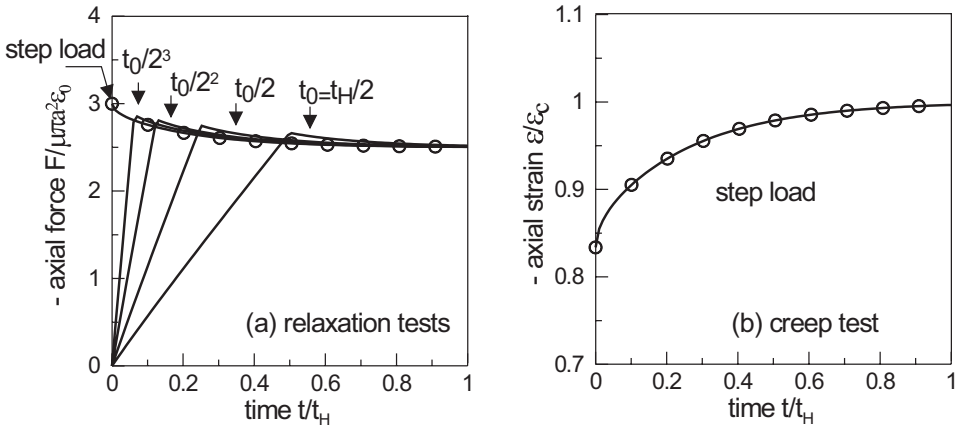

Fig. 7.5.4: (a) Porous cylinder squeezed by a step strain ϵ_0, and by ramp strains until the axial strain ϵ_0 is reached. The highest the loading rate, the largest is the maximum axial force supported by the loading device. (b) Creep test under a step load F_0.

7.5.4.3 Instantaneous and ramp loading: use of the convolution property

The convolution property of linear transforms may be used to deduce, from the response to a simple load function, the response to a more complex load history. Indeed, let $\mathcal{T}(x,s)$ be a linear partial differential operator in the Laplace domain. Omitting the space dependence for simplicity of notation, let $\overline{u}_i(s)$ be the response to the datum $\overline{a}_i(s)$, in the sense that $\mathcal{T}\,\overline{u}_i(s) = \overline{a}_i(s)$, $i = 1, 2$. Then $\overline{u}_2(s) = \overline{u}_1(s)\,\overline{a}_2(s)/\overline{a}_1(s)$, and therefore $u_2(t) = \int_0^t u_1(t-\tau)\,\mathcal{L}^{-1}\{\overline{a}_2(s)/\overline{a}_1(s)\}(\tau)\,d\tau$. Special cases for a_1 may be exploited, for example,

$$\begin{aligned} &a_1(t) = \delta(t) \;\Rightarrow\; u_2(t) = \int_0^t u_1(t-\tau)\,a_2(\tau)\,d\tau; \\ &a_1(t) = \mathcal{H}(t) \;\Rightarrow\; u_2(t) = \int_0^t u_1(t-\tau)\,\frac{da_2(\tau)}{d\tau}\,d\tau \;=\; u_1(t)\,a_2(0)\,\mathcal{H}(t) + \int_0^t u_1(t-\tau)\,\frac{d^+a_2(\tau)}{d\tau}\,d\tau\,. \end{aligned} \tag{7.5.49}$$

In the second line, the operator $d\ /dt$ denotes the derivative in the sense of distributions, $da_2/dt = d^+a_2/dt + a_2(0^+)\,\delta(t)$, with d^+a_2/dt the right (standard) derivative and $\delta(t)$ the Dirac delta function. Note that the Laplace transform of da_2/dt is equal to $s\,\overline{a}_2(s)$, while the Laplace transform of d^+a_2/dt is equal to $s\,\overline{a}_2(s) - a_2(0^+)$.

7.5.5 Creep tests: applied axial load

The sole case considered for creep tests is that of an axial step load $F(t)$,

$$F(t) = -F_0\,\mathcal{H}(t)\,, \tag{7.5.50}$$

where $F_0 > 0$ corresponds to a compression.

Instantaneous response:

The instantaneous response is the same as for the relaxation tests, with ϵ_0 replaced by $-\epsilon(0^+) = F_0/(3\mu\,\pi\,a^2)$.

Transient response in the Laplace domain

The roots involved in calculating the inverse Laplace transforms are those of the numerator $N(s)$ in (7.5.31), namely

$$N(s) = 3\,\frac{H}{2\,\mu}\,I_0(\frac{a}{b}) - 4\,\frac{b}{a}\,I_1(\frac{a}{b})\,. \tag{7.5.51}$$

Therefore, instead of (7.5.33), the roots are now the solutions of the equation,

$$\frac{1}{X}\,\frac{J_1(X)}{J_0(X)} = \frac{3}{4}\,\frac{H}{2\,\mu}\,. \tag{7.5.52}$$

Substitution of $\overline{F}(s)$ for $\overline{\epsilon}(s)$ yields the Laplace transforms of the axial strain, radial displacement, pressure and dilatation,

$$\overline{\epsilon}(s) = \frac{\overline{F}(s)}{\mu\,\pi\,a^2}\,\frac{D(s)}{N(s)}\,; \tag{7.5.53}$$

$$\overline{u}_{sr}(r,s) = r\,\frac{\overline{F}(s)}{2\,\mu\,\pi\,a^2}\,\frac{\frac{b}{r}\,I_1(\frac{r}{b}) - \frac{H}{2\,\mu}\,I_0(\frac{a}{b}) + \frac{b}{a}\,I_1(\frac{a}{b})}{N(s)}\,; \tag{7.5.54}$$

$$\frac{\overline{p}}{\mu}(r,s) = \frac{H}{2\,\mu}\,\frac{\overline{F}(s)}{\mu\,\pi\,a^2}\,\frac{I_0(\frac{r}{b}) - I_0(\frac{a}{b})}{N(s)}\,; \tag{7.5.55}$$

$$\overline{e} = \frac{\overline{F}(s)}{2\,\mu\,\pi\,a^2}\,\frac{I_0(\frac{r}{b})}{N(s)}\,. \tag{7.5.56}$$

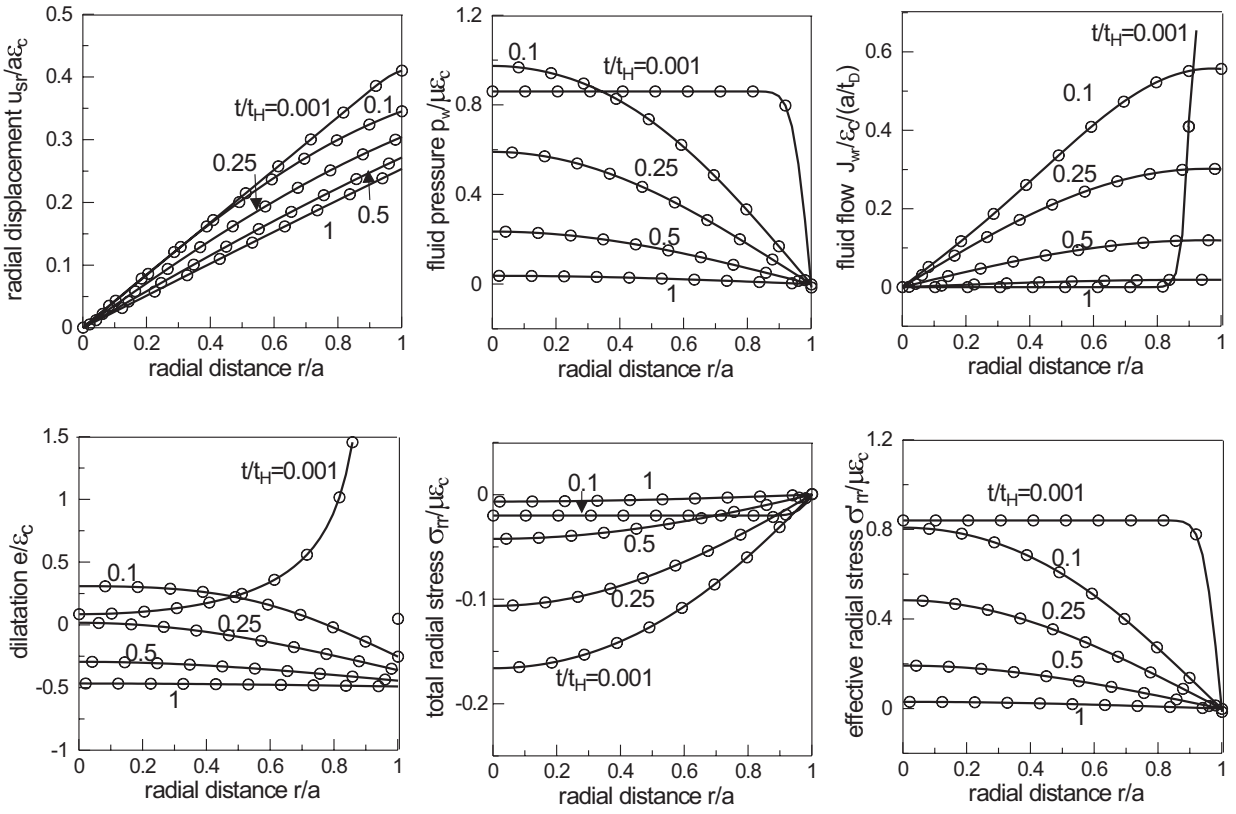

Fig. 7.5.5: Porous cylinder squeezed by a step force $F(t) = -F_0\,\mathcal{H}(t)$ between two frictionless platens, with traction free lateral boundary.

Transient response in the time domain

Instead of (7.5.40), the derivative of the function $N(s)$ with respect to the Laplace variable s can be expressed, for each root $s = s_j$, in the form,

$$N'(s_j) = \frac{t_{\rm H}}{2}\,\frac{9\,(1-\nu)^2\,X_j^2 - 8\,(1+\nu)\,(1-2\,\nu)}{3\,(1-\nu)\,(1-2\,\nu)}\,\frac{J_1(X_j)}{X_j^3}\,. \tag{7.5.57}$$

Let us note for the record $D(0) = 1/(2(1-2\,\nu))$, $N(0) = (1+\nu)/(1-2\,\nu)$. The radial displacement and axial strain become, respectively,

$$\frac{u_{sr}(r,t)}{a\,\epsilon_c} = \nu\,\frac{r}{a} + \sum_j \frac{2\,(1-\nu^2)\,(1-2\,\nu)}{9\,(1-\nu)^2\,X_j^2 - 8\,(1+\nu)\,(1-2\,\nu)}\,(3\,\frac{J_1(\frac{r}{a}X_j)}{J_1(X_j)} - \frac{r}{a})\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.58}$$

and

$$\frac{\epsilon(t)}{\epsilon_c} = -1 + \sum_j \frac{4\,(1-\nu^2)\,(1-2\,\nu)}{9\,(1-\nu)^2\,X_j^2 - 8\,(1+\nu)\,(1-2\,\nu)}\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.59}$$

where the asymptotic axial strain $\epsilon_{zz}(\infty) = -\epsilon_c$ is defined by

$$\epsilon_c = \frac{F_0}{E\,\pi\,a^2}\,. \tag{7.5.60}$$

The pressure,

$$\frac{p_{\rm w}(r,t)}{\mu\,\epsilon_c} = \sum_j \frac{16\,(1-\nu^2)\,(1-2\,\nu)}{9\,(1-\nu)^2\,X_j^2 - 8\,(1+\nu)\,(1-2\,\nu)}\Big(\frac{J_0(\frac{r}{a}X_j)}{J_0(X_j)} - 1\Big)\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.61}$$

provides the radial flux $J_{{\rm w}r} = n^{\rm w}\,(v_{{\rm w}r} - v_{{\rm s}r})$, with help of (7.5.74),

$$\frac{J_{{\rm w}r}(r,t)}{(a/t_{\rm H})\,\epsilon_c} = \sum_j \frac{8\,(1+\nu)\,(1-2\,\nu)^2\,X_j}{9\,(1-\nu)^2\,X_j^2 - 8\,(1+\nu)\,(1-2\,\nu)}\,\frac{J_1(\frac{r}{a}X_j)}{J_0(X_j)}\,e^{-X_j^2\,t/t_{\rm H}}\,. \tag{7.5.62}$$

Finally the dilatation takes the form

$$\frac{e(r,t)}{\epsilon_c} = -(1-2\,\nu) + \sum_j \frac{8\,(1+\nu)\,(1-2\,\nu)^2}{9\,(1-\nu)^2\,X_j^2 - 8\,(1+\nu)\,(1-2\,\nu)}\,\frac{J_0(\frac{r}{a}X_j)}{J_0(X_j)}\,e^{-X_j^2\,t/t_{\rm H}}\,, \tag{7.5.63}$$

while the total radial stress becomes,

$$\frac{\sigma_{rr}(r,t)}{\mu\,\epsilon_0} = \sum_j \frac{2\,(1-\nu)\,(1-2\,\nu)}{(1-\nu)^2\,X_j^2 - (1-2\,\nu)}\Big(1 - \frac{\frac{a}{r}J_1(\frac{r}{a}X_j)}{J_1(X_j)}\Big)\,e^{-X_j^2\,t/t_{\rm H}}\,. \tag{7.5.64}$$

The spatial profiles are plotted in Fig. 7.5.5 at a few instants. The scaled entities corresponding to the step relaxation and step creep tests have very similar values. However, the axial strain $-\epsilon(t)$ increases during creep from its instantaneous value $-\epsilon(0^+) = \epsilon_c(0^+)$ to its steady state value $-\epsilon(\infty) = \epsilon_c$, Fig. 7.5.4,

$$\epsilon_c(0^+) = \frac{F_0}{3\mu\,\pi\,a^2} > \epsilon_c = \frac{F_0}{E\,\pi\,a^2} = \frac{3}{2\,(1+\nu)}\,\epsilon_c(0^+)\,. \tag{7.5.65}$$

Since the scaling refers to steady state, scaled entities differ somehow at short term from their counterparts in the relaxation tests.

7.5.6 Compendium of Bessel functions

Some properties of Bessel functions required in the text above are collected from the books of Carslaw and Jaeger [1959], p. 488, and Sneddon [1980]. The Bessel functions of order $m = 0, 1, 2\cdots$ of the first kind J_m and the modified Bessel functions of the first kind I_m are defined by series expansions,

$$J_m(R) = \sum_{j=0}^{\infty} \frac{(-1)^j}{j!(m+j)!}\Big(\frac{R}{2}\Big)^{m+2j}, \quad I_m(R) = \sum_{j=0}^{\infty} \frac{1}{j!(m+j)!}\Big(\frac{R}{2}\Big)^{m+2j}\,. \tag{7.5.66}$$

Note also the integral representation,

$$J_m(R) = \frac{1}{2\,\pi}\int_0^{2\pi} \exp\big(i(R\sin\theta - m\,\theta)\big)d\theta = \frac{1}{\pi}\int_0^{\pi} \cos(R\sin\theta - m\,\theta)d\theta\,. \tag{7.5.67}$$

The Bessel function of the first kind J_m satisfies the Bessel equation $R^2\,d^2y/dR^2 + R\,dy/dR + (R^2 - m^2)\,y = 0$. If m was not an integer, J_m and J_{-m} would be two independent solutions of the above equation. For m an integer, the second independent solution is the Bessel function of the second kind Y_m.

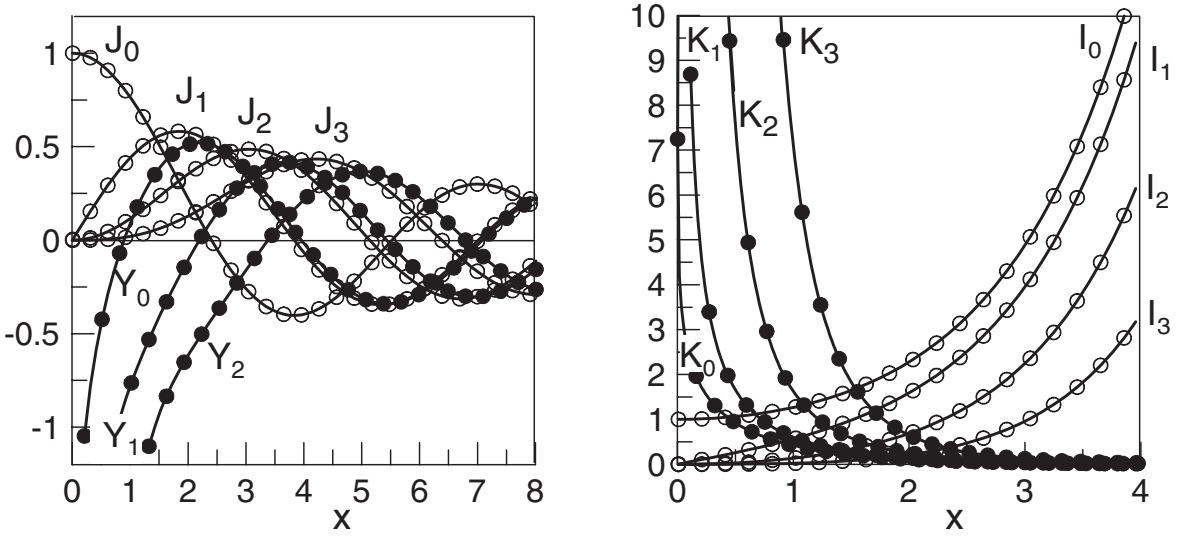

Fig. 7.5.6: Bessel functions of the first kind and second kind, J and Y respectively, and modified Bessel functions of the first kind and second kind, I and K respectively.

The modified Bessel function of the first kind I_m satisfies the Bessel equation $R^2\, d^2y/dR^2 + R\, dy/dR - (R^2 + m^2)\, y = 0$. If m was not an integer, I_m and I_{-m} would be two independent solutions of the above equation. For m an integer, the second independent solution is the modified Bessel function of the second kind K_m, namely

$$K_m(R) = \frac{\pi}{2}\, i^{m+1} \left(J_m(iR) + i\, Y_m(iR) \right). \tag{7.5.68}$$

Fig. 7.5.6 shows the variations of the Bessel and modified Bessel functions of the first kind and second kind over interval of interest. The Bessel function and modified Bessel function of the second kind, $Y_m(R)$ and $K_m(R)$ respectively, are unbounded at $R = 0$.

The relations needed in the derivations are listed below. Let us record first the basic properties,

$$(-1)^m\, J_{-m}(R) = J_m(R), \quad I_{-m}(R) = I_m(R), \quad I_m(R) = i^{-m}\, J_m(i\, R) \quad (i = \sqrt{-1}), \tag{7.5.69}$$

and the recurrence relations,

$$\begin{aligned} J_{m+1}(R) &= -J_{m-1}(R) + \frac{2m}{R}\, J_m(R), \\ I_{m+1}(R) &= I_{m-1}(R) - \frac{2m}{R}\, I_m(R), \\ K_{m+1}(R) &= K_{m-1}(R) + \frac{2m}{R}\, K_m(R). \end{aligned} \tag{7.5.70}$$

Note also the relations for the derivatives,

$$\frac{d}{dR}(R^m\, I_m(R)) = R^m\, I_{m-1}(R), \quad \frac{d}{dR}(R^m\, K_m(R)) = -R^m\, K_{m-1}(R), \tag{7.5.71}$$

$$\frac{d}{dR}(R^{-m}\, I_m(R)) = R^{-m}\, I_{m+1}(R). \tag{7.5.72}$$

The relations below are equivalent to (7.5.71),

$$\frac{d}{dR} I_m(R) = I_{m-1}(R) - \frac{m}{R}\, I_m(R), \quad \frac{d}{dR} K_m(R) = -K_{m-1}(R) - \frac{m}{R}\, K_m(R). \tag{7.5.73}$$

On the other hand,

$$\frac{d}{dR}(R^m\, J_m(R)) = R^m\, J_{m-1}(R), \quad \frac{d}{dR} J_m(R) = \frac{m}{R}\, J_m(R) - J_{m+1}(R) = J_{m-1}(R) - \frac{m}{R}\, J_m(R). \tag{7.5.74}$$

The cross-relations between the Bessel functions of the first kind and second kind on one side, and between the modified Bessel functions of the first kind and second kind on the other side are quite remarkable,

$$\begin{aligned} J_m(R)\,\frac{dY_m}{dR}(R) - \frac{dJ_m}{dR}(R)\,Y_m(R) &= \frac{2}{\pi}\frac{1}{R}, \\ I_m(R)\,\frac{dK_m}{dR}(R) - \frac{dI_m}{dR}(R)\,K_m(R) &= -\frac{1}{R}\,. \end{aligned} \tag{7.5.75}$$

Substitution of (7.5.73) in $(7.5.75)_2$ yields,

$$I_m(R)\,K_{m-1}(R) + I_{m-1}(R)\,K_m(R) = \frac{1}{R}\,. \tag{7.5.76}$$

The asymptotic relations to first order for large R are instrumental to apply the initial value theorem,

$$\begin{aligned} &J_m(R) \sim \sqrt{\frac{2}{\pi\,R}}\,\cos\Big(R - (2\,m+1)\,\frac{\pi}{4}\Big); \quad Y_m(R) \sim \sqrt{\frac{2}{\pi\,R}}\,\sin\Big(R - (2\,m+1)\,\frac{\pi}{4}\Big); \\ &I_m(R) \sim \frac{e^R}{\sqrt{2\,\pi\,R}}\,; \qquad\qquad\qquad\qquad K_m(R) \sim e^{-R}\sqrt{\frac{\pi}{2\,R}}\,. \end{aligned} \tag{7.5.77}$$

For small R, the following approximations hold,

$$\begin{aligned} &J_m(R) \sim \frac{1}{m!}\,\frac{R^m}{2^m}\,; \quad Y_0(R) \sim \frac{2}{\pi}\,(\mathrm{Ln}\,\frac{R}{2} + \gamma), \quad Y_m(R) \sim -\frac{(m-1)!}{\pi}\,\frac{2^m}{R^m}, \quad m \neq 0; \\ &I_m(R) \sim \frac{1}{m!}\,\frac{R^m}{2^m}\,; \quad K_0(R) \sim -(\mathrm{Ln}\,\frac{R}{2} + \gamma), \quad K_m(R) \sim \frac{(m-1)!}{2}\,\frac{2^m}{R^m}, \quad m \neq 0\,, \end{aligned} \tag{7.5.78}$$

where $\gamma \sim 0.5772$ is the Euler constant.

Chapter 8

Viscoelasticity and poro-viscoelasticity

8.1 Viscoelasticity, poroelasticity and poro-viscoelasticity

Overall incompressibility of tissues can be a good approximation only for short term responses. For moderate and long term responses, fluid circulates in and out the tissue, and this diffusion endows the tissues with an overall compressibility. In fact, a clear distinction should be made between overall, or *apparent*, properties of the whole tissue, and *intrinsic* properties of the solid skeleton. Experiments sometimes impose a pre-compression in order to minimize the amount of blood in the vessels before testing. Preconditioning of natural and artificial materials ensures a valid comparison of experimental results from different specimens.

On the other hand, some testing devices are designed to actually measure apparent properties: Parsons and Coger [2002] specifically designed a shear rheometer that keeps the *in situ* tissue hydration, by minimizing the actuator contact area. Common shear plate covers the whole biological layer and therefore modifies the *in situ* hydration conditions, rendering the contact area practically dry.

Both fluid diffusion and intrinsic rate dependence of the mechanical constitutive relations contribute to energy dissipation, even if they serve distinct physiological purposes. Viscous sliding between fibrils of collagen allows their alignment with the load axis, contributing to a progressive increase of stiffness and limited deformation of an initially compliant tissue.

In words, time effects due to fluid flows (*poroelasticity*) and due to the interactions between the (dry) components of the tissues (*intrinsic viscoelasticity*) should be distinguished. The issue arises in acute form in the Poisson's ratio of articular cartilages. For example, *apparent* Poisson's ratios are sometimes measured to vary with time and to be much larger than $1/2$ while an appropriate analysis, recognizing the multiphase nature of the tissue, would identify an intrinsic elastic Poisson's ratio in an admissible range and constant in time. The issue is more complex if the solid skeleton displays a time dependent response, as viscoelastic Poisson's ratio may vary over a wider range than its elastic counterpart.

This chapter represents only an introduction to time effects in soft tissues. It adopts the *rule of time translation invariance* and addresses essentially linear viscoelasticity of non aging tissues while real tissues display both intrinsic time effects and nonlinearity at large strains. Still nonlinear effects in a visco-hyperelastic framework are briefly touched upon at the end of the chapter.

8.2 Intrinsic time dependent behavior of collagen fibrils

Among the first, Mak [1986] developed a continuum model of tissue behavior where rate effects are due to both poroelasticity and viscoelasticity. Intrinsic rate dependence of tissues emanates mainly from the collagen fibrils. Actually, collagen viscoelasticity is thought to account for most of the stress relaxation in tension while poroelastic effects associated with fluid diffusion dominates the relaxation effects in compression, Li et al. [2005].

While the analysis of Wang et al. [2002] considers compression, Charlebois et al. [2004] and Lei and Szeri [2007] address rate effects under tension. Wilson et al. [2004] develop a finite element model of osteoarthritis using a poro-viscoelastic fibril-reinforced model, accounting for the directional non random distribution of fibrils and their spatial inhomogeneities across the depth. In fact, unconfined compression tests exhibit contraction and a poroelastic

behavior dominated by the interactions of water and proteoglycans along the compression direction while the lateral direction undergoes an extension resisted by the activation of collagen fibrils. Di Silvestro and Suh [2001] endow the collagen fibrils with a viscous behavior to better describe the fibril extension along the lateral direction. As an improvement, Huang et al. [2001] [2003] attempt to identify the parameters defining the quasi-linear viscosity (QLV) theory of Fung in conjunction with a linear or conewise linear behavior of articular cartilages. The identification uses results from confined and unconfined compression tests including stress relaxation.

Boyce et al. [2007] address the tensile response of collagen fibrils of the bovine cornea with a QLV theory based on creep tests and tension tests over a range of loading rates. The verification is hampered by the complex directional distribution of collagen fibrils across the stroma and material nonlinearities.

Lei and Szeri [2007] introduced a rate dependent response of collagen fibrils through the standard nonlinear solid, namely a Maxwell model in parallel with a spring with a strain dependent stiffness. In the simulations of confined and unconfined tests on articular cartilages, the relaxation time of fibrils ranges from 100 to 200 s.

The viscous properties addressed here assume that the tissues do not undergo aging, that is, the tissues do not modify their mechanical properties over time. While the validity of this assumption may be rescued by considering restricted time windows, its actual range of applicability remains to be assessed. Charlebois et al. [2004] found that the equilibrium and peak tensile modulus of bovine cartilages from 6 months to 6 years increase significantly with maturation and age, from 0 to 15 MPa at equilibrium and from 10 to 28 MPa at peak. This aging might be linked with the age-dependent content of enzymatic and nonenzymatic collagen crosslinks. The time translation invariance adopted in most of this chapter does not fit with osteoarthritis (OA) which is associated with a damaged collagen network resulting in swelling.

8.3 Complex modulus

Rate effects are associated with energy dissipation which is traditionally detected through hysteresis loops. Quantification of these rate effects is complicated by the nonlinearity of the stress-strain relation that develop at moderate deformations. Moreover, repeatable results require preconditioning of the tissues. The details of the preconditioning (intensity of the stretch, number of cycles, duration of the rest period, etc.) are significant for biological tissues and even more for bio-artificial tissues which display a more pronounced hysteresis curve than native tissues, Wagenseil et al. [2003].

The dissipation in biological materials is relatively constant over a wide range of frequencies: this observation has led to the introduction of a continuous spectrum of relaxation times, Fung [1993], p. 281 et seq. As a discrete alternative, Holzapfel et al. [2002] used a generalized linear solid including 5 parallel Maxwell branches with relaxation times spanning from 10^{-3} s to 10 s. In application to arterial walls, the resulting hysteresis loops and loss modulus are relatively insensitive to strain rates in a frequency range from 0.01 to 100 Hz.

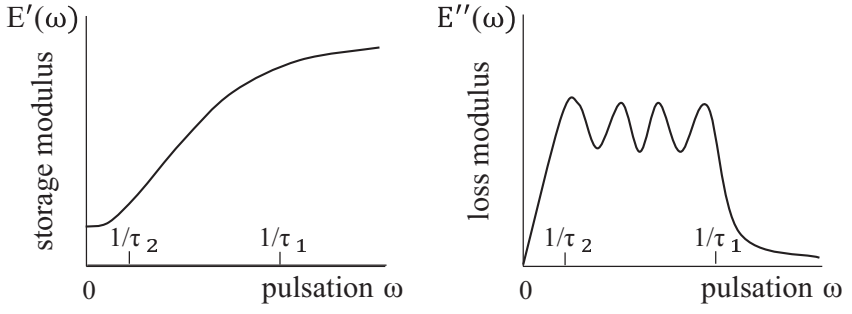

Fig. 8.3.1: Qualitative variation of the storage and loss moduli as a function of pulsation $\omega = 2\pi f$ or frequency f for biological materials. The storage modulus increases monotonically to an asymptotic value at large frequencies. The loss modulus remains pretty constant over a pulsation window and it vanishes at zero and infinite frequencies.

The traditional treatment of viscoelasticity introduces a complex modulus whose real and imaginary parts display over frequencies the key features highlighted in Fig. 8.3.1. For an elastic solid, the complex modulus actually reduces to a frequency independent real number. For a viscoelastic solid, the real part called storage modulus is typically

increasing with frequency while the imaginary part called loss modulus vanishes at very low and very high frequencies and it shows a sort of plateau in a certain frequency range.

8.3.1 Storage and loss moduli

Let us start with a 1D linear context. The configuration at time $t = -\infty$ is taken as reference so that the strain $q(-\infty)$ vanishes. Let $E(t) = E(\infty) + E(t) - E(\infty)$ be the viscoelastic modulus, or relaxation modulus, in which the long range component $E(\infty)$ is isolated. The stress response is obtained as a convolution integral where the viscoelastic modulus plays the role of the kernel,

$$Q(t) = \int_{-\infty}^{t} E(t-u)\, dq(u) = E(\infty)\, q(t) + \int_{-\infty}^{t} \big(E(t-u) - E(\infty)\big)\, dq(u)\,. \tag{8.3.1}$$

For a harmonic strain with pulsation ω,

$$q(t) = \hat{q}(t) = q_0\, e^{i\omega t}, \tag{8.3.2}$$

the stress

$$\hat{Q}(t) = E^*(i\,\omega)\, \hat{q}(t), \tag{8.3.3}$$

expresses in terms of the complex modulus which decomposes additively into a storage modulus E' and a loss modulus E'',

$$E^*(i\,\omega) = E'(\omega) + i\, E''(\omega)\,. \tag{8.3.4}$$

With the change of variable $t - u = v$, the storage and loss moduli become,

$$E'(\omega) = E(\infty) + \omega \int_0^{\infty} \sin(\omega v)\, \big(E(v) - E(\infty)\big)\, dv, \quad E''(\omega) = \omega \int_0^{\infty} \cos(\omega v)\, \big(E(v) - E(\infty)\big)\, dv\,, \tag{8.3.5}$$

which, upon integration by parts, can also be cast in the format,

$$E'(\omega) = E(0) + \int_0^{\infty} \cos(\omega v)\, \frac{dE(v)}{dv}\, dv, \quad E''(\omega) = -\int_0^{\infty} \sin(\omega v)\, \frac{dE(v)}{dv}\, dv\,. \tag{8.3.6}$$

It will be shown that the complex modulus can be interpreted as the Laplace-Carson transform $t \to p = i\,\omega$ of the viscoelastic modulus. Then by the initial and final value theorems,

$$\begin{aligned} E(0) &= E^*(i\infty) = E'(\infty) + i\, E''(\infty), \\ E(\infty) &= E^*(0) = E'(0) + i\, E''(0)\,. \end{aligned} \tag{8.3.7}$$

Therefore the loss modulus typically vanishes at very low and very high pulsations,

$$E''(\omega = 0) = 0, \quad E''(\omega = \infty) = 0\,. \tag{8.3.8}$$

In other words, the material then behaves like an elastic material. In addition,

$$E(0) = E'(\infty), \quad E(\infty) = E'(0)\,. \tag{8.3.9}$$

Introducing the modulus and argument of the complex modulus,

$$E^*(i\,\omega) = E'(\omega) + i\, E''(\omega) = |E^*(i\,\omega)|\, e^{i\phi}, \tag{8.3.10}$$

we see that the stress response is harmonic with a shift of phase,

$$\hat{Q}(t) = E^*(i\,\omega)\, \hat{q}(t) = \overbrace{|E^*(i\,\omega)|\, q_0}^{Q_0}\, e^{i(\omega\, t + \phi)}\,. \tag{8.3.11}$$

The Maxwell model and Kelvin model are defined by a spring of stiffness E [unit : Pa] and a dashpot of viscosity η [unit : Pa×s], respectively in series and in parallel, as indicated in Fig. 8.3.2. The differential equations linking the strain, stress, and their derivatives result by adopting the two basic rules:

(a) the stresses of two parallel branches sum up while the strains are identical;

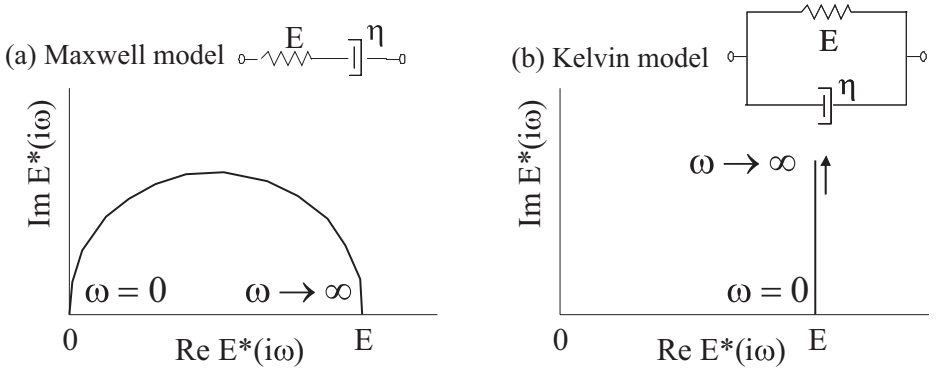

Fig. 8.3.2: Locus in the complex plane of the complex modulus of the models of Maxwell and Kelvin.

(b) the stress is uniform along a branch while the strains of the elements sum up.
From the differential equations governing these models,

$$\text{Maxwell model}: \ \frac{dq}{dt} = \frac{1}{E}\frac{dQ}{dt} + \frac{Q}{\eta}; \quad \text{Kelvin model}: \ Q = E\,q + \eta\,\frac{dq}{dt}\,, \tag{8.3.12}$$

follow their complex moduli and the identifications (8.3.9),

$$\begin{aligned} &\text{Maxwell model}: \ E^*(i\,\omega) = \frac{E\,i\,\omega}{i\,\omega + E/\eta} = \frac{E}{2} + \frac{E}{2}\frac{i\,\omega - E/\eta}{i\,\omega + E/\eta}, \quad E(0) = 0, \ E(\infty) = E; \\ &\text{Kelvin model}: \ E^*(i\,\omega) = E + i\,\omega\,\eta, \quad E(0) = E, \ E(\infty) = E + i\,\infty\,. \end{aligned} \tag{8.3.13}$$

When the pulsation ω varies from to 0 to ∞, the locus in the upper complex plane described by the complex modulus is a half circle for the Maxwell model while it is a half segment for the Kelvin model. The phase shift ϕ is equal to $\arctan\big((E/\eta)/\omega\big)$ for the Maxwell model and to $\arctan\big(\omega/(E/\eta)\big)$ for the Kelvin model.

Given the storage modulus, or the loss modulus, the viscoelastic modulus itself can be obtained by inverse sine or cosine transform[8.1],

$$E(t) - E(\infty) = \frac{2}{\pi}\int_0^\infty \frac{E'(\omega) - E(\infty)}{\omega}\sin(\omega t)\ d\omega, \tag{8.3.19}$$

or, equivalently,

$$E(t) - E(\infty) = \frac{2}{\pi}\int_0^\infty \frac{E''(\omega)}{\omega}\cos(\omega t)\ d\omega\,. \tag{8.3.20}$$

Here $E'(\omega)$ is assumed to be an even function of its argument, while $E''(\omega)$ is odd.

[8.1] Some basic properties of the sine and cosine transforms are required. First the definitions of the sine transform $F_s(\omega) = \mathcal{F}_s\{f(t)\}(\omega)$ of the odd function $f(t)$ and of its inverse,

$$F_s(\omega) = \int_0^\infty \sin(\omega t)\, f(t)\ dt, \quad f(t) = \frac{2}{\pi}\int_0^\infty F_s(\omega)\sin(\omega t)\ d\omega, \tag{8.3.14}$$

and of the cosine transform $F_c(\omega) = \mathcal{F}_c\{f(t)\}(\omega)$ of the even function $f(t)$ and inverse,

$$F_c(\omega) = \int_0^\infty \cos(\omega t)\, f(t)\ dt, \quad f(t) = \frac{2}{\pi}\int_0^\infty F_c(\omega)\cos(\omega t)\ d\omega\,. \tag{8.3.15}$$

The transforms of the exponential function e^{-at}, $a > 0$, are worth recording,

$$\mathcal{F}_s\{e^{-at}\}(\omega) = \frac{\omega}{\omega^2 + a^2}, \quad \mathcal{F}_c\{e^{-at}\}(\omega) = \frac{a}{\omega^2 + a^2}\,. \tag{8.3.16}$$

Also useful are the integral representations of the Heaviside step function $\mathcal{H}$ and Dirac delta function δ,

$$\mathcal{H}(t) = \frac{2}{\pi}\int_0^\infty \frac{\sin(\omega t)}{\omega}\ d\omega, \quad \delta(t) = \frac{2}{\pi}\int_0^\infty \cos(\omega t)\ d\omega\,. \tag{8.3.17}$$

Thus

$$\frac{1}{\omega} = \int_0^\infty \sin(\omega t)\ \mathcal{H}(t)\ dt, \quad 1 = \int_0^\infty \cos(\omega t)\ \delta(t)\ d\omega\,. \tag{8.3.18}$$

As an example, let us start from the complex modulus of the Maxwell model (8.3.13). The inverse transform (8.3.19) of the real part gives the viscoelastic modulus via $(8.3.14)_2$ and $(8.3.16)_1$,

$$\frac{E'(\omega)}{\omega} = E\frac{\omega}{\omega^2 + (E/\eta)^2} \quad \Leftrightarrow \quad E(t) = E\,\exp\big(-t\,\frac{E}{\eta}\big)\,. \tag{8.3.21}$$

The inverse transform (8.3.20) of the imaginary part gives the (same!) viscoelastic modulus via $(8.3.15)_2$ and $(8.3.16)_2$,

$$\frac{E''(\omega)}{\omega} = E\frac{E/\eta}{\omega^2 + (E/\eta)^2} \quad \Leftrightarrow \quad E(t) = E\,\exp\big(-t\,\frac{E}{\eta}\big)\,. \tag{8.3.22}$$

Starting from the viscoelastic modulus $E(t) = E + \eta\,\delta(t)$ of the Kelvin model, the storage and loss moduli derive from (8.3.5) with help of (8.3.18),

$$E'(\omega) - E = \omega\int_0^\infty \sin(\omega v)\;(E(v) - E)\,dv = 0, \quad E''(\omega) = \omega\int_0^\infty \cos(\omega v)\;(E(v) - E)\,dv = \omega\,\eta\,. \tag{8.3.23}$$

Conversely, $E(t) - E$ is retrieved equal to $\eta\,\delta(t)$ by (8.3.20) with help of $(8.3.17)_2$.

Clearly, since the two inverse transforms (8.3.19) and (8.3.20) give the same output, the storage and loss moduli should be related. In fact, it is possible to calculate one in terms of the other, Gross [1953], e.g.,

$$\begin{aligned} E'(\omega) - E(\infty) &= \frac{\omega}{\pi}\,\mathrm{PV}\int_0^\infty \frac{E''(u)}{u}\Big(\frac{1}{u+\omega} - \frac{1}{u-\omega}\Big)\,du; \\ E''(\omega) &= \frac{\omega}{\pi}\,\mathrm{PV}\int_0^\infty \frac{E'(u) - E(\infty)}{u}\Big(\frac{1}{u+\omega} + \frac{1}{u-\omega}\Big)\,du\,. \end{aligned} \tag{8.3.24}$$

The first relation is obtained by introducing (8.3.20) in the first relation of (8.3.5) and by using the trigonometric relation $2\,\sin a\;\cos b = \sin(a+b) + \sin(a-b)$ and $(8.3.18)_1$. The second line of (8.3.24) is obtained by introducing (8.3.19) in the second relation of (8.3.5).

These two relations form a sort of Hilbert transform pair known as Kramers-Kronig relations: with $E'(\omega)$ even and $E''(\omega)$ odd, they result from the fact that the complex modulus $\big(E^*(i\,\omega) - E(\infty)\big)/\omega$ is analytic in the lower half-plane $\mathrm{Im}\,\omega < 0$. The integration is performed in the direct sense along a semi-circle in the lower half-plane closed along the real axis, and accounts for the fact that ω lies on the integration axis, resulting in a Cauchy principal value (PV):

$$\begin{aligned} \frac{1}{\omega}\,\big(E'(\omega) - E(\infty) + i\,E''(\omega)\big) &= -\frac{1}{i\,\pi}\,\mathrm{PV}\int_{-\infty}^{\infty}\frac{E'(x) - E(\infty) + i\,E''(x)}{x\,(x-\omega)}\,dx \\ &= \frac{i}{\pi}\,\mathrm{PV}\int_0^\infty \frac{1}{x}\Big(\frac{1}{x+\omega} + \frac{1}{x-\omega}\Big)\,\big(E'(x) - E(\infty)\big)\,dx \\ &- \frac{1}{\pi}\,\mathrm{PV}\int_0^\infty \frac{1}{x}\Big(-\frac{1}{x+\omega} + \frac{1}{x-\omega}\Big)\,E''(x)\,dx\,, \end{aligned} \tag{8.3.25}$$

which implies the relations (8.3.24).

As an application, the storage modulus of the Maxwell model (8.3.21) may be retrieved from its loss modulus (8.3.22), and conversely, by additive decomposition of the integrands into simple elements and integration in the complex plane.

8.3.2 Time translation invariance

The above derivation has considered the real and imaginary parts of the complex modulus. If the analysis is performed wholly in the complex plane, then the complex modulus appears as the Laplace-Carson transform $t \to p$ of the viscoelastic modulus evaluated at the point $p = i\,\omega$. Indeed, the stress response (8.3.1) to the stimulus (8.3.2) can be cast in the format

$$\hat{Q}(t) = \int_{-\infty}^{t} E(t-u)\,\frac{d\big(q_0\,e^{i\omega u}\big)}{du}\,du \overset{u\to t-v}{=} \Big(i\,\omega\int_0^\infty e^{-i\omega\,v}\,E(v)\,dv\Big)\;\hat{q}(t)\,. \tag{8.3.26}$$

The Laplace-Carson transform $E(t) \to E^*(p)$ at a complex point p is defined as the product of p by the Laplace transform of $E(t)$,

$$E^*(p) = p \int_0^\infty e^{-t\,p}\, E(t)\, dt\,. \tag{8.3.27}$$

In fact, integration by parts of (8.3.1) shows that the response $Q(t)$ in terms of the viscoelastic modulus $E(t)$ and its dual $q(t)$ in terms of viscoelastic, or creep, compliance $J(t)$ can be brought in the form of a convolution that we shall refer to as a Stieltjes convolution integral,

$$Q(t) = \frac{d}{dt} \int_0^t E(t-u)\, q(u)\, du; \quad q(t) = \frac{d}{dt} \int_0^t J(t-u)\, Q(u)\, du\,. \tag{8.3.28}$$

The proof is elementary and proceeds as follows. At time u, let us apply a stress $Q(u)$ and let us note $q(t)$ the strain at time $t \geq u$,

$$Q(t) = Q(u)\, \mathcal{H}(t-u) \quad \to \quad q(t) = J(t,u)\, Q(u)\, \mathcal{H}(t-u)\,. \tag{8.3.29}$$

Here $\mathcal{H} = \mathcal{H}(t)$ denotes the Heaviside step function. The creep function $J(t,u)$ depends (temporarily) on two arguments, the 'source' time u and the 'receptor' time t: in fact, $J(t,u)$ is the strain at time t due to a unit stress applied at time u. The load may actually be changed through infinitesimal increments,

$$dQ(t) = dQ(u)\, \mathcal{H}(t-u) \quad \to \quad dq(t) = J(t,u)\, dQ(u)\, \mathcal{H}(t-u)\,. \tag{8.3.30}$$

Upon integration, the strain at time t may be given various forms, e.g.,

$$\begin{array}{rcll} q(t) & = & J(t,0)\, Q(0)\, \mathcal{H}(t-0) & + \displaystyle\int_{0^+}^t J(t,u)\, \frac{dQ(u)}{du}\, \mathcal{H}(t-u)\, du \\ & = & J(t,t)\, Q(t) & - \displaystyle\int_{0^+}^t \frac{\partial J(t,u)}{\partial u}\, Q(u)\, du\,. \end{array} \tag{8.3.31}$$

The assumption of time translation invariance is henceforth adopted, which states that the response to a stimulus depends not on the receptor and source times individually but only on their difference

$$\text{time translation invariance} \quad J(t,u) = J(t-u,0) \tag{8.3.32}$$

With an abuse of notation, we shall note $J(t-u)$ instead of $J(t-u,0)$. The assumption of time translation invariance is very strong. Although it does not hold for most materials from fabrication to degradation, it is quite acceptable in time windows where the microstructure evolves little. Materials which obey this invariance are also termed 'non-aging'. Early-age concrete, say before 200 days, does not enter this family while mature concrete does at least over a few years. Even if the structural modifications of articular cartilages over time are not so significant as in concrete, aging is mentioned to increase its stiffness, Charlebois et al. [2004].

The strain may now be cast in the format of a Stieltjes convolution integral, and the dual relation that provides the stress as a function of the strain time history may be derived in a similar manner,

$$\begin{array}{rcll} q(t) & = & J(0)\, Q(t) + \displaystyle\int_{0^+}^t \frac{dJ(t-u)}{d(t-u)}\, Q(u)\, du & = \displaystyle\frac{d}{dt} \int_0^t J(t-u)\, Q(u)\, du; \\ Q(t) & = & E(0)\, q(t) + \displaystyle\int_{0^+}^t \frac{dE(t-u)}{d(t-u)}\, q(u)\, du & = \displaystyle\frac{d}{dt} \int_0^t E(t-u)\, q(u)\, du\,. \end{array} \tag{8.3.33}$$

Denoting the Stieltjes convolution integral by the symbol $\otimes$, we have reached the relations,

$$q(t) = \big(J \otimes Q\big)(t), \quad Q(t) = \big(E \otimes q\big)(t)\,. \tag{8.3.34}$$

The fact that the Laplace-Carson transform of the Stieltjes convolution integral is equal to the product of the Laplace-Carson transforms,

$$q^*(p) = J^*(p)\, Q^*(p); \quad Q^*(p) = E^*(p)\, q^*(p)\,, \tag{8.3.35}$$

implies the relation $E^*(p)\, J^*(p) = 1$.

This essential property can be recovered by proceeding somehow formally. Indeed, we shall admit the following properties of the Stieltjes convolution integral for arbitrary time dependent functions f, g and h (for which the convolution exists):

$$\begin{aligned} &\text{Commutativity :} && f \otimes g = g \otimes f, \\ &\text{Associativity :} && f \otimes \big(g \otimes h\big) = \big(f \otimes g\big) \otimes h, \\ &\mathcal{H}\ \text{single neutral element :} && f \otimes \mathcal{H} = \mathcal{H} \otimes f = f\,. \end{aligned} \tag{8.3.36}$$

The time argument has been dropped for simplicity. Combining the two results (8.3.34) and the three above properties,

$$\begin{aligned} q &= J \otimes Q = J \otimes (E \otimes q) = (J \otimes E) \otimes q \\ Q &= E \otimes q = E \otimes (J \otimes Q) = (E \otimes J) \otimes Q\,, \end{aligned} \tag{8.3.37}$$

implies, since $\mathcal{H}$ is the single neutral element, the nice result that the modulus and compliance are the inverse of one another in the transformed space, namely

$$E \otimes J = E \otimes J = \mathcal{H} \quad \Rightarrow \quad E^*(p)\, J^*(p) = 1\,. \tag{8.3.38}$$

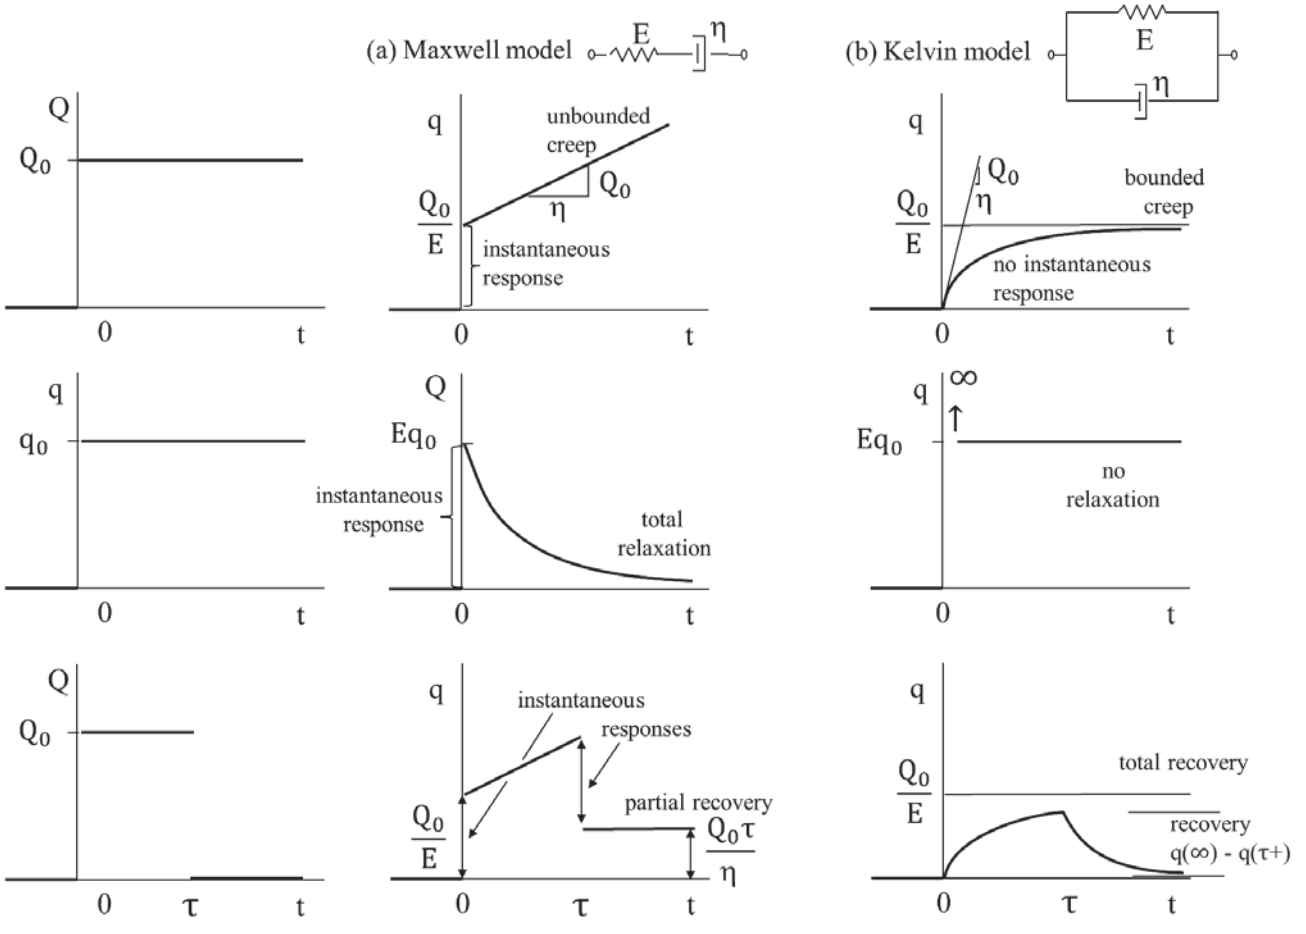

Fig. 8.3.3: Responses of the models of Maxwell and Kelvin to creep, relaxation and recovery. If the deviatoric response of a viscoelastic material is governed by a Maxwell model, its deviatoric stress in a relaxation test vanishes at large time: the Maxwell model is said 'fluid-like' while the Kelvin model is said 'solid-like'.

As a simple application, from the complex modulus of the Maxwell model obtained from (8.3.13) follow in turn its viscoelastic modulus by inverse Laplace-Carson transform, its complex compliance by (8.3.38) and its real compliance

by inverse Laplace-Carson transform,

$$E^*(p) = E\,\frac{p}{E/\eta + p}; \quad E(t) = E\,\exp\big(-t\,\frac{E}{\eta}\big); \quad J^*(p) = \frac{1}{E} + \frac{1}{\eta}\,\frac{1}{p}; \quad J(t) = \frac{1}{E} + \frac{t}{\eta}\,, \tag{8.3.39}$$

and, in the same mood, but in a different order for the Kelvin model,

$$J(t) = \frac{1}{E}\,\Big(1 - \exp\big(-t\,\frac{E}{\eta}\big)\Big); \quad J^*(p) = \frac{1}{\eta}\,\frac{1}{E/\eta + p}; \quad E^*(p) = E + \eta\,p; \quad E(t) = E + \eta\,\delta(t)\,. \tag{8.3.40}$$

One may proceed similarly with another common viscoelastic compliance, or creep function, namely the power law $J(t) = J_0\,t^\alpha$ with $\alpha \in]0,1[$:

$$J(t) = J_0\,t^\alpha; \quad J^*(p) = J_0\,\frac{\Gamma(1+\alpha)}{p^\alpha}; \quad E^*(p) = \frac{1}{J_0}\,\frac{p^\alpha}{\Gamma(1+\alpha)}; \quad E(t) = \frac{1}{J_0}\,\frac{\sin(\pi\alpha)}{\pi\alpha}\,t^{-\alpha}\,. \tag{8.3.41}$$

Finally, here is another way due to Mandel [1966] to recover the expression (8.3.3) for a harmonic strain via the Laplace-Carson formalism. With help of (8.3.45) and of the Laplace-Carson transform (8.3.35),

$$q(t) = q_0\,e^{i\omega t} \quad \to \quad q^*(p) = q_0\,\frac{p}{p - i\,\omega} \quad \to \quad Q^*(p) = E^*(p)\,q^*(p) = q_0\,E^*(p)\,\frac{p}{p - i\,\omega}\,. \tag{8.3.42}$$

The stress response $Q(t)$ may be obtained by inversion of the Laplace-Carson transform via a Bromwich contour $\mathcal{C}$ in the complex plane, by adapting the expression known for the inverse Laplace transform, namely

$$Q(t) = \frac{1}{2\,i\,\pi}\,\int_{\mathcal{C}}\,\frac{Q^*(p)}{p}\,e^{t\,p}\,dp = \frac{1}{2\,i\,\pi}\,\int_{\mathcal{C}}\,q_0\,\frac{E^*(p)}{p - i\,\omega}\,e^{t\,p}\,dp\,. \tag{8.3.43}$$

We shall assume the poles of $E^*(p)$ to have strictly negative real parts so that their contributions die out over time. Then the sole contribution at large time will be due to the imaginary pole $p = i\,\omega$ and, by the Cauchy formula, $Q(t) = E^*(i\,\omega)\,\big(q_0\,e^{i\omega\,t}\big)$.

8.3.3 The fading memory principle

Whether they obey the property of time translation invariance or not, the relaxation function $E(t)$ and the creep function $J(t)$ agree with the *fading memory principle*. In essence, the fading memory principle states that the past history of the strain has less effects on the current stress than its more recent history, Coleman and Noll [1960], Coleman [1964]. Thermodynamic considerations imply that the time derivative of the relaxation function is a non-negative $E(t) \geq 0$, continuously decreasing function of time $dE(t)/dt \leq 0$, e.g., Christensen [1982], p. 87. As can be appreciated from the second line of (8.3.33), the fading memory principle implies in addition that the absolute value of the time derivative of the relaxation function should be a decreasing function of time and therefore the 2nd derivative of the relaxation function should be nonnegative $d^2E(t)/dt^2 \geq 0$. In summary,

$$E(t) \geq 0, \quad \frac{dE(t)}{dt} \leq 0, \quad \frac{d^2E(t)}{dt^2} \geq 0\,. \tag{8.3.44}$$

8.3.4 Basics of Laplace-Carson transform

The Laplace-Carson transform $f(t) \to f^*(p)$ enjoys properties similar, but not exactly identical, to the one-sided Laplace transform. With the convention that all real functions are tacitly multiplied by the Heaviside step function $\mathcal{H}(t)$, some basic properties are worth recording, namely

$$t^n\,\mathcal{H}(t) \to \frac{n!}{p^n}, \quad \frac{d^n f}{dt^n} \to p^n\,f^*(p), \quad n \geq 0 \text{ integer}; \quad \exp(-a\,t) \to \frac{p}{a+p},\ \mathrm{Re}\,a \geq 0; \quad \delta(t) \to p\,. \tag{8.3.45}$$

Also, for $\alpha \in]0,1[$,

$$t^\alpha\,\mathcal{H}(t) \to \frac{\Gamma(1+\alpha)}{p^\alpha}, \tag{8.3.46}$$

Γ being the Gamma function, some information on which is provided in Section 15.3.2.3.

The transform of the Stieltjes convolution integral is most noticeable,

$$\frac{d}{dt}\int_0^t f(t-u)\,g(u)\,du \to f^*(p)\,g^*(p)\,. \tag{8.3.47}$$

In (8.3.46) and (8.3.47), the operator $d\,/dt$ denotes the derivative in the sense of distributions, $df/dt = d^+f/dt + f(0^+)\,\delta(t)$, with d^+f/dt the right derivative and $\delta(t)$ the Dirac delta function, Section 7.5.4.3.

The Laplace-Carson transform is a useful tool to apply *the elastic viscoelastic correspondence principle*. Roughly speaking, this principle states that a viscoelastic boundary value problem expressed in the Laplace-Carson domain has the same form as the (associated) elastic boundary value problem expressed in the time domain (the time scale here being possibly given by the loading process). It assumes that the viscoelastic response obeys time translation invariance. Provided that the partition of the boundary defining the zones where either the displacement or the traction are prescribed is fixed, it is a quite handy and powerful tool for applications in strength of materials and continuum mechanics.

8.3.5 Loss coefficient and hysteresis loops

The long-term response to a harmonic stress stimulus may be expressed in real form,

$$Q(t) = Q_0\,\sin(\omega\,t), \quad q(t) = q_0\,\sin(\omega\,t-\phi)\,. \tag{8.3.48}$$

The trajectory in the $(q/q_0, Q/Q_0)$ plane is sketched in Fig. 8.3.4.

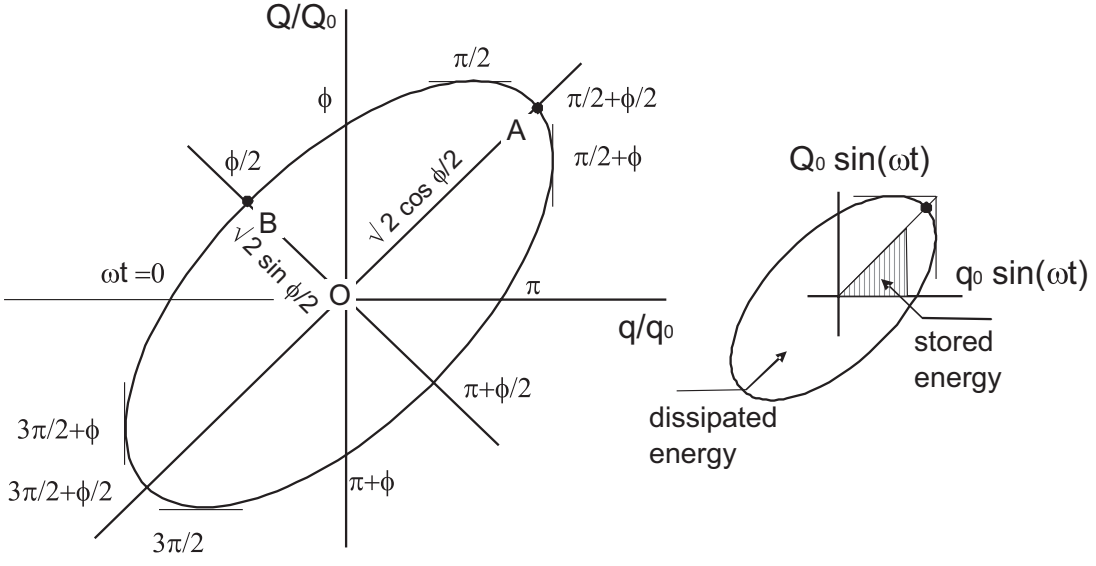

Fig. 8.3.4: Trajectory, stored energy and dissipated energy for a viscoelastic solid with a phase shift ϕ. In biological tissues, the hysteresis loops are believed to depend weakly on the loading rate, Fung [1993], p. 283 et seq.

It is an ellipse with semi-axes equal to $\sqrt{2}\,\cos(\phi/2)$ and $\sqrt{2}\,\sin(\phi/2)$ oriented at $\pi/4$ and $3\,\pi/4$ respectively. Indeed,

$$\frac{1}{(\sqrt{2}\,\cos(\phi/2))^2}\Big(\frac{1}{\sqrt{2}}\,\frac{q}{q_0}+\frac{1}{\sqrt{2}}\,\frac{Q}{Q_0}\Big)^2+\frac{1}{(\sqrt{2}\,\sin(\phi/2))^2}\Big(-\frac{1}{\sqrt{2}}\,\frac{q}{q_0}+\frac{1}{\sqrt{2}}\,\frac{Q}{Q_0}\Big)^2=1\,. \tag{8.3.49}$$

The energy spent

$$W(t)=\int_0^t Q\,dq = W_{\rm e}(t)+W_{\rm loss}(t)\,, \tag{8.3.50}$$

may be split in an elastic stored contribution and a dissipated contribution. The in phase stored contribution

$$W_{\rm e}(t)=\int_0^{\omega t} Q_0\,\sin(\omega\,u)\,d\big(q_0\sin(\omega\,u)\big)\,\cos\phi\;=\frac{Q_0\,q_0}{2}\,\cos\phi\,\sin^2(\omega\,t)\,, \tag{8.3.51}$$

corresponds to the triangular area below the curve $(q_0\,\sin(\omega\,t), Q_0\,\cos(\omega\,t))$. Its maximum $W_{\rm e}^{\rm max} = \frac{1}{2}\,Q_0\,q_0\,\cos\phi$ takes place for $\omega\,t = \frac{1}{2}\,\pi$. It has an average value of

$$\overline{W}_{\rm e} = \frac{1}{T}\int_0^T W_{\rm e}(t)\,dt = \frac{Q_0\,q_0}{4}\,\cos\phi\,, \tag{8.3.52}$$

over a cycle $T = 2\,\pi/\omega$. The dissipated energy stems from the out of phase response,

$$W_{\rm loss}(t) = \int_0^{\omega t} Q_0\,\sin(\omega\,u)\,d\big(q_0\cos(\omega\,u)\big)\,(-\sin\phi) = \frac{Q_0\,q_0}{2}\,\sin\phi\,\Big(\omega\,t - \frac{1}{2}\sin(2\omega\,t)\Big)\,. \tag{8.3.53}$$

The dissipated energy over a cycle

$$\Delta W_{\rm loss} = W_{\rm loss}(T) - W_{\rm loss}(0) = Q_0\,q_0\,\pi\,\sin\phi\,. \tag{8.3.54}$$

is, as expected, equal to the area of the hysteresis loop (the area of an ellipse is equal to π times the product of the semi-axes). The loss coefficient L is defined in terms of the out of phase angle,

$$\frac{1}{L} = \frac{1}{4\,\pi}\,\frac{\Delta W_{\rm loss}}{\overline{W}_{\rm e}} = \tan\phi = \frac{E''(\omega)}{E'(\omega)}\,, \tag{8.3.55}$$

the last relation resulting from (8.3.10).

8.3.6 Complex modulus of the standard linear solid model

The standard linear solid is defined by a spring E_P in parallel with a Maxwell model as shown in Fig. 8.3.5. The differential equation of the model,

$$\frac{1}{E_P}\Big[Q + t_q\,\frac{dQ}{dt}\Big] = q + t_Q\,\frac{dq}{dt}, \tag{8.3.56}$$

is phrased in terms of two characteristic times,

- $t_q = \eta/E_S$ the characteristic time at constant strain,
- $t_Q = (1 + E_S/E_P)\,t_q$ the characteristic time at constant stress.

In this context, $t_q = \eta/E_S$, $t_Q = \infty$ for a Maxwell model ($E_P = 0$), while $t_q = 0$, $t_Q = \eta/E_P$ for a Kelvin model ($E_S = \infty$).

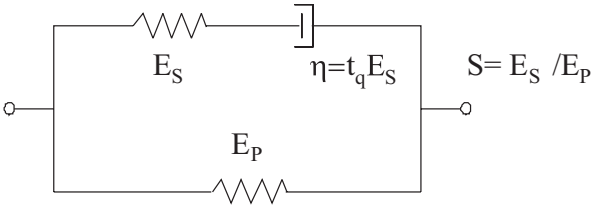

Fig. 8.3.5: The standard linear solid model defined by a Maxwell model in parallel with a spring.

The differential equation (8.3.56) can be transformed in integral form through the relaxation modulus $E(t)$ or through the compliance $J(t)$ as

$$Q(t) = \int_{-\infty}^{t} E(t-u)\;dq(u)\,, \quad q(t) = \int_{-\infty}^{t} J(t-u)\;dQ(u)\,, \tag{8.3.57}$$

with

$$\frac{E(t)}{E_P} = 1 + S\,e^{-t/t_q}, \quad S = \frac{t_Q}{t_q} - 1 = \frac{E_S}{E_P}\,, \tag{8.3.58}$$

and

$$E_P\,J(t) = 1 - \frac{S}{1+S}\,e^{-t/t_Q}\,. \tag{8.3.59}$$

Alternatively, still assuming $q(-\infty)=0$, and with the change of variable $t-u=v$,

$$\frac{Q(t)}{E_P} = q(t) - S\int_0^\infty e^{-v/t_q}\,\frac{dq(t-v)}{dv}\,dv\,. \tag{8.3.60}$$

Note that a purely elastic response $Q(t)=(E_P+E_S)\,q(t)$ is characterized by $\eta\ \to\infty$ and $t_q\ \to\infty$ and not by $S=0$.

The response $\hat{Q}(t)=E^*(i\,\omega)\,\hat{q}(t)$ to a harmonic strain $\hat{q}(t)=q_0\,e^{i\omega t}$ introduces the complex modulus,

$$\frac{E(t)}{E_P} = 1+S\,e^{-t/t_q} \longmapsto \frac{E^*(i\,\omega)}{E_P} = 1+S\,\frac{i\,\omega\,t_q}{1+i\,\omega\,t_q} = 1+S\,\frac{\omega\,t_q+i}{(\omega\,t_q)^{-1}+\omega\,t_q}\,, \tag{8.3.61}$$

whence the storage and loss moduli,

$$\frac{E'(\omega)}{E_P} = 1+S\,\frac{\omega\,t_q}{(\omega\,t_q)^{-1}+\omega\,t_q}\,,\quad \frac{E''(\omega)}{E_P} = S\,\frac{1}{(\omega\,t_q)^{-1}+\omega\,t_q}\,. \tag{8.3.62}$$

The loss angle,

$$\tan\phi = \frac{E''(\omega)}{E'(\omega)} = \frac{S\,\omega\,t_q}{1+(1+S)\,(\omega\,t_q)^2}\,, \tag{8.3.63}$$

vanishes at zero and infinite frequencies and has a maximum equal to $S/(2\,\sqrt{1+S})$ at $\omega\,t_q=1/\sqrt{1+S}$. It tends to zero at high frequencies for a Maxwell model, namely $E''(\omega)/E'(\omega)=E_S/(\eta\,\omega)$, while it tends to infinity for a Kelvin model, namely $E''(\omega)/E'(\omega)=\eta\,\omega/E_P$.

8.4 Relaxation spectrum

8.4.1 A discrete spectrum

The complex modulus of a model constituted by n parallel Maxwell models plus a spring branch is obtained by simple summation,

$$\frac{E(t)}{E_P} = 1+\sum_{k=1}^n S_k\,e^{-t/t_{qk}}\,,\quad \frac{E^*(i\,\omega)}{E_P} = 1+\sum_{k=1}^n S_k\,\frac{i\,\omega\,t_{qk}}{1+i\,\omega\,t_{qk}}\,, \tag{8.4.1}$$

where $S_k=E_{Sk}/E_P$ and $t_{qk}=\eta_k/E_{Sk}$ is the relaxation time at constant strain associated with the branch $k\in[1,n]$. The proof is left as an exercise, Exercise 8.1. The real part of the complex modulus,

$$\frac{E'(i\,\omega)}{E_P} = 1+\sum_{k=1}^n S_k\,\frac{(\omega\,t_{qk})^2}{1+(\omega\,t_{qk})^2} = 1+S\,-\sum_{k=1}^n S_k\,\frac{1}{1+(\omega\,t_{qk})^2}\,, \tag{8.4.2}$$

with $S=\sum_{k=1}^n S_k$ is clearly increasing continuously with frequency,

$$\frac{1}{E_P}\,\frac{dE'(i\,\omega)}{d\omega} = \sum_{k=1}^n 2\,S_k\,t_{qk}\,\frac{\omega\,t_{qk}}{(1+(\omega\,t_{qk})^2)^2}\,,\quad \frac{1}{E_P}\,\frac{d^2E'(i\,\omega)}{d\omega^2} = \sum_{k=1}^n 2\,S_k\,(t_{qk})^2\,\frac{1-3\,(\omega\,t_{qk})^2}{(1+(\omega\,t_{qk})^2)^3}\,, \tag{8.4.3}$$

as sketched in Figs. 8.3.1 and 8.4.1. On the other hand, the imaginary part,

$$\frac{E''(i\,\omega)}{E_P} = \sum_{k=1}^n S_k\,\frac{\omega\,t_{qk}}{1+(\omega\,t_{qk})^2}\,,\quad \frac{1}{E_P}\,\frac{dE''(i\,\omega)}{d\omega} = \sum_{k=1}^n S_k\,t_{qk}\,\frac{1-(\omega\,t_{qk})^2}{(1+(\omega\,t_{qk})^2)^2}\,, \tag{8.4.4}$$

has maxima at the relaxation times, namely for $\omega\sim(t_{qk})^{-1}$, $k\in[1,n]$, and minima on each side of the relaxation times, as sketched in Fig. 8.4.1. To prove this pattern, let us assume the relaxation times numbered in increasing values, namely $t_{q1}<t_{q2}<\cdots$ to be well separated, say $t_{qj}\ll t_{qk}\ll t_{ql}$ with $j=k-1$ and $l=k+1$. For frequencies around $(t_{qk})^{-1}$,

$$\omega\,t_{qj}\ll 1;\quad \omega\,t_{qk}\sim 1;\quad 1\ll\omega\,t_{ql}, \tag{8.4.5}$$

the subsequent implications follow,

$$\begin{aligned}
&\frac{(\omega\,t_{qj})^2}{1+(\omega\,t_{qj})^2}\ll 1;\quad \frac{(\omega\,t_{qk})^2}{1+(\omega\,t_{qk})^2}\sim\frac{1}{2};\quad \frac{(\omega\,t_{ql})^2}{1+(\omega\,t_{ql})^2}\sim 1;\\
&\frac{\omega\,t_{qj}}{1+(\omega\,t_{qj})^2}\ll 1;\quad \frac{\omega\,t_{qk}}{1+(\omega\,t_{qk})^2}\sim\frac{1}{2};\quad \frac{\omega\,t_{ql}}{1+(\omega\,t_{ql})^2}\ll 1\,.
\end{aligned} \tag{8.4.6}$$

Consequently the value of the storage modulus $E'(i\,\omega)/E_P$ at $\omega=(t_{qk})^{-1}$ is about $1+S_k/2+\sum_{l>k}S_l$. Conversely, a single term dominates the loss modulus around this frequency. As indicated by (8.4.3), the derivative is increasing for $\omega<(t_{qk})^{-1}$, it vanishes at $\omega=(t_{qk})^{-1}$ and it is negative for $\omega>(t_{qk})^{-1}$. This pattern repeats around each frequency $\omega\sim(t_{qk})^{-1}$, $k\in[1,n]$. The value of the loss modulus $E''(i\,\omega)/E_P$ at $\omega=(t_{qk})^{-1}$ is about $S_k/2$.

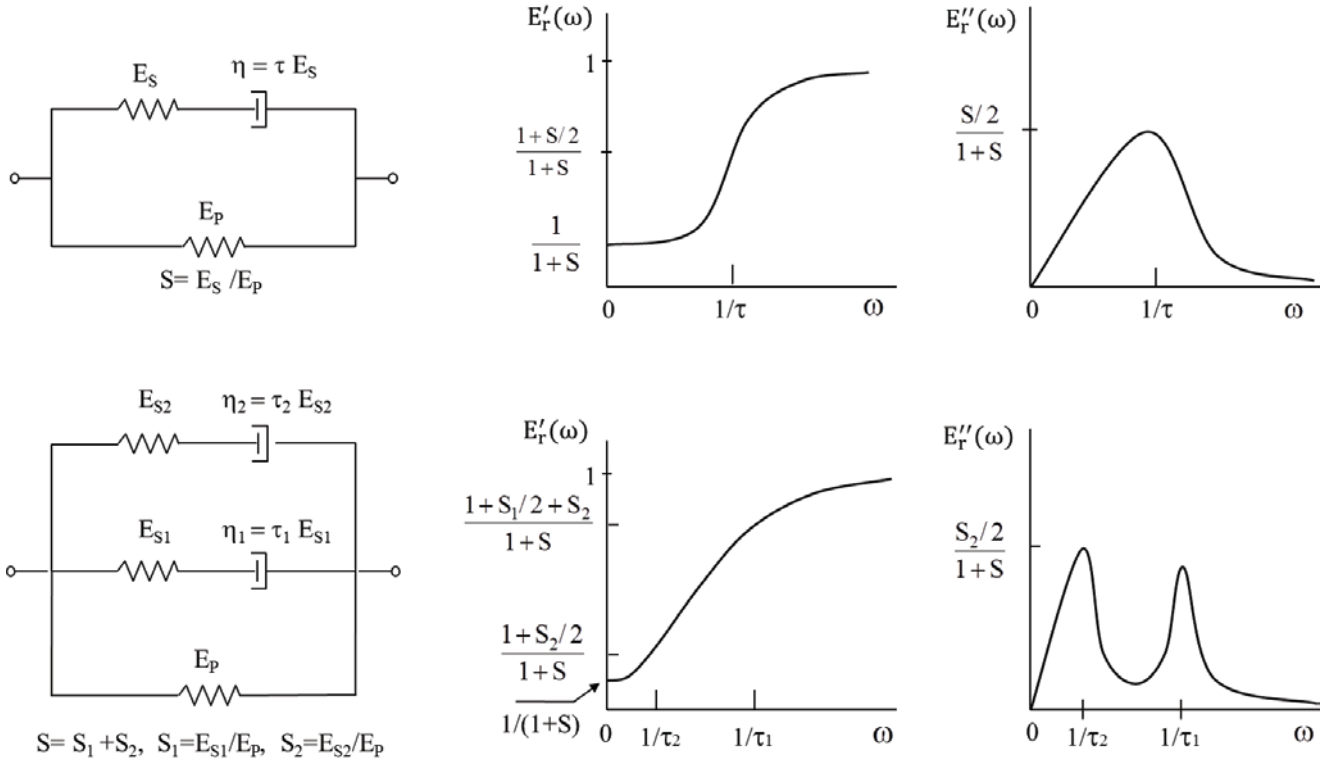

Fig. 8.4.1: Reduced storage and loss moduli of two viscoelastic materials. Parallel branches endowed with their own distinct relaxation times at constant strain allow for dissipation for a large range of frequencies. The local maxima of the loss modulus take place at pulsations linked to the inverses of the relaxation times.

8.4.2 A continuous spectrum

The discrete generalization of the previous section motivates the continuous (integral) generalization,

$$\begin{aligned} \frac{E(t)}{E(\infty)} &= 1+\int_0^\infty S(\tau)\, e^{-t/\tau} d\tau, \\ \frac{E^*(i\,\omega)}{E(\infty)} &= 1+\int_0^\infty \frac{i\,\omega\,\tau\, S(\tau)}{1+i\,\omega\,\tau}\, d\tau, \\ &= 1+\int_0^\infty \frac{\omega\tau\, S(\tau)}{(\omega\tau)^{-1}+\omega\tau}\, d\tau + i\, \int_0^\infty \frac{S(\tau)}{(\omega\tau)^{-1}+\omega\tau}\, d\tau\,. \end{aligned} \tag{8.4.7}$$

The discrete spectra for the standard linear solid and the generalization above are recovered for $E(\infty) = E_P$ and, respectively,

$$S(\tau) = S\,\delta(\tau - t_q), \quad S(\tau) = \sum_{k=1}^{n} S_k\,\delta(\tau - t_{qk})\,. \tag{8.4.8}$$

For biological tissues, the loss moduli and energy dissipation are widely believed to be significant and virtually constant over a wide range of frequency, Fung [1993], p. 283 et seq. This observation motivates the *relaxation spectrum*,

$$S(\tau) = a_v \begin{cases} \dfrac{1}{\tau}, & \tau \in [\tau_1, \tau_2] \\ 0, & \text{elsewhere,} \end{cases} \tag{8.4.9}$$

with τ_1 and τ_2 the short and long relaxation times and $a_v > 0$ a dimensionless material constant. With $E_1(u) = \int_u^\infty e^{-v}/v\, dv$[8.2], the relaxation modulus and the complex modulus can be given an explicit form, namely

$$\frac{E(t)}{E(\infty)} = 1 + a_v \left(E_1(\frac{t}{\tau_2}) - E_1(\frac{t}{\tau_1}) \right), \tag{8.4.11}$$

and

$$\frac{E^*(i\,\omega)}{E(\infty)} = 1 + \frac{a_v}{2} \mathrm{Ln} \frac{1+(\omega\tau_2)^2}{1+(\omega\tau_1)^2} + i\, a_v \left(\tan^{-1}(\omega\tau_2) - \tan^{-1}(\omega\tau_1) \right). \tag{8.4.12}$$

Here we have defined the viscoelastic modulus and complex modulus from the relaxation spectrum. The converse point of view may also be considered. Setting $\lambda = 1/\tau$ in (8.4.7), then $E(t)/E(\infty) - 1$ appears as the Laplace transform of $S(1/\lambda)/\lambda^2$. The converse relation is obtained by inversion of the Laplace transform via an appropriate Bromwich contour $\mathcal{C}$ in the complex plane,

$$\frac{1}{\lambda^2} S(\frac{1}{\lambda}) = \frac{1}{2\,i\pi} \int_{\mathcal{C}} e^{\lambda\, p} \Big(\frac{E(p)}{E(\infty)} - 1 \Big)\, dp\,. \tag{8.4.13}$$

The spectrum may also be derived from the complex modulus, Gross [1953], Christensen [1982].

8.4.3 A specific relaxation spectrum

Note that, with a logarithmic time scale,

$$\frac{E(t)}{E(\infty)} = 1 + \int_0^\infty \tilde{S}(\tau)\, e^{-t/\tau} d\,\mathrm{Ln}\,\tau, \tag{8.4.14}$$

the relaxation spectrum $\tilde{S}(\tau) \equiv \tau\, S(\tau) = a_v \left(\mathcal{H}(\tau - \tau_1) - \mathcal{H}(\tau - \tau_2) \right)$ corresponding to (8.4.9) is piecewise constant. This observation leads to define the *relaxation spectrum* S via $\tilde{S}(\xi) = \xi\, S(\xi)$ which is now centered at τ and has half-width $\Delta\tau$, Fung [1993],

$$\tilde{S}(\xi) = \begin{cases} \dfrac{\tau}{\Delta\tau}, & \xi \in [\tau - \Delta\tau, \tau + \Delta\tau], \\ 0, & \text{otherwise.} \end{cases} \tag{8.4.15}$$

The *memory function* $m(t)$,

$$m(t) = \int_0^{+\infty} \tilde{S}(\xi)\, e^{-t/\xi}\, d\,\mathrm{Ln}\,\xi\,, \tag{8.4.16}$$

has Laplace transform $t \to p$[8.3],

$$\overline{m}(p) = \int_0^{+\infty} e^{-tp}\, m(t)\, dt = \int_0^{+\infty} \frac{\tilde{S}(\xi)}{\xi\, p + 1}\, d\xi = \frac{\tau}{\Delta\tau} \frac{1}{p} \mathrm{Ln}\, \frac{p\,(\tau + \Delta\tau) + 1}{p\,(\tau - \Delta\tau) + 1}\,. \tag{8.4.17}$$

Note the limits for infinitely short and infinitely large relaxation times τ,

$$\lim_{\tau \to 0}\ p\,\overline{m}(p) = 0; \quad \lim_{\tau \to \infty}\ p\,\overline{m}(p) = 2\,. \tag{8.4.18}$$

These limits can be checked on the relaxation modulus in time space (8.4.11) using the properties of the function E_1 provided in footnote 8.2: at small and large τ_1 and τ_2, the viscous contribution to the relaxation modulus $E(t)/E(\infty)$ for $t > 0$ is equal, respectively, to 0 and to $2\,a_v\,\Delta\tau/\tau = 2$ for $a_v = \tau/\Delta\tau$.

[8.2] The function $E_1(t)$ is defined for any real $t \neq 0$ as,

$$E_1(t) = \int_t^\infty \frac{e^{-v}}{v}\, dv = -\gamma - \mathrm{Ln}\,|t| - \sum_{k=1,\infty} \frac{(-t)^k}{k \times k!}\,, \tag{8.4.10}$$

with $\gamma = 0.5772\cdots$ the Euler's constant. As t varies from $-\infty$ to 0, it increases monotonically from $-\infty$ to $+\infty$ with a single zero at $t \sim -0.37250$. As t varies from 0 to $+\infty$, it decreases monotonically from $+\infty$ to 0. It behaves like e^{-t}/t at large positive or negative t.

[8.3] If p was real, the argument of the logarithm should be in absolute value. However, the Laplace transform is a priori complex and, in fact, to be accurate, a definition of the logarithm in the complex plane should be given.

8.5 The quasi-linear viscoelasticity QLV model of Fung

8.5.1 Elastic response and reduced relaxation function

The above relations for the standard linear solid are rewritten along the scheme proposed by Fung [1993]. First the elastic (instantaneous) response is introduced, e.g., for the example above,

$$Q^{\rm e}(t) = E_P\,(1+S)\,q(t) = (E_P + E_S)\,q(t)\,. \tag{8.5.1}$$

The viscoelastic relation can be recast in integral form through the *reduced* dimensionless relaxation modulus $E_r(t)$

$$Q(t) = \int_{-\infty}^{t} E_r(t-u)\; dQ^{\rm e}(u)\,, \tag{8.5.2}$$

with

$$E_r(t) = \frac{1+S\,e^{-t/t_q}}{1+S}, \quad S = \frac{t_Q}{t_q} - 1 = \frac{E_S}{E_P}\,. \tag{8.5.3}$$

Note the particular values,

$$E_r(0) = 1, \quad E_r(\infty) = \frac{1}{1+S} < 1\,. \tag{8.5.4}$$

As for the reduced complex modulus,

$$E_r(t) = \frac{1}{1+S}\Big(1+S\,e^{-t/t_q}\Big) \longmapsto E_r^*(i\,\omega) = \frac{1}{1+S}\Big(1+S\,\frac{i\,\omega\,t_q}{1+i\,\omega\,t_q}\Big)\,, \tag{8.5.5}$$

the variations with the pulsation ω of its real and imaginary parts,

$$E_r'(\omega) = \frac{1}{1+S}\Big(1+S\,\frac{\omega\,t_q}{(\omega\,t_q)^{-1}+\omega\,t_q}\Big), \quad E_r''(\omega) = \frac{S}{1+S}\Big(\frac{1}{(\omega\,t_q)^{-1}+\omega\,t_q}\Big)\,, \tag{8.5.6}$$

are sketched in Fig. 8.4.1 for the standard linear solid (with two parallel branches) and for a generalized model (with three parallel branches).

A *de visu* extension of the reduced relaxation modulus can be suggested,

$$E_r(t) = \frac{1+\displaystyle\int_0^\infty S(\tau)\,e^{-t/\tau}d\tau}{1+\displaystyle\int_0^\infty S(\tau)\,d\tau}, \tag{8.5.7}$$

from which follows the associated complex modulus,

$$E_r^*(i\,\omega) = \frac{1+\displaystyle\int_0^\infty \frac{i\,\omega\,\tau\,S(\tau)}{1+i\,\omega\,\tau}\,d\tau}{1+\displaystyle\int_0^\infty S(\tau)\,d\tau} = \frac{1+\displaystyle\int_0^\infty \frac{\omega\tau\,S(\tau)}{(\omega\tau)^{-1}+\omega\tau}\,d\tau}{1+\displaystyle\int_0^\infty S(\tau)\,d\tau} + i\;\frac{\displaystyle\int_0^\infty \frac{S(\tau)}{(\omega\tau)^{-1}+\omega\tau}\,d\tau}{1+\displaystyle\int_0^\infty S(\tau)\,d\tau}\,. \tag{8.5.8}$$

For the continuous spectrum (8.4.9),

$$\int_0^\infty S(\tau)\,d\tau = a_v\,{\rm Ln}\frac{\tau_2}{\tau_1}\,, \tag{8.5.9}$$

the reduced relaxation modulus and the reduced complex modulus specialize to,

$$E_r(t) = \frac{1+a_v\,\big(E_1(t/\tau_2) - E_1(t/\tau_1)\big)}{1+a_v\,{\rm Ln}(\tau_2/\tau_1)}\,, \tag{8.5.10}$$

and

$$E_r^*(i\,\omega) = \frac{1+\dfrac{a_v}{2}{\rm Ln}(\omega^2\tau_2^2+1)/(\omega^2\tau_1^2+1)}{1+a_v\,{\rm Ln}(\tau_2/\tau_1)} + i\,a_v\;\frac{\tan^{-1}(\omega\tau_2)-\tan^{-1}(\omega\tau_1)}{1+a_v\,{\rm Ln}(\tau_2/\tau_1)}\,. \tag{8.5.11}$$

An identification procedure for the viscoelastic parameters is proposed by Sarver et al. [2003]. The unconfined compression tests of articular cartilages in Huang et al. [2003] use different parameters depending whether the tissue is viewed as a biphasic-conewise linear elastic or as a biphasic poro-viscoelastic. These parameters are reported in Table 8.5.1.

Table 8.5.1: Viscoelastic parameters defining the reduced relaxation function (8.5.10).

Tissue	Model	Reference	a_v (-)	τ_1 (s)	τ_2 (s)
Articular cartilage	Biphasic-conewise elastic	Huang et al. [2003]	0.51 ± 0.23	0.77 ± 0.54	162 ± 90
Articular cartilage	Biphasic poro-viscoelastic	Huang et al. [2003]	5.98 ± 2.31	0.38 ± 0.39	448 ± 327
Cornea	Viscoelastic	Boyce et al. [2007]	0.2	1.0	10 000

8.5.2 The three-dimensional reduced relaxation tensor

The three-dimensional format of the one-dimensional model defined by (8.5.2),

$$\boldsymbol{\sigma}(t) = \int_{-\infty}^{t} \mathbb{E}_r(t-u) : d\boldsymbol{\sigma}^{\mathrm{e}}(u)\,, \tag{8.5.12}$$

is expressed via the fourth order *reduced* relaxation tensor $\mathbb{E}_r(t)$ and the 'elastic' stress $\boldsymbol{\sigma}^{\mathrm{e}}$. The elastic stress is obtained via a potential $W^{\mathrm{e}} = W^{\mathrm{e}}(\boldsymbol{\epsilon})$ as $\boldsymbol{\sigma}^{\mathrm{e}} = \partial W^{\mathrm{e}}/\partial\boldsymbol{\epsilon}$. It is viewed as embodying strain nonlinearity, and typically defined in terms of the strain invariants. Consistency implies that the *reduced* relaxation tensor satisfies the relation,

$$\mathbb{E}_r(0) = \text{identity tensor of order four}\,. \tag{8.5.13}$$

In a relaxation experiment at a fixed strain $\boldsymbol{\epsilon}_0$, the equilibrium (asymptotic) stress is seen as the product of the reduced relaxation tensor times the elastic stress,

$$\boldsymbol{\sigma}(\infty) = \mathbb{E}_r(\infty) : \boldsymbol{\sigma}^{\mathrm{e}}(\boldsymbol{\epsilon}_0)\,. \tag{8.5.14}$$

If the material enjoys isotropic viscoelastic properties, the reduced relaxation tensor is defined by two scalar dimensionless relaxation functions $\lambda_r(t)$ and $\mu_r(t)$,

$$\begin{aligned} \mathbb{E}_r(t) &= \lambda_r(t)\,\mathbf{I}\otimes\mathbf{I} + 2\,\mu_r(t)\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I}, \\ \boldsymbol{\sigma}(t) &= \int_{-\infty}^{t} \lambda_r(t-u)\ \mathrm{tr}\ d\boldsymbol{\sigma}^{\mathrm{e}}(u)\,\mathbf{I} + 2\,\mu_r(t-u)\,d\boldsymbol{\sigma}^{\mathrm{e}}(u)\,. \end{aligned} \tag{8.5.15}$$

If the material is incompressible, the isotropic constitutive equations specify the effective stress

$$\boldsymbol{\sigma}(t) + p_i(t)\,\mathbf{I} = \int_{-\infty}^{t} 2\,\mu_r(t-u)\ d\boldsymbol{\sigma}^{\mathrm{e}}(u)\,, \tag{8.5.16}$$

the incompressibility pressure p_i being defined by boundary conditions.

8.6 Overall viscoelastic properties: ECM and a contractile cell

In the parallel model of Fig. 8.6.1, the upper branch represents the extracellular matrix (M) and the lower branch the cells (C). For each branch individually, the strain is denoted by q and the stress by Q.

1. The matrix branch:

The governing differential equation of the upper branch,

$$\frac{dQ_{\mathrm{M}}}{dt} + \frac{Q_{\mathrm{M}}}{t_{\mathrm{M}}} = (E_{\mathrm{PM}} + E_{\mathrm{SM}})\frac{dq_{\mathrm{M}}}{dt} + E_{\mathrm{PM}}\frac{q_{\mathrm{M}}}{t_{\mathrm{M}}}, \tag{8.6.1}$$

with $t_{\mathrm{M}} = \eta_{\mathrm{M}}/E_{\mathrm{SM}}$ the relaxation time at constant strain, can be recast in the integral form,

$$Q_{\mathrm{M}}(t) = \int_{-\infty}^{t} \left((E_{\mathrm{PM}} + E_{\mathrm{SM}}) - E_{\mathrm{SM}}\,(1 - e^{-(t-u)/t_{\mathrm{M}}})\right)\frac{dq_{\mathrm{M}}(u)}{du}\,du\,. \tag{8.6.2}$$

Upon comparison with the general integral representation (8.3.1) of the relaxation modulus E_{M}, we see that

$$E_{\mathrm{PM}} = E_{\mathrm{M}}(\infty),\ E_{\mathrm{SM}} = E_{\mathrm{M}}(0) - E_{\mathrm{M}}(\infty),\ \eta_{\mathrm{M}} = t_{\mathrm{M}}\,(E_{\mathrm{M}}(0) - E_{\mathrm{M}}(\infty))\,. \tag{8.6.3}$$

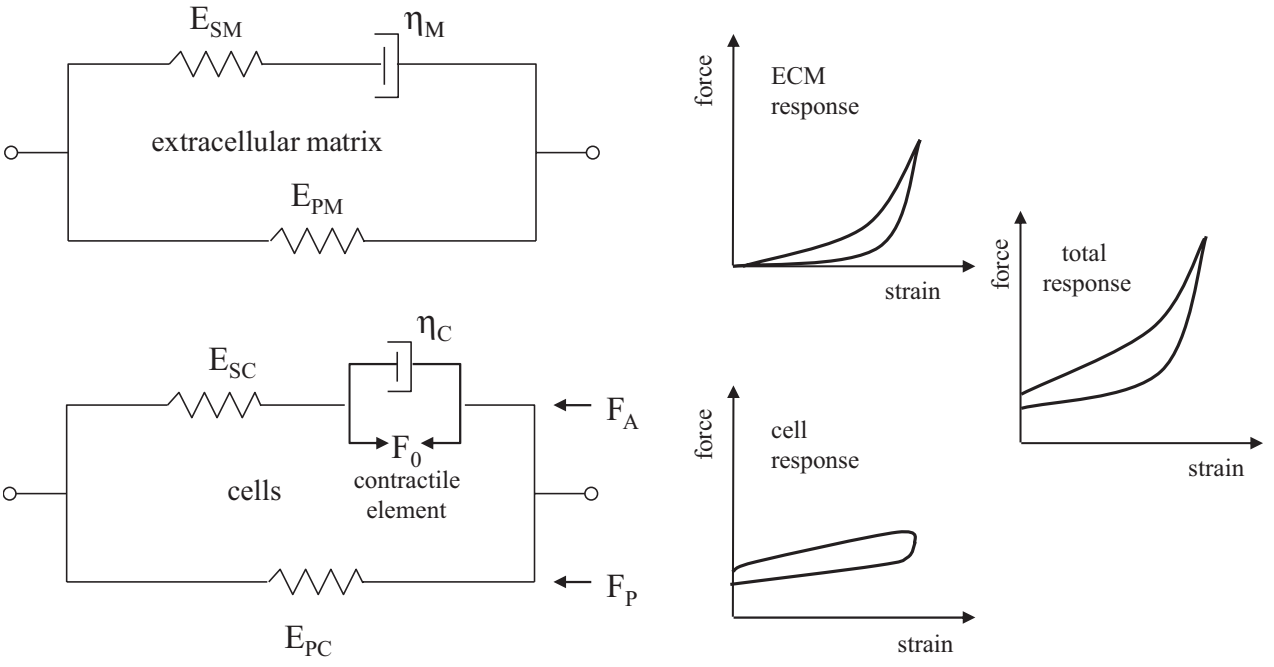

Fig. 8.6.1: The extracellular matrix and the cells are assumed to work in parallel in the model of Zahalak et al. [2000]. The cells contain a contractile element. Physiologically, the force due to cells can be activated by serum and abolished by drugs, e.g., cytochalasin D. Similarly papaverine, a calcium antagonist, abolishes the contractive activity of the gastro-intestinal tractus. These properties are used to measure the tissue (ECM+cells) and ECM contributions independently. Similarly, low concentration of cytochalasin D inhibits the *spreading* of cells, Wakatsuki et al. [2003].

The active branch displays a force that increases approximately linearly with the strain while the passive branch displays an exponential increase, Wakatsuki et al. [2000]. The relative contributions of the two parallel branches depend on the number of cells per unit volume and volume fraction of ECM. In a growing tissue, hyperplasia and ECM growth are unlikely to keep constant proportional contributions.

2. The cell branch:

The differential equation of the lower branch writes,

$$\frac{dQ_{\rm C}}{dt} + \frac{Q_{\rm C}}{t_{\rm C}} = \frac{F_0}{t_{\rm C}} + (E_{\rm PC} + E_{\rm SC})\frac{dq_{\rm C}}{dt} + E_{\rm PC}\frac{q_{\rm C}}{t_{\rm C}}, \tag{8.6.4}$$

again with $t_{\rm C} = \eta_{\rm C}/E_{\rm SC}$ the relaxation time. The single difference with respect to the matrix branch comes from *the contractile isometric force* F_0 which depends on time through various physiological sources.

Now compare the integral representation,

$$Q_{\rm C}(t) = \int_{-\infty}^{t} e^{-(t-u)/t_{\rm C}}\,\frac{F_0(u)}{t_{\rm C}}\,du + \int_{-\infty}^{t} \left[(E_{\rm PC} + E_{\rm SC}) - E_{\rm SC}\,(1 - e^{-(t-u)/t_{\rm C}})\right]\frac{dq_{\rm C}(u)}{du}\,du\,, \tag{8.6.5}$$

with a general integral representation of the relaxation modulus $E_{\rm C}$. Then, similarly to (8.6.3),

$$E_{\rm PC} = E_{\rm C}(\infty),\ E_{\rm SC} = E_{\rm C}(0) - E_{\rm C}(\infty),\ \eta_{\rm C} = t_{\rm C}\,(E_{\rm C}(0) - E_{\rm C}(\infty))\,. \tag{8.6.6}$$

8.7 An electrical analogy applied to the corneal endothelium

Consider the viscoelastic model displayed in Fig. 8.7.1(a). Let Q and q be respectively the stress and strain at the bounds of the model. The governing differential equation,

$$\begin{aligned}&(\frac{t_a}{E_b} + \frac{t_b}{E_a})\,\frac{dQ}{dt} + (\frac{1}{E_b} + \frac{1}{E_a})\,Q = \\ &= t_a\,t_b\,\frac{d^2q}{dt^2} + \big(t_a + t_b + (\frac{t_a}{E_b} + \frac{t_b}{E_a})\,E_S\big)\frac{dq}{dt} + \big(1 + (\frac{1}{E_a} + \frac{1}{E_b})\,E_S\big)\,q\,,\end{aligned} \tag{8.7.1}$$

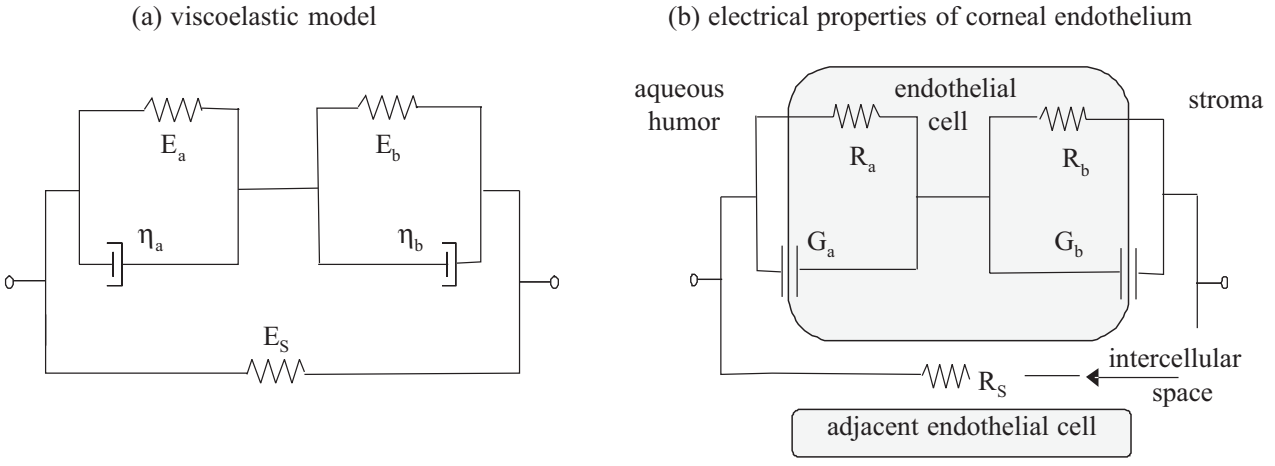

Fig. 8.7.1: (a) A viscoelastic model; (b) the analog used by Lim and Fischbarg [1981] to characterize the electrical properties of the corneal endothelium.

is established in Exercise 8.3. Here $t_k = \eta_k/E_k$, $k = a, b$, is a characteristic time.

The complex modulus results by assuming the strain q of the form (8.3.2),

$$E^*(i\,\omega) = E_S + E_a\,E_b\,\frac{(1+i\,\omega\,t_a)\,(1+i\,\omega\,t_b)}{E_a\,(1+i\,\omega\,t_a) + E_b\,(1+i\,\omega\,t_b)}\,. \tag{8.7.2}$$

The viscoelastic model can be associated with an electrical analog through the following correspondences[8.4],

$$\begin{aligned} \text{strain } q \quad &\rightleftharpoons \quad \text{electrical potential } \phi \\ \text{stress } Q \quad &\rightleftharpoons \quad \text{electrical current } I \\ \text{viscosity } \eta \quad &\rightleftharpoons \quad \text{areal capacitance } G \\ \text{elastic modulus } E \quad &\rightleftharpoons \quad \text{electrical conductance } \sigma \end{aligned} \tag{8.7.3}$$

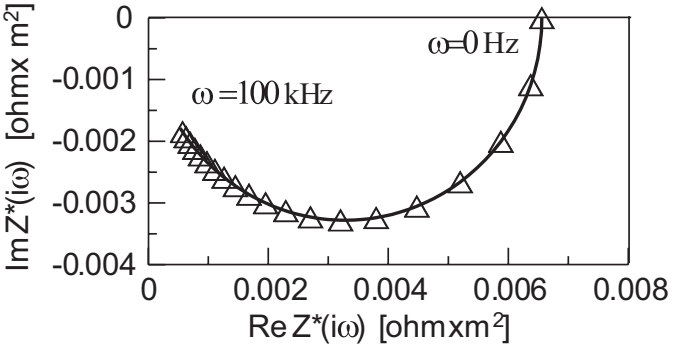

Fig. 8.7.2: Locus in the complex plane of the impedance of the electrical circuit shown in Fig. 8.7.1-(b), with the following physical constants, Lim and Fischbarg [1981]: resistances $R_a = 0.158\,\text{Ohm}\times\text{m}^2$, $R_b = 0.153\,\text{Ohm}\times\text{m}^2$, $R_S = 0.0067\,\text{Ohm}\times\text{m}^2$, capacitances $G_a = G_b = 0.0103\,\text{F}/\text{m}^2$, and associated relaxation times $t_a \sim t_b = 1.6\,\text{ms}$.

As an alternative to the last correspondence, one may use

$$\text{elastic compliance } 1/E \quad \rightleftharpoons \quad \text{electrical resistance } R = 1/\sigma \tag{8.7.4}$$

[8.4] Note that another analog is also used based on the correspondences: strain rate $\dot{q} \rightleftharpoons$ electric current I, stress $Q \rightleftharpoons$ electric potential ϕ, viscosity $\eta \rightleftharpoons$ electric resistance R, compliance $1/E \rightleftharpoons$ capacitance G.

In this context, the impedance $Z^* = Z^*(i\,\omega) \equiv \hat{\phi}(t)/\hat{I}(t)$ is defined as the ratio of the electrical potential and current assumed in harmonic form, namely $\hat{I}(t) = I_0\,\exp(i\,\omega t)$,

$$\frac{1}{Z^*(i\,\omega)} = \frac{1}{R_S} + \frac{1}{Z_1(i\,\omega)}\,, \quad Z_1(i\,\omega) \equiv \frac{R_a}{1 + i\,\omega\,t_a} + \frac{R_b}{1 + i\,\omega\,t_b}\,. \tag{8.7.5}$$

The characteristic times express now as $t_k = G_k\,R_k = G_k/\sigma_k$, $k = a, b$. The electrical resistances R_a and R_b and capacitances G_a and G_b are shown on the electrical analog of Fig. 8.7.1. The locus of this impedance in the complex plane with material data associated with the corneal endothelium is displayed in Fig. 8.7.2.

8.8 Fluid infusion in a viscoelastic polymer gel

A localized fluid infusion in a viscoelastic polymer gel is considered in Netti et al. [2003]. The model aims at describing the drug delivery process in a dynamically changing mechanical environment as the drug transport affects, and is affected by, the mechanical state. In fact, while polymer gels are engineered to deliver drugs according to a specific time course, the mechanical state *in vivo* has to be accounted for. An application could be intratumoral drug injection, which, unlike systemic drug delivery, has not to overcome the high interstitial fluid pressure barrier. Practical issues for such a goal are that a fast infusion may lead to tissue fracture (by tensile hoop stress) around the injection point, which may compromise the homogeneous delivery of the drug in the tumor. On the other hand, cyclic mechanical compression of a polymer gel with bound macromolecules (VEGF, etc.) results in larger release than static compression, K.Y. Lee et al. [2000].

A viscoelastic analysis addresses the relaxation properties of the polymer chains. The memory function is chosen according to Fung's formalism in which the imaginary part of the relaxation modulus shows a weak dependence in frequency, Fung [1993], p. 284. The two characteristic times are the polymer relaxation time t_v and the percolation time $t_{\rm H}$ defined by (8.8.40). While Péclet number Eqn (15.5.3) characterizes the relative effects of convection and diffusion, the Deborah number is defined as the ratio of a characteristic relaxation time over the seepage (fluid diffusion) time,

$$D_{\rm eb} = \frac{t_v}{t_{\rm H}}\,. \tag{8.8.1}$$

The modulus involved in the percolation time is affected by the viscoelastic properties of the tissue. With the spectrum of relaxation centered at τ and of half-width $\Delta\tau$ and the memory function m defined in Section 8.4.3, the Laplace-Carson transform of the viscoelastic modulus (with variable p),

$$\lambda + 2\,\mu + (\lambda_{ve} + 2\,\mu_{ve})\,p\,\overline{m}(p) = \lambda + 2\,\mu + (\lambda_{ve} + 2\,\mu_{ve})\,\frac{\tau}{\Delta\tau}\,\mathrm{Ln}\,\frac{p(\tau + \Delta\tau) + 1}{p(\tau - \Delta\tau) + 1}\,, \tag{8.8.2}$$

simplifies to $\lambda + 2\,\mu$ for poroelasticity ($\tau = 0$), and to $\lambda + 2\,\mu + 2\,(\lambda_{ve} + 2\,\mu_{ve})$ for very large τ.

The characteristic time t_v is expected to be a multiple of the relaxation time τ. From the numerical results obtained in the following boundary value problem, rate effects are observed to influence the constitutive response up to $t_v \simeq 50\,\tau$.

However, for some loadings that the poroelastic gel may have difficulties to accommodate, these effects remain significant as shown in Section 8.9 until $t = t_{\rm H}$, partly due to large values of the viscoelastic moduli λ_{ve} and μ_{ve} relative to the elastic Lamé moduli.

The viscoelastic constitutive equations, field equations, and boundary conditions defining the infusion problem are described in the next sections. The solutions are calculated analytically in the Laplace domain, and next transformed back to the time domain either analytically or using numerical inversion, e.g., Durbin [1974], Hoog et al. [1982], Honig and Hirdes [1984], Hollenbeck [1998]. The influence of the tissue stiffness on fluid flow and pressure profiles is seen only in the dynamic analysis, the steady state being identical to a rigid tissue. Of course, the stresses differ in the transient period and at steady state.

8.8.1 Poro-viscoelastic field and constitutive equations

Netti et al. [2000] [2003] considered the infusion of a polymer gel by a point source. The gel is viewed as a viscoelastic porous medium. The *effective stress* $\boldsymbol{\sigma} + p_i\,\mathbf{I}$, where p_i is the interstitial, or tissue, pressure, obeys the quasi-linear

viscoelastic Fung's format. The following field and constitutive equations govern the process,

$$\begin{aligned}
&\text{Balance of mass} && \operatorname{div}\,(n^{\mathrm{s}}\,\mathbf{v}_{\mathrm{s}} + n^{\mathrm{w}}\,\mathbf{v}_{\mathrm{w}}) = 0,\\
&\text{Balance of momentum} && \operatorname{div}\,\boldsymbol{\sigma} = \mathbf{0}\,,\\
&\text{Darcy's law} && n^{\mathrm{w}}\,(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) = -k_{\mathrm{H}}\,\boldsymbol{\nabla} p_i,\\
&\text{Viscoelastic equation} && \boldsymbol{\sigma} + p_i\,\mathbf{I} = \lambda\, e\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon} + \int_{-\infty}^{t} m(t-u)\,\frac{\partial}{\partial u}(\lambda_{ve}\, e\,\mathbf{I} + 2\,\mu_{ve}\,\boldsymbol{\epsilon})(u)\,du\,,
\end{aligned} \tag{8.8.3}$$

where $e \equiv \operatorname{tr}\boldsymbol{\epsilon}$ is the dilatation. The $\mathbf{v}_\alpha$'s are the velocities of the solid ($\alpha = \mathrm{s}$) and fluid ($\alpha = \mathrm{w}$) phases of the mixture. The volume fractions n^{s} and n^{w} sum up to 1, $n^{\mathrm{s}} + n^{\mathrm{w}} = 1$, The species are all incompressible.

The poro-viscoelastic model is isotropic in both its transport and mechanical properties. The poroelastic response is defined by the tissue hydraulic permeability k_{H} [unit : $\mathrm{m}^2/\mathrm{s}/\mathrm{Pa}$] and the Lamé moduli of the drained tissue λ and μ [unit : Pa]. The viscoelastic response is defined by the constants λ_{ve} and μ_{ve} and by the memory function $m(t)$, e.g., that given by Eqn (8.4.16), that does not need to be specified for the analytical derivations.

The solution of the problem in terms of displacement and pressure can be obtained by complementing the field and constitutive equations (8.8.3) by initial and boundary conditions as described below.

8.8.2 The initial and boundary value problem

A polymer gel is injected by a point source at constant pressure or constant flow, Fig. 8.8.1(a). The problem displays spherical symmetry with radial motions and flows about a fixed center. In practice, the source has "radius" a and the gel has radius $R \gg a$.

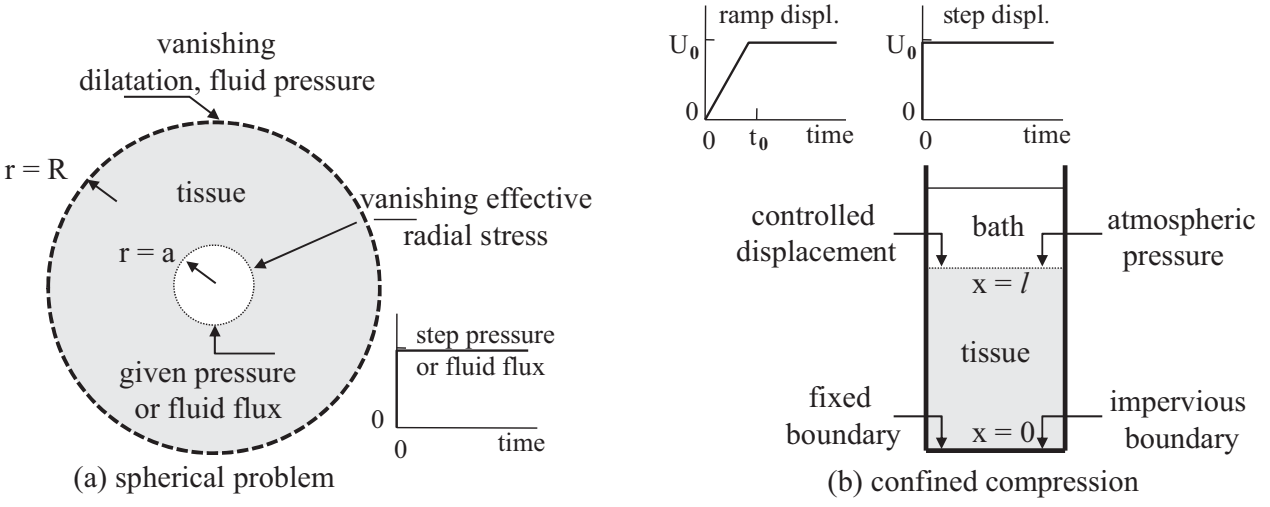

Fig. 8.8.1: Two boundary value problems on a poro-viscoelastic gel: (a) fluid infusion in a spherical cavity; (b) confined compression with controlled displacement.

As the ratio a/R is small, the pressure p_i and dilation e at the outer boundary remain equal to 0,

$$p_i(r = R, t) = 0; \quad e(r = R, t) = 0, \quad t \geq 0\,. \tag{8.8.4}$$

The displacements and strains are reckoned from time $t = 0$, namely, for $t \leq 0$,

$$\mathbf{u}_\alpha(r, t) = \mathbf{0}, \quad \alpha = \mathrm{s}, \mathrm{w}; \quad e(r, t) = 0, \quad \forall r \in [a, R]\,. \tag{8.8.5}$$

As for the infusion source, either a constant pressure

$$p_i(r = a, t) = PI\,\mathcal{H}(t)\,, \tag{8.8.6}$$

where $\mathcal{H}(t)$ is Heaviside step function, or a constant flow rate Q are imposed. In the latter case, the radial fluid velocity at $r = a$ is constant in time,

$$v_{\mathrm{w}r}(r = a, t) = \frac{Q}{4\,\pi\,a^2}\,\mathcal{H}(t)\,. \tag{8.8.7}$$

The infusion surface is not loaded mechanically, so that the effective radial stress vanishes,

$$\sigma_r(r = a, t) + p_i(r = a, t) = 0\,. \tag{8.8.8}$$

8.8.3 The differential equation for the dilatation, or pressure

For irrotational motions, the field equations (11.2.42) simplify. Combining Eqns $(8.8.3)_{2,4}$ yields

$$\boldsymbol{\nabla} p_i = (\lambda + 2\,\mu)\,\boldsymbol{\nabla} e + (\lambda_{ve} + 2\,\mu_{ve}) \int_{-\infty}^{t} m(t-u)\,d\,\boldsymbol{\nabla} e(u)\,. \tag{8.8.9}$$

Insertion of Eqn $(8.8.3)_1$ into Eqn $(8.8.3)_3$ provides Darcy's law in terms of the dilation rate, namely

$$\operatorname{div} \mathbf{v}_{\mathrm{s}} = \frac{de}{dt} = k_{\mathrm{H}} \operatorname{div} \boldsymbol{\nabla} p_i\,. \tag{8.8.10}$$

Elimination of the pressure in (8.8.9) yields a partial differential equation for the dilation e,

$$\frac{de}{dt}(r,t) = k_{\mathrm{H}}\,(\lambda + 2\,\mu) \operatorname{div}\, \boldsymbol{\nabla} e(r,t) + k_{\mathrm{H}}\,(\lambda_{ve} + 2\,\mu_{ve}) \int_{-\infty}^{t} m(t-u)\,\frac{\partial}{\partial u}(\operatorname{div}\, \boldsymbol{\nabla} e(r,u))\,du\,. \tag{8.8.11}$$

The Laplace transform $e(r,t) \to \overline{e}(r,p)$ of this equation,

$$p\,\overline{e}(r,p) - e(r,0) = k_{\mathrm{H}}\,(\lambda + 2\,\mu) \operatorname{div}\, \boldsymbol{\nabla}\overline{e}(r,p) + k_{\mathrm{H}}\,(\lambda_{ve} + 2\,\mu_{ve})\,\overline{m}(p) \operatorname{div}\, \boldsymbol{\nabla}\big(p\,\overline{e}(r,p) - \overline{e}(r,0)\big)\,, \tag{8.8.12}$$

simplifies with help of (8.8.5) to,

$$\beta^2\,\overline{e}(r,p) = R^2 \operatorname{div} \boldsymbol{\nabla}\overline{e}(r,p)\,, \tag{8.8.13}$$

with,

$$\beta^2 = \frac{p}{\gamma^2}, \quad \gamma^2 = \frac{k_{\mathrm{H}}}{R^2}\,\overline{H}(p)\ [\text{unit : s}^{-1}], \quad \overline{H}(p) = \lambda + 2\,\mu + (\lambda_{ve} + 2\,\mu_{ve})\,p\,\overline{m}(p)\,. \tag{8.8.14}$$

The relation (8.8.20) below shows that the pressure satisfies the differential equation (8.8.13) as well.

Table 8.8.1: Parameters used in the simulations, extracted from Netti et al. [2003].

Entity	Value or Range	Unit
Seepage properties		
Fluid volume fraction in gel n^{w}	0.2	-
Hydraulic permeability k_{H}	$7.6 \times 10^{-13} - 7.6 \times 10^{-15}$	$\mathrm{m}^2/\mathrm{Pa/s}$
Viscoelastic properties		
Drained elastic moduli $\lambda = 2\,\mu$	13×10^3	Pa
Drained viscoelastic moduli $\lambda_{ve} = 2\,\mu_{ve}$	$0 - 52 \times 10^3$	Pa
Relaxation time τ	300	s
Half-width $\Delta\tau$	$\tau/10$	s
Geometry		
Inner diameter a	0.35×10^{-3}	m
Outer diameter R	1×10^{-2}	m
Loading		
Infusion pressure PI	$0.65 - 2.6 \times 10^3$	Pa
Infusion flux Q	$0.1 - 10 \times 10^{-9}/60$	m^3/s

8.8.4 Radial displacement in a spherical setting

A scaled spatial coordinate is introduced as $\hat{r} = r/R$. The relations simplify by introduction of the entity $E(\hat{r}, t) = \hat{r}\, e(\hat{r}, t)$. Eqn (8.8.13), which takes the form,

$$\beta^2\, \overline{E} - \frac{d^2}{d\hat{r}^2} \overline{E} = 0\,, \tag{8.8.15}$$

has solution

$$\overline{E}(\hat{r}, p) \equiv \hat{r}\, \overline{e}(\hat{r}, p) = A(p)\, \sinh \beta\hat{r} + B(p)\, \cosh \beta\hat{r}\,, \tag{8.8.16}$$

where $A(p)$ and $B(p)$ are fixed by the boundary conditions, e.g., $(8.8.4)_2$ for the outer boundary,

$$\overline{E}(1, p) = \overline{e}(1, p) = A(p)\, \sinh \beta + B(p)\, \cosh \beta = 0\,, \tag{8.8.17}$$

and therefore,

$$\overline{E}(\hat{r}, p) = \hat{r}\, \overline{e}(\hat{r}, p) = \frac{A(p)}{\cosh \beta}\, \sinh\big(\beta\,(\hat{r} - 1)\big)\,. \tag{8.8.18}$$

With the outer boundary conditions (8.8.4), the differential equation (8.8.9) can be integrated in space,

$$p_i = (\lambda + 2\,\mu)\, e + (\lambda_{ve} + 2\,\mu_{ve}) \int_{-\infty}^{t} m(t - u)\, \frac{\partial}{\partial u} e(u)\, du\,, \tag{8.8.19}$$

and transformed to Laplace domain,

$$\overline{p}_i(\hat{r}, p) = \overline{H}(p)\, \overline{e}(\hat{r}, p)\,. \tag{8.8.20}$$

Over the infusion surface $r = a$, the effective radial stress $\sigma_r + p_i$ is vanishing, thus providing a link between the dilatation e and the radial and circumferential strains, $\epsilon_r = du_{\rm sr}/dr$ and $\epsilon_\theta = \epsilon_\phi = u_{\rm sr}/r$, respectively,

$$\frac{d\overline{u}_{sr}}{dr}(\hat{a}, p) = -\frac{\overline{\lambda}(p)}{2\,\overline{\mu}(p)}\, \overline{e}(\hat{a}, p), \quad \frac{\overline{u}_{sr}}{a}(\hat{a}, p) = \frac{1}{2}\, \frac{\overline{H}(p)}{2\,\overline{\mu}(p)}\, \overline{e}(\hat{a}, p)\,, \tag{8.8.21}$$

with $\overline{\lambda}(p)$ and $2\,\overline{\mu}(p)$ the viscoelastic moduli in the Laplace domain,

$$\overline{\lambda}(p) = \lambda + \lambda_{ve}\, p\, \overline{m}(p), \quad 2\,\overline{\mu}(p) = 2\,\mu + 2\,\mu_{ve}\, p\, \overline{m}(p)\,. \tag{8.8.22}$$

Two types of conditions may be considered on the inner boundary.

8.8.4.1 Given infusion pressure

With help of (8.8.20), the boundary condition (8.8.6) takes the following form in the Laplace domain,

$$\frac{PI}{p} = \overline{H}(p)\, \overline{e}(\hat{a}, p)\,. \tag{8.8.23}$$

Thus using (8.8.17), Eqn (8.8.16) becomes,

$$\overline{E}(\hat{a}, p) = \hat{a}\, \overline{e}(\hat{a}, p) = \frac{PI}{\overline{H}(p)}\, \frac{\hat{a}}{p} = \frac{A(p)}{\cosh \beta}\, \sinh\big(\beta\,(\hat{a} - 1)\big)\,, \tag{8.8.24}$$

which allows to fix $A(p)$, and finally,

$$\overline{e}(\hat{r}, p) = \frac{X(p)}{\hat{r}}\, \sinh\big(\beta\,(1 - \hat{r})\big)\,, \tag{8.8.25}$$

with

$$X(p) = \frac{PI}{\overline{H}(p)}\, \frac{\hat{a}}{p}\, \frac{1}{\sinh\big(\beta(1 - \hat{a})\big)}\,. \tag{8.8.26}$$

Given $\overline{e}(\hat{r}, p)$, the Laplace transforms at arbitrary $(\hat{r}, p)$ of the following entities can be obtained in turn.

First, the fluid pressure is defined by (8.8.20). Next, the Laplace transform of the radial solid displacement u_{sr} and of its radial derivative are known at $r = a$ by (8.8.21). The radial solid displacement $\overline{u}_{sr}$ then follows by integration of $\overline{e} = r^{-2} d(r^2 \overline{u}_{sr})/dr$, with the condition $(8.8.21)_2$ at $\hat{r} = \hat{a}$,

$$\frac{\overline{u}_{sr}}{R}(\hat{r}, p) = \frac{\hat{a}^2}{\hat{r}^2} \frac{\overline{u}_{sr}}{R}(\hat{a}, p) - \frac{1}{\hat{r}} \frac{X(p)}{\beta} \left(\eta(\hat{r}, p) - \frac{\hat{a}}{\hat{r}} \eta(\hat{a}, p) \right). \tag{8.8.27}$$

The fluid velocity results from Darcy's law and $(8.8.5)_1$,

$$\frac{\overline{v}_{wr}}{R}(\hat{r}, p) = \frac{\hat{a}^2}{\hat{r}^2} p \frac{\overline{u}_{sr}}{R}(\hat{a}, p) + \frac{p}{\hat{r}} \frac{X(p)}{\beta} \left(\frac{n^s}{n^w} \eta(\hat{r}, p) + \frac{\hat{a}}{\hat{r}} \eta(\hat{a}, p) \right). \tag{8.8.28}$$

In the above relations, the function $\eta(\hat{\rho}, p)$ is defined as

$$\eta(\hat{\rho}, p) \equiv -\frac{\hat{\rho}}{\beta} \frac{d}{d\hat{\rho}} \left(\frac{1}{\hat{\rho}} \left(\sinh\left(\beta\,(1 - \hat{\rho})\right) \right) \right) = \cosh\left(\beta\,(1 - \hat{\rho})\right) + \frac{1}{\beta\,\hat{\rho}} \sinh\left(\beta\,(1 - \hat{\rho})\right). \tag{8.8.29}$$

Note that[8.5]

$$\eta(\hat{\rho}, p \sim 0) = \frac{1}{\hat{\rho}} + \frac{\beta^2}{6\,\hat{\rho}} (1 - \hat{\rho})^2 (2\,\hat{\rho} + 1), \tag{8.8.30}$$

and it can be verified that $\beta^2 = 0$ does not imply a branch point.

Laplace transforms of the strain and stress components follow readily, e.g.,

- the radial strain $\overline{\epsilon}_r(\hat{r}, p) = d\overline{u}_{sr}(\hat{r}, p)/(R\,d\hat{r})$,
- the circumferential strain $\overline{\epsilon}_\theta(\hat{r}, p) = \overline{u}_{sr}(\hat{r}, p)/(R\,\hat{r})$,
- the total radial stress $\overline{\sigma}_r(\hat{r}, p) = -2\,\overline{\mu}(p)\ \times 2\,\overline{\epsilon}_\theta(\hat{r}, p)$, and
- the total circumferential stress $\overline{\sigma}_\theta(\hat{r}, p) = -2\,\overline{\mu}(p)\,(\overline{\epsilon}_r(\hat{r}, p) + \overline{\epsilon}_\theta(\hat{r}, p))$.

8.8.4.2 Given infusion flux

Inserting the boundary condition (8.8.7) and $(8.8.21)_2$ in Darcy's law, accounting for (8.8.20) and $u_{sr}(\hat{r}, 0) = 0$, yields an equation for $\overline{e}(\hat{a}, p)$,

$$\frac{d\overline{e}}{d\hat{r}}(\hat{a}, p) - n^w\,\hat{a}\,\frac{p}{2\,\gamma_2^2}\,\overline{e}(\hat{a}, p) + n^w\,\frac{Q}{4\,\pi\,a^2}\,\frac{R}{p}\,\frac{1}{k_H\,\overline{H}(p)} = 0, \tag{8.8.31}$$

that in fact provides $X(p)$. The Laplace transform of the dilatation still assumes the form (8.8.25), with now

$$X(p) = n^w\,\frac{Q}{4\,\pi\,a}\,\frac{1}{\beta\,p}\,\frac{1}{k_H\,\overline{H}(p)}\,\frac{1}{\cosh\left(\beta(1 - \hat{a})\right) + \dfrac{x}{\beta\,\hat{a}} \sinh\left(\beta(1 - \hat{a})\right)}, \tag{8.8.32}$$

with $x = 1 + \hat{a}^2\,n^w\,p/(2\,\gamma_2^2)$ and $\gamma_2^2 = 2\,\overline{\mu}(p)\,k_H/R^2$. The Laplace transforms of the entities of interest derive as for the case of given infusion pressure.

8.8.5 The solution in time domain

If the relaxation time τ is very small or very large and if the memory function satisfies the associated relation in (8.4.18), then the characteristic time that governs the transient process can be extracted from (8.8.15) as if the mixture was elastic, namely $l^2/\overline{H}(0)\,k_H$, with $\overline{H}(0)$ equal to $\lambda + 2\,\mu$ and $l = R - a$ the drainage length. For finite non vanishing relaxation time τ, the details of the relaxation function affects the transient process.

For given infusion flux, the complete solution in time is best obtained through numerical inversion of the Laplace transforms. For given infusion pressure, the analytical inversion is manageable.

[8.5] $\cosh x = 1 + x^2/2! + x^4/4! + \cdots$, $\sinh x = x + x^3/3! + \cdots$

8.8.5.1 Steady state

The steady state at large time is directly obtained by the final value theorem, e.g., for the dilatation e,

$$\lim_{t\to\infty} e(\hat{r},t) = \lim_{p\to 0} p\,\overline{e}(\hat{r},p)\,, \tag{8.8.33}$$

provided all poles of $p\,\overline{e}(\hat{r},p)$ are in the left half-plane. The results below are independent of the relaxation function provided the latter satisfies the limit condition $\lim_{p\to 0} p\,\overline{m}(p) = 0$. The relaxation function of Section 8.4.3 satisfies this condition, namely $p\,\overline{m}(p) \sim 2\,\tau\,p$ for small p.

The results hold for both the pressure controlled infusion and the flux controlled infusion and indicate that the spatial profiles are identical in the two cases,

$$e(\hat{r},\infty) = \frac{p_i(\hat{r},\infty)}{\lambda+2\,\mu} = \frac{Y}{\lambda+2\,\mu}\,\frac{1-\hat{r}}{\hat{r}} \geq 0\,; \tag{8.8.34}$$

$$\frac{u_{sr}}{R}(\hat{r},\infty) = \frac{Y}{4\,\mu}\,(1-\hat{a})\,\frac{\hat{a}^2}{\hat{r}^2} - \frac{Y}{\lambda+2\,\mu}\,\frac{1}{6\,\hat{r}^2}\Big[2\,(\hat{r}^3-\hat{a}^3) - 3\,(\hat{r}^2-\hat{a}^2)\Big]\,; \tag{8.8.35}$$

$$v_{\rm wr}(\hat{r},\infty) = \frac{k_{\rm H}}{n^{\rm w}\,R}\,\frac{Y}{\hat{r}^2} \geq 0\,, \tag{8.8.36}$$

with

$$Y = \begin{cases} \dfrac{\hat{a}}{1-\hat{a}}\,PI & \text{pressure controlled infusion,} \\[2ex] \dfrac{n^{\rm w}}{k_{\rm H}}\,\dfrac{Q}{4\,\pi\,R} & \text{flux controlled infusion}\,. \end{cases} \tag{8.8.37}$$

Note that the (visco)elastic behavior affects the steady state of the dilatation and solid displacement, but not the pressure nor fluid flow.

From the ensuing steady state values of the strains,

$$\begin{aligned} \epsilon_r(\hat{r},\infty) &= -\frac{\hat{a}^2}{\hat{r}^3}\,(1-\hat{a})\,\frac{Y}{2\,\mu} + \frac{Y}{\lambda+2\,\mu}\,\frac{1}{3\,\hat{r}^3}\Big[2\,(\hat{r}^3-\hat{a}^3) - 3\,(\hat{r}^2-\hat{a}^2)\Big] + \frac{Y}{\lambda+2\,\mu}\,\frac{1-\hat{r}}{\hat{r}}\,; \\ \epsilon_\theta(\hat{r},\infty) &= \epsilon_\phi(\hat{r},\infty) = \frac{\hat{a}^2}{\hat{r}^3}\,(1-\hat{a})\,\frac{Y}{4\,\mu} - \frac{Y}{\lambda+2\,\mu}\,\frac{1}{6\,\hat{r}^3}\Big[2\,(\hat{r}^3-\hat{a}^3) - 3\,(\hat{r}^2-\hat{a}^2)\Big]\,, \end{aligned} \tag{8.8.38}$$

follow in turn the effective and total stresses, e.g., for the latter,

$$\sigma_r(\hat{r},\infty) = -4\,\mu\,\epsilon_\theta(\hat{r},\infty); \quad \sigma_\theta(\hat{r},\infty) = -2\,\mu\,\big(\epsilon_r(\hat{r},\infty) + \epsilon_\theta(\hat{r},\infty)\big)\,. \tag{8.8.39}$$

8.8.5.2 The transient solution for given infusion pressure

The solution is obtained by inversion of the Laplace transform in the complex plane, where the following entities are involved:

- Darcy's seepage time $t_{\rm H}$ associated with the purely elastic porous mixture of modulus $\overline{H}(0) = \lambda + 2\,\mu$,

$$t_{\rm H} = \frac{l^2}{\overline{H}(0)\,k_{\rm H}}\,, \tag{8.8.40}$$

  with the drainage length l equal to $R - a = (1-\hat{a})\,R$;
- the poles p_j, $j \geq 1$, that contribute to the inverse transform which are the real negative solutions of the equation [8.6],

$$p_j = -\frac{X_j^2}{t_{\rm H}}, \quad X_j = j\,\pi\,\Big(\frac{\overline{H}(p_j)}{\overline{H}(0)}\Big)^{\frac{1}{2}}\,; \tag{8.8.41}$$

[8.6] For the record: 1. for β real, $\sinh(i\,\beta) = i\,\sin\beta$ and $\cosh(i\,\beta) = \cos\beta$; 2. $\sinh\beta = 0$, for $\beta = i\,j\,\pi$ and then $\cosh\beta = \cos(j\,\pi) = (-1)^j$; 3. $\cosh\beta = 0$, for $\beta = i\,\pi/2 + i\,j\,\pi$ and then $\sinh\beta = i\,\cos(j\,\pi) = i\,(-1)^j$.

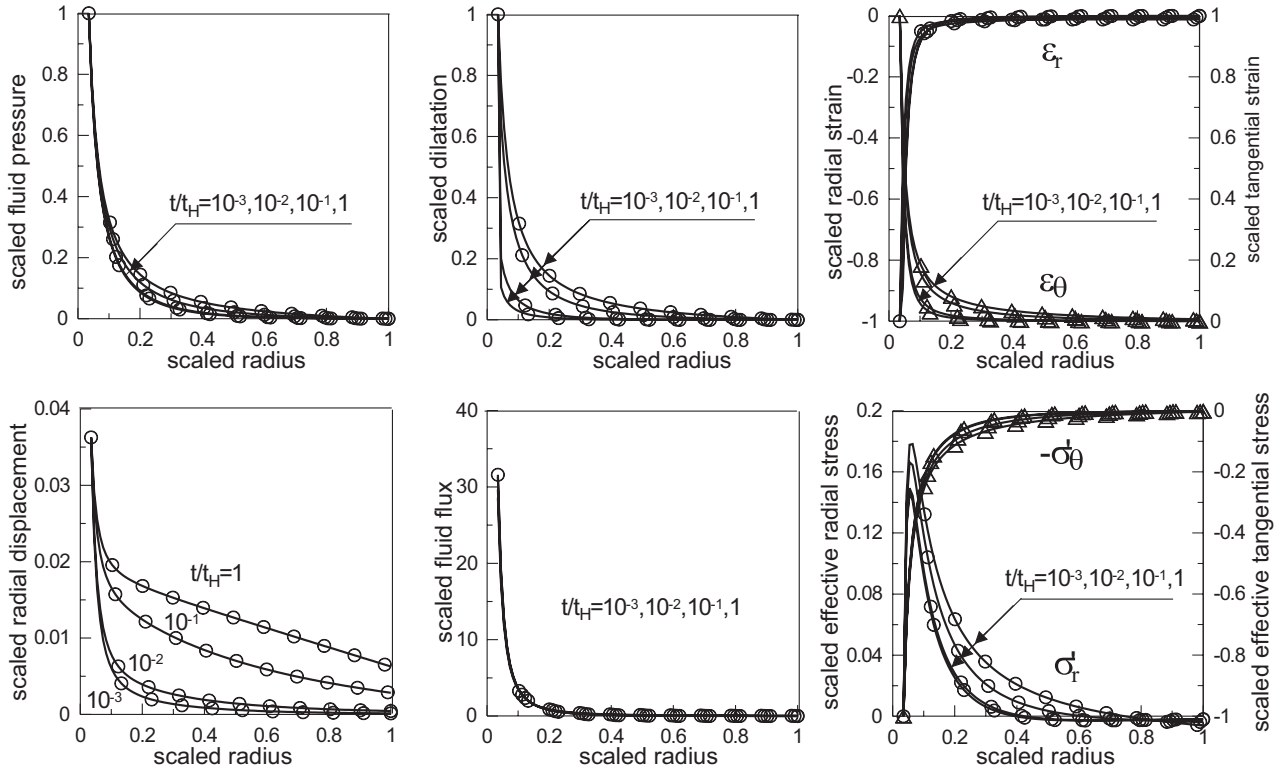

Fig. 8.8.2: Poro-viscoelastic hollow sphere subjected to a pressure jump on its inner radius as sketched in Fig. 8.8.1. Scaled spatial profiles at four instants. The scaling rules for displacement, velocity, deformation, pressure and stress are indicated in (8.8.43).

- terms peculiar to the viscous behavior, associated with the derivative $d\beta/dp = \Delta\beta/(2\,p)$, estimated at the poles p_j, namely when the relaxation function of Section 8.4.3 is used,

$$\Delta(p) = 1 - \frac{p}{\overline{H}(p)}\,\frac{d\overline{H}}{dp}(p), \quad \frac{d\overline{H}}{dp}(p) = \frac{2\,\tau\,(\lambda_{ve} + 2\,\mu_{ve})}{(p\,(\tau + \Delta\tau) + 1)\,(p\,(\tau - \Delta\tau) + 1)}\,. \tag{8.8.42}$$

The fluid pressure p_i, dilatation e, solid displacement u_{sr}, solid velocity v_{sr} and fluid velocity v_{wr} are contributed by a stationary value and by a sum of transient terms,

$$\frac{\overline{H}(0)}{PI}\begin{bmatrix} \dfrac{p_i(\hat r,t)}{\overline{H}(0)} \\ e(\hat r,t) \\ \dfrac{u_{sr}(\hat r,t)}{l} \\ \dfrac{v_{sr}(\hat r,t)}{l/t_H} \\ \dfrac{v_{wr}(\hat r,t)}{l/t_H} \end{bmatrix} = \begin{bmatrix} \dfrac{\hat a}{\hat r}\,\dfrac{1-\hat r}{1-\hat a} \\ \dfrac{\hat a}{\hat r}\,\dfrac{1-\hat r}{1-\hat a} \\ \dfrac{u_{sr}(\hat r,\infty)}{l\,PI/\overline{H}(0)} \\ 0 \\ \dfrac{1}{n^w}\,\dfrac{\hat a}{\hat r^2} \end{bmatrix} + 2\,\frac{\hat a}{\hat r}\sum_{j=1}^{\infty}\frac{(-1)^j}{\Delta(p_j)}\begin{bmatrix} \sin\left(j\,\pi\,\dfrac{1-\hat r}{1-\hat a}\right)\dfrac{1}{j\,\pi} \\ \sin\left(j\,\pi\,\dfrac{1-\hat r}{1-\hat a}\right)\dfrac{1}{j\,\pi}\,\dfrac{\overline{H}(0)}{\overline{H}(p_j)} \\ \left(\xi_j(\hat r) - \dfrac{\hat a}{\hat r}(-1)^j\right)\dfrac{1}{(j\,\pi)^2}\,\dfrac{\overline{H}(0)}{\overline{H}(p_j)} \\ -\xi_j(\hat r) + \dfrac{\hat a}{\hat r}(-1)^j \\ \dfrac{n^s}{n^w}\,\xi_j(\hat r) + \dfrac{\hat a}{\hat r}(-1)^j \end{bmatrix} e^{-X_j^2\,t/t_H}\,, \tag{8.8.43}$$

with

$$\xi_j(\hat r) = \cos\left(j\,\pi\,\frac{1-\hat r}{1-\hat a}\right) + \frac{1-\hat a}{j\,\pi\,\hat r}\,\sin\left(j\,\pi\,\frac{1-\hat r}{1-\hat a}\right). \tag{8.8.44}$$

Fig. 8.8.2 displays spatial profiles of the solution while Fig. 8.8.3 compares the time courses of the poroelastic and poro-viscoelastic gels.

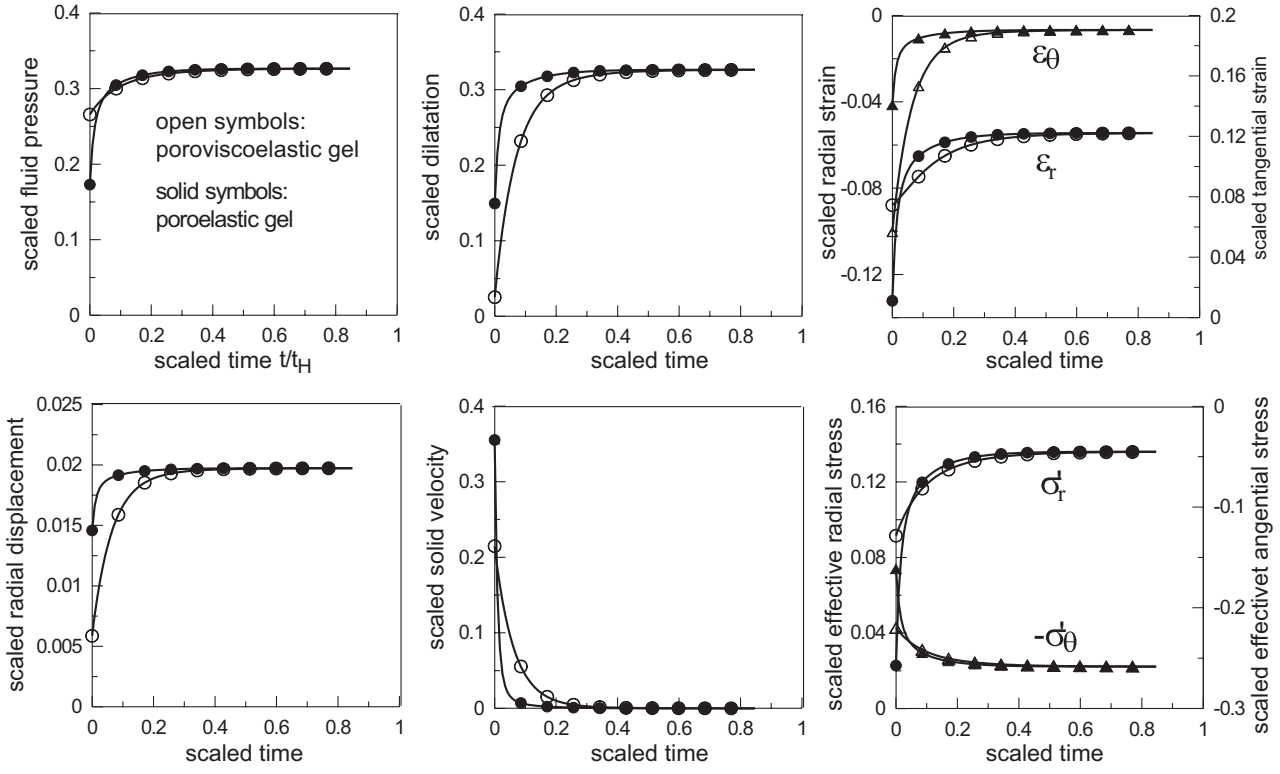

Fig. 8.8.3: Hollow sphere subjected to a pressure jump on its inner radius as sketched in Fig. 8.8.1. Scaled time profiles at radius $r = 2\,a$ for the poro-viscoelastic gel (open symbols) with parameters as indicated in Table 8.8.1 and for the poroelastic gel with $\lambda_{ve} = \mu_{ve} = 0$. Seepage time $t_{\rm H} = 50 \times 10^3$ s, relaxation time of the poro-viscoelastic gel $\tau = 300$ s so that $\tau/t_{\rm H} = 0.006$. The viscous effect shows up at early times but it affects the constitutive response up to time $t/t_{\rm H} = 0.3$, i.e. $50\,\tau$.

For the poroelastic gel, the fluid pressure p_i is equal to $\lambda + 2\,\mu$ times the dilatation e at any point of space and at any time.

The results are insensitive to the width of the relaxation interval defined by the time $\Delta\tau \in [0, \tau]$.

For $k_{\rm H} = 7.6 \times 10^{-14}\,{\rm m}^2/{\rm Pa/s}$ and a drainage length $l = 9.65 \times 10^{-3}\,{\rm m}$, the seepage times $t_{\rm H} = l^2/(H\,k_{\rm H})$ range as follows depending on the relaxation time τ:

- for a very small relaxation time τ corresponding to a poroelastic response, the confined compression modulus $H = \lambda + 2\,\mu$ is equal to 26 kPa, and $t_{\rm H}$ to about 50×10^3 s $\sim$ 14 hours;
- for a very large relaxation time τ, the confined compression modulus $H = \lambda + 2\,\mu + 2\,(\lambda_{ve} + 2\,\mu_{ve})$ is equal to 130 kPa, and $t_{\rm H}$ to about 10×10^3 s $\sim$ 2.8 hour.

Following a sudden loading, viscous effects are expected mainly at early times, up to some multiples of τ, actually up to $50\,\tau$ as shown in Fig. 8.8.3. Therefore, the Deborah number (8.8.1) should be defined as $50\,\tau/t_{\rm H}$.

8.9 Confined compression of a viscoelastic polymer gel

Netti et al. [2000] address the confined compression of the poro-viscoelastic medium defined in Section 8.8. The material is confined laterally as sketched in Fig. 8.8.1(b) so that the motion is one-dimensional. The solid displacement is prescribed at the boundaries $\hat{x} \equiv x/l = 0$ and $\hat{x} = 1$, namely

$$u_{\rm s}(\hat{x} = 0, t) = 0, \quad u_{\rm s}(\hat{x} = 1, t) = U(t), \quad t \geq 0\,. \tag{8.9.1}$$

The bottom of the column is impervious while the top is in chemical equilibrium with a bath at atmospheric pressure,

$$u_{\rm w}(\hat{x} = 0, t) = 0, \quad p_i(\hat{x} = 1, t) = 0, \quad t \geq 0\,. \tag{8.9.2}$$

The analysis takes advantage of the developments of Section 8.8.

8.9.1 The solution in the Laplace domain

The dilatation $e = du_{\rm s}/dx$ (not the displacement) satisfies the differential equation (8.8.13),

$$\beta^2\,\overline{e}(\hat{x},p) - \frac{d^2}{d\hat{x}^2}\overline{e}(\hat{x},p) = 0\,, \tag{8.9.3}$$

with $\beta^2 = p/\gamma^2$, $\gamma^2 = k_{\rm H}\,\overline{H}(p)/l^2$, so that its solution expresses as

$$\overline{e}(\hat{x},p) = A(p)\,\sinh\beta\hat{x} + B(p)\,\cosh\beta\hat{x}\,, \tag{8.9.4}$$

where $A(p)$ and $B(p)$ are fixed by the boundary conditions. The Laplace transform of Eqn (8.8.9) yields a relation between pressure and dilatation similar to (8.8.20), but, this time, for the gradients,

$$\frac{d}{d\hat{x}}\overline{p}_i(\hat{x},p) = \overline{H}(p)\,\frac{d}{d\hat{x}}\overline{e}(\hat{x},p)\,. \tag{8.9.5}$$

Since the bottom $\hat{x}=0$ is impervious, the gradient of pressure should vanish at this point according to Darcy's law. So does the dilatation gradient by (8.9.5), and therefore $A(p)=0$. Since the operators of spatial differentiation and Laplace transform commute, one thus has $d\overline{u}_{\rm s}/d\hat{x} = l\,B(p)\,\cosh\beta\hat{x}$. Accounting for the conditions at the bottom and top boundaries, the Laplace transform of the solid displacement takes the form

$$\overline{u}_{\rm s}(\hat{x},p) = \overline{U}(p)\,\frac{\sinh\beta\,\hat{x}}{\sinh\beta}\,. \tag{8.9.6}$$

All the boundary conditions of this coupled problem are now satisfied. The dilatation deduces from the displacement by simple differentiation, and the pressure by integration in space of (8.9.5),

$$\overline{e}(\hat{x},p) = \beta\,\frac{\overline{U}(p)}{l}\,\frac{\cosh\beta\,\hat{x}}{\sinh\beta}\,,\quad \overline{p}_i(\hat{x},p) = \overline{H}(p)\,\beta\,\frac{\overline{U}(p)}{l}\,\frac{\cosh\beta\,\hat{x}-\cosh\beta}{\sinh\beta}\,. \tag{8.9.7}$$

Also since the strain is uniaxial,

$$\overline{\sigma'_x}(\hat{x},p) = \overline{\sigma_x}(\hat{x},p) + \overline{p}_i(\hat{x},p) = \overline{H}(p)\,\overline{e}(\hat{x},p)\,. \tag{8.9.8}$$

8.9.2 The steady state solution

For ramp loading, the applied displacement and its Laplace transform read,

$$U(t) = \frac{U_0}{t_0}\Big(t\,\mathcal{H}(t) - (t-t_0)\,\mathcal{H}(t-t_0)\Big) \quad\Rightarrow\quad \overline{U}(p) = \frac{U_0}{t_0}\,\frac{1-e^{-t_0 p}}{p^2}\,. \tag{8.9.9}$$

In the limit case of a step loading, namely $t_0\to 0$, then $U(t) = U_0\,\mathcal{H}(t)$ and $\overline{U}(p) = U_0/p$.

The steady state solution follows trivially from the final value theorem, given that $\lim_{p\to 0}\,p\,\overline{U}(p) = U_0$ for both loading cases:

$$\frac{\sigma'_x(\hat{x},\infty)}{\overline{H}(0)} = \frac{\sigma_x(\hat{x},\infty)}{\overline{H}(0)} = e(\hat{x},\infty) = \frac{U_0}{l}\,;\quad p_i(\hat{x},\infty) = 0\,;\quad u_{\rm s}(\hat{x},\infty) = U_0\,\hat{x}\,;\quad v_{\rm w}(\hat{x},\infty) = 0\,. \tag{8.9.10}$$

8.9.3 The transient solution

For the two loading functions defined in Section 8.9.2, the scaled displacement, dilatation, fluid pressure, effective stress, stress and fluid velocity express as follows:

$$\begin{bmatrix} \dfrac{u_{\rm s}(\hat{x},t)}{U_0} \\ \dfrac{e(\hat{x},t)}{U_0/l} \\ \dfrac{p_i(\hat{x},t)}{\overline{H}(0)\,U_0/l} \\ \dfrac{\sigma'_x(\hat{x},t)}{\overline{H}(0)\,U_0/l} \\ \dfrac{\sigma_x(\hat{x},t)}{\overline{H}(0)\,U_0/l} \\ \dfrac{v_{\rm w}(\hat{x},t)}{U_0/t_{\rm H}} \end{bmatrix} = \begin{bmatrix} \hat{x} \\ 1 \\ 0 \\ 1 \\ 1 \\ 0 \end{bmatrix} + 2\sum_{j=1}^{\infty}\frac{(-1)^j}{\Delta(p_j)}\,A(p_j) \begin{bmatrix} \dfrac{\sin(j\,\pi\,\hat{x})}{j\,\pi} \\ \cos(j\,\pi\,\hat{x}) \\ \dfrac{\overline{H}(p_j)}{\overline{H}(0)}\,\big(\cos(j\,\pi\,\hat{x}) - (-1)^j\big) \\ \dfrac{\overline{H}(p_j)}{\overline{H}(0)}\,\cos(j\,\pi\,\hat{x}) \\ \dfrac{\overline{H}(p_j)}{\overline{H}(0)}\,(-1)^j \\ \dfrac{n^{\rm s}}{n^{\rm w}}\,\dfrac{\overline{H}(p_j)}{\overline{H}(0)}\,j\,\pi\,\sin(j\,\pi\,\hat{x}) \end{bmatrix} e^{-X_j^2\,t/t_{\rm H}}\,, \tag{8.9.11}$$

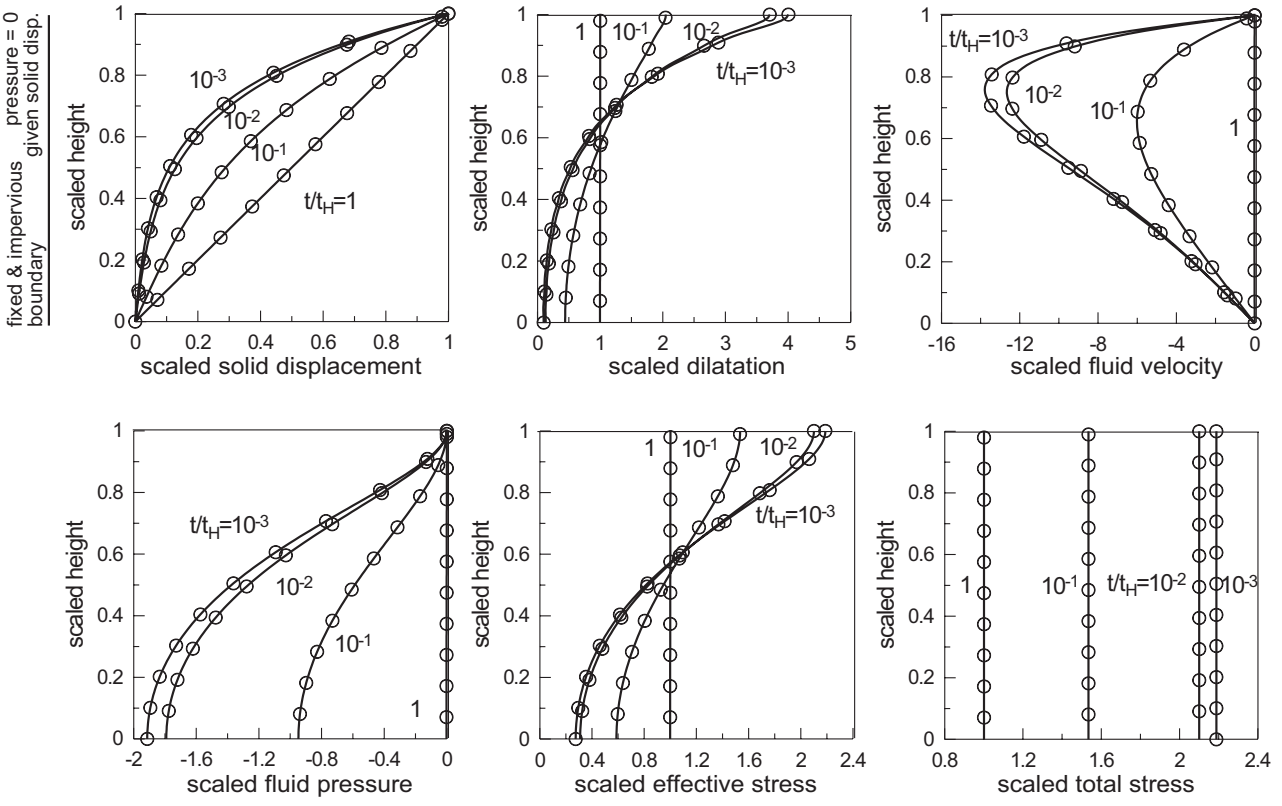

Fig. 8.9.1: Poro-viscoelastic layer subjected to a displacement at the top and fixed at its bottom as sketched in Fig. 8.8.1. Scaled quantities as indicated in (8.9.11) at different instants. The seepage time $t_{\rm H}$ appears as actually indicating the time to equilibrium. The very early time response does not differ much from the response at $t/t_{\rm H} = 10^{-3}$.

where the definitions (8.8.40) to (8.8.42) still hold and

$$A(p) = p\,\frac{\overline{U}(p)}{U_0} = \begin{cases} 1, & \text{step load,} \\ \dfrac{1-e^{-t_0\,p}}{t_0\,p}, & \text{ramp load.} \end{cases} \tag{8.9.12}$$

The plots shown in Fig. 8.9.1 aim at highlighting
- the influence of the loading rate U_0/t_0 on a purely poroelastic medium;
- the additional influence of the loading rate due to the intrinsic viscous response of the skeleton;
- the influence of the amplitude of the viscous parameter $(\lambda_{ve} + 2\,\mu_{ve})/(\lambda + 2\,\mu)$;
- the relative influence of the relaxation and Darcy's seepage times, namely $\tau/t_{\rm H}$.

8.10 Compression of a poroelastic layer: displacement control

The solution of the displacement controlled confined compression developed in Section 8.9, sketched in Fig. 8.8.1(b), applies as a limit case to a poroelastic layer where the modulus $H = \overline{H}(0) = \lambda + 2\,\mu$ is constant.

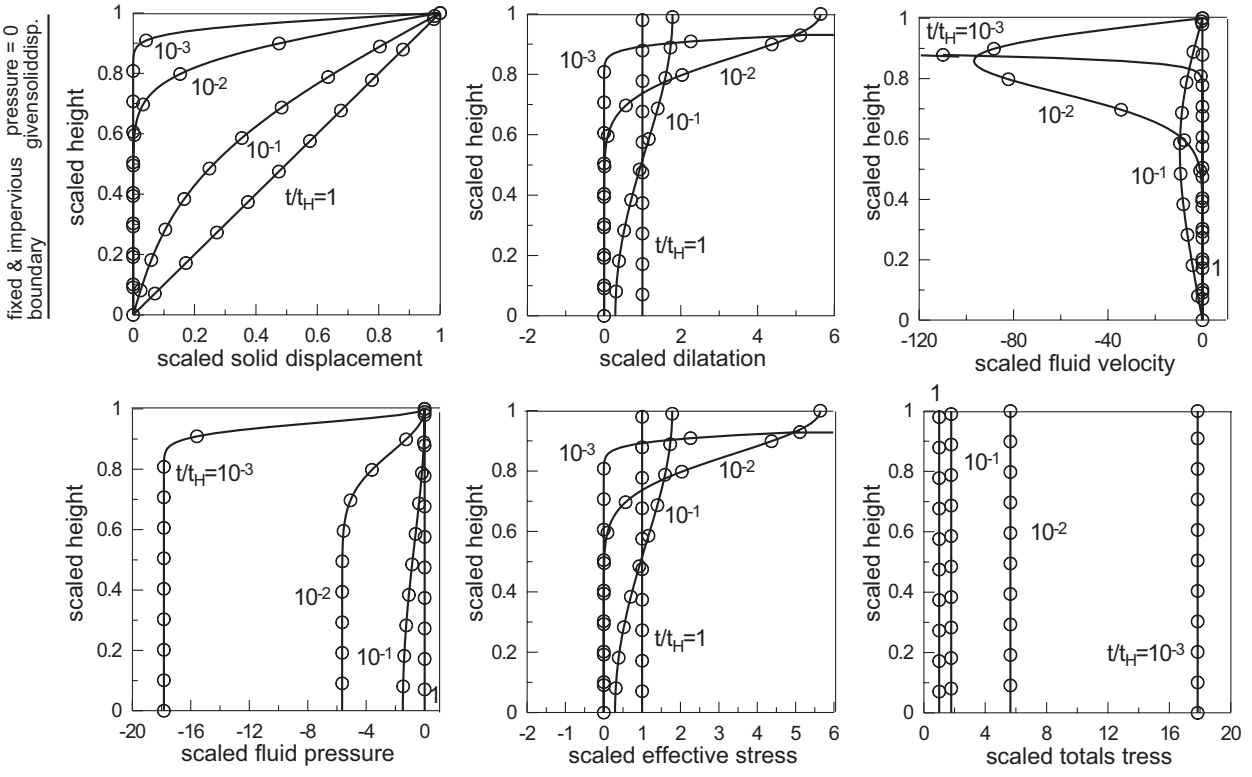

Fig. 8.10.1: Same as Fig. 8.9.1 but for a poroelastic layer. The mechanical response at early times to the instantaneous loading is significantly higher than for the poro-viscoelastic gel. At very early times, the fluid velocity in a skin close to the top surface and the fluid pressure on the complementary depth are large. Since the strain is one-dimensional, the scaled dilatation and the scaled effective stress have identical spatial profiles: this feature does not apply to the poro-viscoelastic gel.

8.10.1 The analytical solution

For both the ramp loading and step loading defined in Section 8.9.2, the scaled solution can be cast in the format,

$$\begin{bmatrix} \dfrac{u_{\rm s}(\hat{x},t)}{U_0} \\ \dfrac{e(\hat{x},t)}{U_0/l} \\ \dfrac{p_i(\hat{x},t)}{H\,U_0/l} \\ \dfrac{\sigma'_x(\hat{x},t)}{\overline{\overline{H}}(0)\,U_0/l} \\ \dfrac{\sigma_x(\hat{x},t)}{\overline{\overline{H}}(0)\,U_0/l} \\ \dfrac{v_{\rm w}(\hat{x},t)}{U_0/t_{\rm H}} \end{bmatrix} = \begin{bmatrix} \hat{x} \\ 1 \\ 0 \\ 1 \\ 1 \\ 0 \end{bmatrix} + 2\sum_{j=1}^{\infty} (-1)^j\, A(p_j) \begin{bmatrix} \dfrac{\sin(j\,\pi\,\hat{x})}{j\,\pi} \\ \cos(j\,\pi\,\hat{x}) \\ \cos(j\,\pi\,\hat{x}) - (-1)^j \\ \cos(j\,\pi\,\hat{x}) \\ (-1)^j \\ \dfrac{n^{\rm s}}{n^{\rm w}}\, j\,\pi\, \sin(j\,\pi\,\hat{x}) \end{bmatrix} e^{-X_j^2\, t/t_{\rm H}}\,, \tag{8.10.1}$$

where

$$t_{\rm H} = \frac{l^2}{H\,k_{\rm H}}, \quad p_j = -\frac{X_j^2}{t_{\rm H}}, \quad X_j = j\,\pi\,, \tag{8.10.2}$$

and $A(p)$ is defined by (8.9.12).

8.10.2 The elastic gel as a limit of the viscous gel with a zero relaxation time

Formally, the poroelastic response is obtained as the limit of the poro-viscoelastic response while the relaxation time τ tends to 0 based on (8.4.18). The spatial profiles are shown in Fig. 8.10.1. The actual rate of convergence towards the poroelastic response is quite slow and a good approximation of the poroelastic gel via the poro-viscoelastic gel requires tiny relaxation times. Fig. 8.10.2 shows the position of the first thousand poles involved in the inversion of the Laplace transform. The x- and y-axes are scaled so that the curve is a straight segment for the poroelastic gel. A visual inspection requires the actual relaxation time to be scaled down by a factor 10^{-7} for the inviscid limit to be reached.

8.10.3 Inversion of the Laplace transform: the minimum number of poles

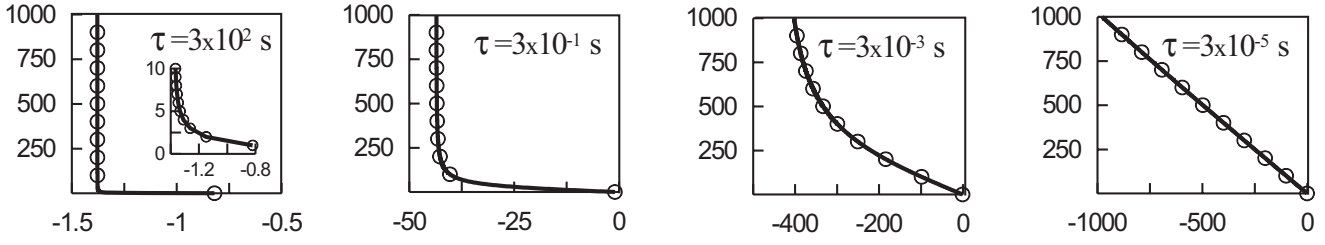

Fig. 8.10.2: The poles p_j, $j \geq 1$, involved in the inversion of the Laplace transform in the complex plane are real negative:

$$\text{x}-\text{axis} \equiv \frac{\sqrt{-p_j\, t_{\text{H}}}}{\pi} = j\sqrt{\frac{\overline{H}(p_j)}{\overline{H}(0)}}, \quad \text{y}-\text{axis} = \text{pole nb } 1, 2 \cdots, 1000$$

Their actual positions depend on the poro-viscoelastic properties. For a non zero relaxation time τ, the poles accumulate at the lower bound. For a zero relaxation time, the lower bound does not exist. Since the range covered by the poles increases as the relaxation time decreases, the number of poles required for a smooth solution increases as well. The fact that the lower bound of the range of the poles increases towards negative values is not an issue since the contributions of these terms are damped by the exponential involved in the inverse Laplace transform.

The poles involved in the inversion of the Laplace transform p_j's are the negative real roots of the equation,

$$p_j = -\frac{(j\,\pi)^2}{t_{\text{H}}}\,\frac{\overline{H}(p_j)}{\overline{H}(0)}, \quad \frac{\overline{H}(p_j)}{\overline{H}(0)} = 1 + \frac{\lambda_{ve} + 2\,\mu_{ve}}{\overline{H}(0)}\,\frac{\tau}{\Delta\tau}\,\text{Ln}\,\frac{p_j(\tau+\Delta\tau)+1}{p_j(\tau-\Delta\tau)+1}\,. \tag{8.10.3}$$

The minimum number of poles required to obtain a smooth response should be considered. Fig. 8.10.2 shows that the poles of the poro-viscoelastic gel range over an interval whose size increases inversely with the relaxation time. The poles accumulate at the lower bound of this interval. As the relaxation time is decreased, the neighbor to neighbor distance homogenizes gradually while the interval becomes larger and actually turns unbounded at the poroelastic limit. The minimum number of poles necessary for a smooth response depends on the time at which the response is sought. For the results shown in Figs. 8.9.1 and 8.10.1, at least 20 poles should be used for the poro-viscoelastic gel and 50 poles for the poroelastic gel. The mechanical response at earlier time $t/t_{\text{H}} = 10^{-4}$ requires more than 100 poles for the poroelastic gel: an insufficient number of poles is witnessed by spurious wavy curves for some quantity, typically the fluid velocity.

8.11 Visco-hyperelasticity and other memory effects

In this section, a derivative with respect to time t is denoted either by the symbol $d(\cdot)/dt$ or by a superimposed dot $\dot{(\cdot)}$, when the former symbol is too cumbersome.

8.11.1 Linear viscous fluids

A thermodynamic presentation of viscous models embedding a growth strain is proposed in Sections 21.6.4.1 and 21.6.4.2. The short introduction below addresses a barotropic fluid, namely an isotropic compressible viscous fluid

with a pressure $p = p(\rho, T)$ that may depend on density ρ and temperature T,

$$\boldsymbol{\sigma} + p\,\mathbf{I} = \boldsymbol{\sigma}_v = \mathbb{E}_v : \dot{\boldsymbol{\epsilon}} = \lambda_v \,\mathrm{tr}\,\dot{\boldsymbol{\epsilon}}\,\mathbf{I} + 2\,\mu_v\,\dot{\boldsymbol{\epsilon}}\,, \tag{8.11.1}$$

where $\dot{\boldsymbol{\epsilon}}$ is the strain rate and λ_v and μ_v [unit : Pa×s] are the viscosity coefficients.

The free energy $e = e(\rho, T)$ is considered a function of mass density ρ and temperature T. Ensuring a positive mechanical dissipation $\hat{S}_{(\mathrm{i},1)}$,

$$\begin{aligned} T\,\hat{S}_{(\mathrm{i},1)} &= -\rho\,\dot{e} + \boldsymbol{\sigma} : \dot{\boldsymbol{\epsilon}} - \rho\,s\,\dot{T} \\ &= \Big(-p + \rho^2\,\frac{\partial e}{\partial \rho}\Big)\,\mathrm{tr}\,\dot{\boldsymbol{\epsilon}} - \rho\,\Big(\frac{\partial e}{\partial T} + s\Big)\,\dot{T} + \boldsymbol{\sigma}_v : \dot{\boldsymbol{\epsilon}}\,, \end{aligned} \tag{8.11.2}$$

poses restrictions on the constitutive equation. Note that use has been made here of the balance of mass $\dot{\rho} = -\rho\,\mathrm{tr}\,\dot{\boldsymbol{\epsilon}}$. Since the free energy is independent of the strain rate and of the temperature rate, a standard argument yields the constitutive relations for the pressure p and entropy s,

$$p = \rho^2\,\frac{\partial e}{\partial \rho}, \quad s = -\frac{\partial e}{\partial T}\,, \tag{8.11.3}$$

and we are left with the reduced inequality to be satisfied,

$$\begin{aligned} T\,\hat{S}_{(\mathrm{i},1)} &= \boldsymbol{\sigma}_v : \dot{\boldsymbol{\epsilon}} \\ &= (\lambda_v + \frac{2}{3}\,\mu_v)\,(\mathrm{tr}\,\dot{\boldsymbol{\epsilon}})^2 + 2\,\mu_v\,\mathrm{dev}\,\dot{\boldsymbol{\epsilon}} : \mathrm{dev}\,\dot{\boldsymbol{\epsilon}} \geq 0\,. \end{aligned} \tag{8.11.4}$$

The constraint requires the viscosity coefficients to satisfy the inequalities,

$$\lambda_v + \frac{2}{3}\,\mu_v \geq 0, \quad \mu_v \geq 0\,. \tag{8.11.5}$$

These coefficients may depend on density and temperature. Actually, they are mostly independent of density although they may increase at very high pressures. As indicated in Section 7.3.3, the shear viscosity coefficient μ_v of liquids decreases as the temperature increases and the converse holds for gases.

8.11.2 Maxwell and Kelvin models in a dynamic context

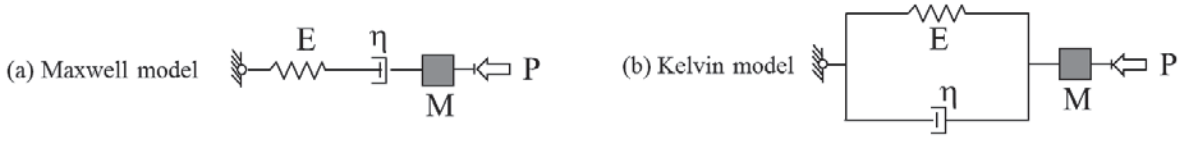

Fig. 8.11.1: Rheological representation of Maxwell and Kelvin models.

Consider a mass M attached to a Kelvin model with a fixed end and subjected to a load P at the other end as sketched in Fig. 8.11.1. Let q be the generalized coordinate describing the motion of the mass. Then the spring sustains a stress $Q_e = E\,q$ and the dashpot the stress $Q_v = \eta\,\dot{q}$, yielding the total stress

$$Q = \eta\,\dot{q} + E\,q\,. \tag{8.11.6}$$

Let us record the kinetic energy T, the elastic energy V and the dissipation potential $\mathcal{D} \geq 0$, namely

$$T(\dot{q}) = \frac{1}{2}\,M\,\dot{q}^2, \quad V(q) = \frac{1}{2}\,E\,q^2, \quad \mathcal{D}(\dot{q}) = \frac{1}{2}\,\eta\,\dot{q}^2 \geq 0\,, \tag{8.11.7}$$

so that the Lagrange equation, which then reduces to

$$\frac{d}{dt}\Big(\frac{\partial T}{\partial \dot{q}}\Big) - \frac{\partial T}{\partial q} + \frac{\partial V}{\partial q} = P + Q_v, \quad Q_v \equiv -\frac{\partial \mathcal{D}}{\partial \dot{q}}, \tag{8.11.8}$$

takes the form,

$$M\,\ddot{q} + \eta\,\dot{q} + E\,q = P \quad \Leftrightarrow \quad M\,\ddot{q} = P - Q\,. \tag{8.11.9}$$

Upon multiplying $M\,\ddot{q} = P - Q$ by $\dot{q}$ and replacing Q in the product $\dot{q}\,Q$ by (8.11.6) follows the general result that the rate of the sum of the kinetic and elastic energies is equal to the external power supply minus the power dissipated by the dashpot,

$$\frac{d}{dt}\big(T + V\big) = -2\,\mathcal{D} + P\,\dot{q}\,. \tag{8.11.10}$$

For a Maxwell model, the strain on the spring is equal to $q_e = Q/E$ while the strain rate on the dashpot is equal to $\dot{q}_v = Q/\eta$, yielding the total strain rate,

$$\dot{q} = \frac{\dot{Q}}{E} + \frac{Q}{\eta}\,. \tag{8.11.11}$$

However, we have a problem here because the energy of the spring $E\,q_e^2/2$ depends on the elastic part of the generalized variable and we do not know how to take its partial differential. In fact, the same problem arises in all models where the constitutive equations involve an 'effective' coordinate, e.g., thermoelasticity, growth, etc.

The equation of motion is simply $M\,\ddot{q} = P - Q$. It can be integrated in time as well as the constitutive equation (8.11.11), yielding

$$\frac{\ddot{u}}{E} + \frac{\dot{u}}{\eta} + \frac{u}{M} = \dot{q}(0) + \frac{1}{M}\int_0^t P(\tau)\,d\tau \quad \text{with} \quad u(t) = \int_0^t Q(\tau)\,d\tau\,. \tag{8.11.12}$$

Following Sivaselvan and Reinhorn [2006], by analogy with (8.11.9), we redefine the energies in terms of the pair $(u,\,\dot{u})$ in place of the pair $(q,\,\dot{q})$ for the Kelvin model,

$$T(\dot{u}) = \frac{\dot{u}^2}{2E}\,, \quad V(u) = \frac{u^2}{2M}\,, \quad \mathcal{D}(\dot{u}) = \frac{\dot{u}^2}{2\eta} \geq 0\,, \tag{8.11.13}$$

and use the Lagrange equation,

$$\frac{d}{dt}\Big(\frac{\partial T}{\partial \dot{u}}\Big) - \frac{\partial T}{\partial u} + \frac{\partial V}{\partial u} = \dot{q}(0) + \frac{1}{M}\int_0^t P(\tau)\,d\tau + U_v, \quad U_v \equiv -\frac{\partial \mathcal{D}}{\partial \dot{u}}\,. \tag{8.11.14}$$

Upon multiplying $M\,\ddot{q} = P - Q$ by $\dot{q}$ and replacing $\dot{q}$ in the product $\dot{q}\,Q$ by (8.11.11), the balance of energy takes now the form,

$$\frac{d}{dt}\big(\frac{1}{2}\,M\,\dot{q}^2 + \frac{Q^2}{2\,E}\big) = -\frac{Q^2}{\eta} + P\,\dot{q} = -2\,\mathcal{D} + P\,\dot{q}\,. \tag{8.11.15}$$

8.11.3 Rate effects as non-equilibrium thermodynamically consistent processes

The thermodynamic potentials per unit volume shown in Table 9.1.1, namely the internal energy U, the free energy E, the enthalpy H and the free enthalpy (or Gibbs potential) G, deduce from one another through a partial Legendre transform. The dissipation inequality may be expressed in terms of either one,

$$\begin{aligned} T\,\hat{S}_{(\mathrm{i})} &= -\dot{U} + \boldsymbol{\sigma} : \dot{\boldsymbol{\epsilon}} + T\,\dot{S} + \mathbf{A}\cdot\dot{\mathbf{a}} \\ &= -\dot{E} + \boldsymbol{\sigma} : \dot{\boldsymbol{\epsilon}} - S\,\dot{T} + \mathbf{A}\cdot\dot{\mathbf{a}} \\ &= -\dot{H} - \boldsymbol{\epsilon} : \dot{\boldsymbol{\sigma}} + T\,\dot{S} + \mathbf{A}\cdot\dot{\mathbf{a}} \\ &= -\dot{G} - \boldsymbol{\epsilon} : \dot{\boldsymbol{\sigma}} - S\,\dot{T} + \mathbf{A}\cdot\dot{\mathbf{a}} \\ &= -\dot{F} - \boldsymbol{\epsilon} : \dot{\boldsymbol{\sigma}} - S\,\dot{T} - \mathbf{a}\cdot\dot{\mathbf{A}}\,. \end{aligned} \tag{8.11.16}$$

Here $(\mathbf{a},\,\mathbf{A})$ is an arbitrary formal conjugate pair, possibly associated with damage/healing, plasticity or some other dissipative processes.

With the generic potential $\phi(\mathbf{x})$ can be associated the generalized potential $\phi^*(\mathbf{x},\,\mathbf{y})$,

$$\phi^*(\mathbf{x},\,\mathbf{y}) = \phi(\mathbf{x}) - \mathbf{y}\cdot\mathbf{x}\,. \tag{8.11.17}$$

Here $\mathbf{x}$ denotes the set of state variables and $\mathbf{y}$ is the set of control variables. For example, the internal energy U and the potential F feature the following conjugate sets of variables,

$$\text{state variables}: \ \mathbf{x} = (\boldsymbol{\epsilon},\, S,\, \mathbf{a}); \quad \text{control variables}: \ \mathbf{y} = (\boldsymbol{\sigma},\, T,\, \mathbf{A})\,, \tag{8.11.18}$$

and

$$F = U^* = U - \boldsymbol{\sigma} : \boldsymbol{\epsilon} - T\,S - \mathbf{A}\cdot\mathbf{a}\,. \tag{8.11.19}$$

From (8.11.17) derives the *affinity* $\mathbf{X}$,

$$\mathbf{X} = \frac{\partial \phi^*(\mathbf{x},\,\mathbf{y})}{\partial \mathbf{x}} = \frac{\partial \phi(\mathbf{x})}{\partial \mathbf{x}} - \mathbf{y}\,, \tag{8.11.20}$$

which vanishes at equilibrium, namely $\mathbf{X} = \mathbf{0}$. Thus at equilibrium, the elements of sets $\mathbf{x}$ and $\mathbf{y}$ can be termed respectively *independent* variables and *dependent* variables.

If $\mathbf{H} = \partial\mathbf{X}/\partial\mathbf{x} = \partial^2\phi/\partial\mathbf{x}\partial\mathbf{x}$ is invertible, the relation (8.11.20) can be used to express the set of state variables $\mathbf{x}$ in terms of the affinity $\mathbf{X}$ and control variables $\mathbf{y}$, namely $\delta\mathbf{X} = \mathbf{H}\cdot\delta\mathbf{x} - \delta\mathbf{y}$. Then the generalized thermodynamic function $\phi^*(\mathbf{x},\,\mathbf{y})$ can be cast in the format $\Phi^*(\mathbf{X},\,\mathbf{y})$ and

$$\mathbf{X} = \frac{\partial \Phi^*(\mathbf{X},\,\mathbf{y})}{\partial \mathbf{X}} \cdot \frac{\partial \mathbf{X}}{\partial \mathbf{x}} \quad \Rightarrow \quad \frac{\partial \Phi^*(\mathbf{X},\,\mathbf{y})}{\partial \mathbf{X}} = \mathbf{X}\cdot\mathbf{H}^{-1}\,. \tag{8.11.21}$$

Haslach [2005] developed a procedure to generate out-of-equilibrium rate equations for the state variables that respect the dissipation inequality. Haslach postulates the rate of the affinity as a gradient of a non equilibrium process,

$$\dot{\mathbf{X}} = -k_v\,\frac{\partial \Phi^*(\mathbf{X},\,\mathbf{y})}{\partial \mathbf{X}}\,, \tag{8.11.22}$$

with $k_v \geq 0$ a positive constitutive parameter. With help of (8.11.21), this rate may be expressed as

$$\dot{\mathbf{X}} = -k_v\,\mathbf{X}\cdot\mathbf{H}^{-1}\,. \tag{8.11.23}$$

Moreover $\dot{\mathbf{X}} = (\partial\mathbf{X}/\partial\mathbf{x})\cdot\dot{\mathbf{x}}$ at $\mathbf{y}$ fixed. Hence

$$\dot{\mathbf{x}} = -k_v\,\mathbf{H}^{-1}\cdot(\mathbf{X}\cdot\mathbf{H}^{-1})\,. \tag{8.11.24}$$

This relation is given the following interpretation. If, starting from equilibrium, the control variables $\mathbf{y}$ are changed suddenly to a value which is maintained fixed, the material relaxes to the new equilibrium $\dot{\mathbf{x}} = \mathbf{0}$ which corresponds to $\mathbf{X} = \mathbf{0}$. The dissipation inequality may now be shown to be non negative,

$$\begin{aligned} T\,\hat{S}_{(\mathrm{i})} &= -\dot{\phi}^*(\mathbf{x},\,\mathbf{y}) - \mathbf{x}\cdot\dot{\mathbf{y}} \\ &= -\dot{\phi}(\mathbf{x}) + \mathbf{y}\cdot\dot{\mathbf{x}} && \text{by (8.11.17)} \\ &= -\mathbf{X}\cdot\dot{\mathbf{x}} && \text{by (8.11.20)} \\ &= k_v\,(\mathbf{X}\cdot\mathbf{H}^{-1})\cdot(\mathbf{X}\cdot\mathbf{H}^{-1}) \geq 0 && \text{by (8.11.24)}\,. \end{aligned} \tag{8.11.25}$$

As a basic purely mechanical one-dimensional example, x is viewed as the strain ϵ and y as the stress σ. Denoting the stiffness by k_σ [unit : Pa], the internal energy ϕ and associated energy ϕ^* adopt the format $\phi = \frac{1}{2}\,k_\sigma\,\epsilon^2$ and $\phi^* = \frac{1}{2}\,k_\sigma\,\epsilon^2 - \sigma\,\epsilon$, whence the affinity $X = \partial\phi^*/\partial\epsilon = k_\sigma\,\epsilon - \sigma$ and $H = k_\sigma$. At equilibrium $X = 0$, the formalism retrieves the elastic relation $\sigma = k_\sigma\,\epsilon$. The potential $\phi^*(\epsilon,\sigma)$ can now be expressed as $\Phi^*(X,\sigma)$, namely $\Phi^* = (X+\sigma)^2/(2\,k_\sigma) - \sigma\,(X+\sigma)/k_\sigma$. Now at constant σ, (8.11.23) becomes $k_\sigma\,\dot{\epsilon} = -k_v/k_\sigma\,(k_\sigma\,\epsilon - \sigma)$ which may rephrased in the format $\sigma = k_\sigma\,\epsilon + k_\sigma^2/k_v\,\dot{\epsilon}$. The constitutive coefficient k_v has dimension Pa/s. The viscoelastic Kelvin model is recovered by interpreting the coefficient k_σ^2/k_v as a viscosity coefficient with dimension Pa×s. On the other hand, the standard linear solid model does not fit in this construction. Haslach [2005] used this approach to introduce rate effects consistent with the dissipation inequality in several elastic constitutive relations of biological tissues. The extension of Fung's QLV model accounts for the equilibrium relations (8.5.14), namely $\mathbf{X} \equiv \mathbb{E}_r(\infty) : \boldsymbol{\sigma}^{\mathrm{e}}(\boldsymbol{\epsilon}) - \boldsymbol{\sigma}$.

8.11.4 Visco-hyperelasticity

Visco-hyperelasticity expresses the 2nd Piola-Kirchhoff stress in terms of the Green strain $\mathbf{E}_{\rm G}$ and its rate via an elastic potential and a viscoelastic potential per unit initial volume, $\underline{\mathcal{W}}^{\rm e}(\mathbf{E}_{\rm G})$ and $\underline{\mathcal{W}}^{\rm v}(\dot{\mathbf{E}}_{\rm G})$ respectively,

$$\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\tau}}}^{\rm e} + \underline{\underline{\boldsymbol{\tau}}}^{\rm v} = \frac{\partial \underline{\mathcal{W}}^{\rm e}(\mathbf{E}_{\rm G})}{\partial \mathbf{E}_{\rm G}} + \frac{\partial \underline{\mathcal{W}}^{\rm v}(\dot{\mathbf{E}}_{\rm G})}{\partial \dot{\mathbf{E}}_{\rm G}} \,. \tag{8.11.26}$$

The viscoelastic potential describes short term dissipative effects. The dissipation inequality

$$T\,\underline{\hat{S}}^{1}_{\rm (i)} = \underline{\underline{\boldsymbol{\tau}}} : \dot{\mathbf{E}}_{\rm G} - \dot{\underline{\mathcal{W}}}^{\rm e} \geq 0, \tag{8.11.27}$$

which simplifies to

$$T\,\underline{\hat{S}}^{1}_{\rm (i)} = \frac{\partial \underline{\mathcal{W}}^{\rm v}(\dot{\mathbf{E}}_{\rm G})}{\partial \dot{\mathbf{E}}_{\rm G}} : \dot{\mathbf{E}}_{\rm G} \geq 0, \tag{8.11.28}$$

can be ensured by appropriate convexity properties of $\underline{\mathcal{W}}^{\rm v}(\dot{\mathbf{E}}_{\rm G})$ as detailed in Section 6.2.3.

The tissue may be endowed with anisotropic properties. Their variation gives rise to dissipation. Explicit expressions of the potentials may be obtained using representation theorems of isotropic scalar invariants that depend on tensorial arguments, see, e.g., Limbert and Middleton [2004] for transversely isotropic biological materials.

8.11.5 Long range memory

Collecting the ideas of the parallel assembly of Maxwell models, of the QLV concept of Fung and of visco-hyperelasticity, a more general model consists in considering the additive contributions of an elastic response $\underline{\underline{\boldsymbol{\tau}}}^{\rm e}$, of a short range viscous memory $\underline{\underline{\boldsymbol{\tau}}}^{\rm vs}$ and of a long range memory $\underline{\underline{\boldsymbol{\tau}}}^{\rm vl}$ that obeys the fading memory principle,

$$\underline{\underline{\boldsymbol{\tau}}} = \underline{\underline{\boldsymbol{\tau}}}^{\rm e} + \underline{\underline{\boldsymbol{\tau}}}^{\rm vs} + \underline{\underline{\boldsymbol{\tau}}}^{\rm vl} = \frac{\partial \underline{\mathcal{W}}^{\rm e}(\mathbf{E}_{\rm G})}{\partial \mathbf{E}_{\rm G}} + \frac{\partial \underline{\mathcal{W}}^{\rm v}(\dot{\mathbf{E}}_{\rm G})}{\partial \dot{\mathbf{E}}_{\rm G}} + \int_{0^+}^{t} \underline{\underline{\boldsymbol{\tau}}}^{\rm e}\big(\mathbf{E}_{\rm G}(t-u)\big)\,\frac{d\phi(u)}{du}\,du \,. \tag{8.11.29}$$

Pioletti and Rakotomanana [2000] apply such a relation to isotropic tendons, including in addition a coupling in the short range memory $\underline{\mathcal{W}}^{\rm v}(\dot{\mathbf{E}}_{\rm G}, \mathbf{E}_{\rm G})$. They define the reduced relaxation function $\phi(t)$ by an exponential Prony series with n terms, the term k having a modulus E_k and a relaxation time t_k,

$$\Big(\sum_{k=1,n} E_k\Big)\,\phi(t) = \sum_{k=1,n} E_k\; e^{-t/t_k} = \sum_{k=1,n} E_k - \sum_{k=1,n} E_k\,(1 - e^{-t/t_k}) \,. \tag{8.11.30}$$

8.11.6 Fading memories in a mixture context

Humphrey and Rajagopal [2002] [2003] apply the QLV idea but, instead of a convolution integral for the viscous term, they use an ordinary mass weighted time integration.

They address the stress in a mixture of incompressible constituents, specifically a fluid/proteoglycan-dominated gel matrix, an elastin-dominated gel matrix (referred by the index gel), a smooth muscle (m) and the collagen (c). The two last constituents grow at much faster pace than the two first ones.

Time $t = 0$ separates development ($t < 0$) and regular growth and maintenance ($t > 0$). For $t < 0$, the constitutive relations use the individual gradient decomposition (21.3.32) with a common homogenized intermediate configuration. The stress is taken in the form

$$\begin{aligned}
\boldsymbol{\sigma}(t) \;&=\; -p(t)\,\mathbf{I} + \phi_{\rm gel}(t)\,\boldsymbol{\sigma}^{\rm e,gel}(t) && \text{homogenized solid} \\
&+ \sum_{k=\rm m,c} \phi_k(t)\,\boldsymbol{\sigma}^{{\rm e},k}(t) && \text{removed early smooth muscle, collagen} \\
&+ \sum_{k=\rm m,c} \int_0^t \frac{\det\mathbf{F}^{\rm e}_k(\tau)}{\det\mathbf{F}^{\rm e}_k(t)}\,\boldsymbol{\sigma}^{{\rm e},k}\big(\mathbf{F}^{\rm e}_k(\tau)\big)\,S^k(\tau)\,\frac{\hat{\rho}^k(\tau)}{\rho(t)}\,d\tau && \text{growing smooth muscle, collagen}\,.
\end{aligned} \tag{8.11.31}$$

The elastic stress $\boldsymbol{\sigma}^{\mathrm{e},k}(\mathbf{F}^{\mathrm{e}}_k)$ is obtained from an elastic potential for collagen and elastin. It is contributed by the passive and active responses for the muscle. The mass fraction of constituent k is defined from the relative mass densities, namely $\phi_k(t) = \rho^k(t)/\rho(t)$. The mass fractions of smooth muscle and collagen are decaying exponentials that indicate the pace at which these materials, which are produced during development, are removed. The 'survival functions' S, which pertain to each constituent, indicate the time period during which a constituent exists, typically $S(t) = \mathcal{H}(t - t_\alpha) - \mathcal{H}(t - t_\omega)$, where t_α and t_ω are the times at which the constituent is respectively produced and removed, with $\mathcal{H}$ the Heaviside step function. The rates of mass supply $\hat{\rho}^k$ are functions of the total stress and the time constants reflect levels of nutrients, growth factors and regulators like nitric oxide NO, a vasodilator, and endothelin-1, a vasoconstrictor. The overall density is assumed to remain constant. If this property applies to a growing constituent, the dilatational part of its growth velocity 'gradient' is known from the rate of mass supply. The deviatoric part of response remains to be provided.

8.11.7 Nonlinear viscoelastic models for collagen gels

In Fung's quasi-linear model (8.5.12), the nonlinearities are included in the 'elastic' stress $\boldsymbol{\sigma}^{\mathrm{e}} = \boldsymbol{\sigma}^{\mathrm{e}}(\boldsymbol{\epsilon})$. These nonlinearities correspond to a stiffened behavior at larger strains. Moreover, the model decouples memory effects (through the reduced relaxation function) and the nonlinear elastic response.

1. Nonlinear collagen gels:

Pryse et al. [2003] consider a model with n parallel units (spring $\mathbb{E}_i(\boldsymbol{\epsilon})$, dashpot with relaxation time $\tau_i(\boldsymbol{\epsilon})$, $i \in [1, n]$) where the stiffnesses $\mathbb{E}_i$ and relaxation times τ_i depend on strain,

$$\mathbb{E}(t, \boldsymbol{\epsilon}) = \sum_{i=1}^{n} \mathbb{E}_i(\boldsymbol{\epsilon})\, e^{-t/\tau_i(\boldsymbol{\epsilon})} = \sum_{i=1}^{n} \mathbb{E}_i(\boldsymbol{\epsilon}) - \sum_{i=1}^{n} \mathbb{E}_i(\boldsymbol{\epsilon})\,(1 - e^{-t/\tau_i(\boldsymbol{\epsilon})})\,. \tag{8.11.32}$$

They test the model on self-assembled solutions of pure collagen gels and on solutions of collagen and fibroblasts. Note that this model,

$$\boldsymbol{\sigma}(t) = \int_{-\infty}^{t} \mathbb{E}(t - u,\, \boldsymbol{\epsilon}) : \frac{d\boldsymbol{\epsilon}(u)}{du}\, du \tag{8.11.33}$$

generalizes Fung's model

$$\boldsymbol{\sigma}(t) = \int_{-\infty}^{t} \mathbb{E}_r(t - u) : \Big(\frac{d\boldsymbol{\sigma}^{\mathrm{e}}(\boldsymbol{\epsilon})}{d\boldsymbol{\epsilon}} : \frac{d\boldsymbol{\epsilon}(u)}{du}\Big)\, du\,, \tag{8.11.34}$$

in which the relaxation times are constant while the reduced stiffnesses depend on strain but their ratios do not.

2. Wiener-Volterra kernels:

Along an idea attributed to Volterra, a mathematical scheme to represent nonlinear viscoelasticity consists in developing the response in series using a number of kernels, e.g., below j_0, $j_1(\tau)$ and $j_2(\tau_1, \tau_2)$,

$$\boldsymbol{\epsilon}(t) = j_0 + \int_0^\infty j_1(\tau)\, \boldsymbol{\sigma}(t - \tau)\; d\tau + \int_0^\infty j_2(\tau_1, \tau_2)\, \boldsymbol{\sigma}(t - \tau_1) \cdot \boldsymbol{\sigma}(t - \tau_2)\; d\tau_1 d\tau_2\,. \tag{8.11.35}$$

The zeroth order term provides the mean strain response, the first order term represents the viscoelastic response through a convolution integral and the second order term the nonlinear response. As such, the series has a weakness: the terms are not orthogonal, so that a refinement would modify all terms. The orthogonalization of the Volterra expansion proposed by Wiener [1958] is based on a Gram-Schmidt orthogonalization procedure requiring the covariance between any two terms to vanish for a Gaussian white noise stimulus. The Laguerre functions are used to build the basis. The Wiener expansion involves at time increment n (time increments have a uniform size), besides the kernels j_0, j_1 and j_2, the memory length R,

$$\boldsymbol{\epsilon}(n) = j_0 + \sum_{k=0}^{R-1} j_1(k)\, \boldsymbol{\sigma}(n - k) + \sum_{k_1=0}^{R-1} \sum_{k_2=0}^{R-1} j_2(k_1, k_2)\, \boldsymbol{\sigma}(n - k_1) \cdot \boldsymbol{\sigma}(n - k_2)\,. \tag{8.11.36}$$

Identification procedures are tested to the viscoelastic behavior of diabetic rat skin and ligaments in Hoffman and Grigg [2002].

Exercises on Chapter 8

Exercise 8.1 Complex modulus of series and parallel groups of Maxwell models

The set of Maxwell models (E_k, η_k), $k \in [1,n]$, assembled in series shown at the top of Fig. 8.E.1 is still a Maxwell model with modulus E and viscosity η, such that $E^{-1} = \sum_{k=1}^n E_k^{-1}$, and $\eta^{-1} = \sum_{k=1}^n \eta_k^{-1}$. The complex modulus is given by (8.3.39).

Below we address the parallel assembly of viscoelastic elements shown at the bottom of Fig. 8.E.1.

1. Consider a viscoelastic model composed by $n+1$ parallel branches, namely n models of Maxwell defined by the elastic moduli E_{Sk} and viscosities η_k, $k \in [1,n]$, and a spring E_P. Write the differential equation governing the response of this model.

Answer: Let q be the strain and $Q = E_P\, q + \sum_{k=1}^n Q_k$ the stress at the boundaries of the model. Let

$$M_k = \frac{1}{E_{Sk}}\,\frac{d}{dt} + \frac{1}{\eta_k}, \quad k \in [1,n]\,, \tag{8.E.1}$$

be the differential operator associated with the Maxwell model k. Then the strain q and stress Q are linked by the relations,

$$\frac{dq}{dt} = M_k\, Q_k, \quad k \in [1,n]\,. \tag{8.E.2}$$

Then,

$$\begin{aligned} \prod_{j=1,j\neq k}^{n} M_j\,\frac{dq}{dt} &= (\prod_{j=1}^{n} M_j)\, Q_k, \quad k \in [1,n], \\ \sum_{k=1}^{n}\prod_{j=1,j\neq k}^{n} M_j\,\frac{dq}{dt} &= \prod_{j=1}^{n} M_j \sum_{k=1}^{n} Q_k\,, \end{aligned} \tag{8.E.3}$$

so that the governing equation is a linear differential equation of order n,

$$\sum_{k=1}^{n}\prod_{j=1,j\neq k}^{n} M_j\,\frac{dq}{dt} = \prod_{j=1}^{n} M_j\ \ (Q - E_P\, q)\,, \tag{8.E.4}$$

or

$$\Big(\sum_{k=1}^{n}\prod_{j=1,j\neq k}^{n} M_j\Big)\,\frac{dq}{dt}\ +\ E_P\,\Big(\prod_{j=1}^{n} M_j\Big)\,q = \Big(\prod_{j=1}^{n} M_j\Big)\,Q\,. \tag{8.E.5}$$

To derive the above relations, the fact that the operators M commute has been accounted for, so that the products can be written in arbitrary orders.

For $n=1$, the relation (8.E.4) should be understood as

$$\frac{dq}{dt} = M_1\ \ (Q - E_P\, q)\,. \tag{8.E.6}$$

For $n=2$, the differential equation is of second order,

$$\Big((\frac{1}{E_{S1}} + \frac{1}{E_{S2}})\,\frac{d}{dt} + \frac{1}{\eta_1} + \frac{1}{\eta_2}\Big)\,\frac{dq}{dt} = \Big(\frac{d^2}{dt^2} + (\frac{E_{S1}}{\eta_1} + \frac{E_{S2}}{\eta_2})\,\frac{d}{dt} + \frac{E_{S1}}{\eta_1}\,\frac{E_{S2}}{\eta_2}\Big)\,\frac{Q - E_P\, q}{E_{S1}\, E_{S2}}\,. \tag{8.E.7}$$

2. Obtain the complex modulus $E^*(i\,\omega)$ of this model and the relaxation modulus $E(t)$.

Answer: For a harmonic strain with pulsation ω, the complex modulus is obtained from (8.E.5) as defined by (8.3.3),

$$\frac{E^*(i\,\omega)}{E_P} = 1 + \sum_{k=1}^{n} S_k\,\frac{i\,\omega}{i\,\omega + \dfrac{1}{t_{qk}}}\,, \tag{8.E.8}$$

where $S_k = E_{Sk}/E_P$ and $t_{qk} = \eta_k/E_{Sk}$ is the relaxation time at constant strain associated with the branch k, $k \in [1,n]$.

If the above expression is interpreted as a Laplace-Carson transform at $p = i\,\omega$, then its inverse is

$$\frac{E(t)}{E_P} = 1 + \sum_{k=1}^{n} S_k\, e^{-t/t_{qk}}\,. \tag{8.E.9}$$

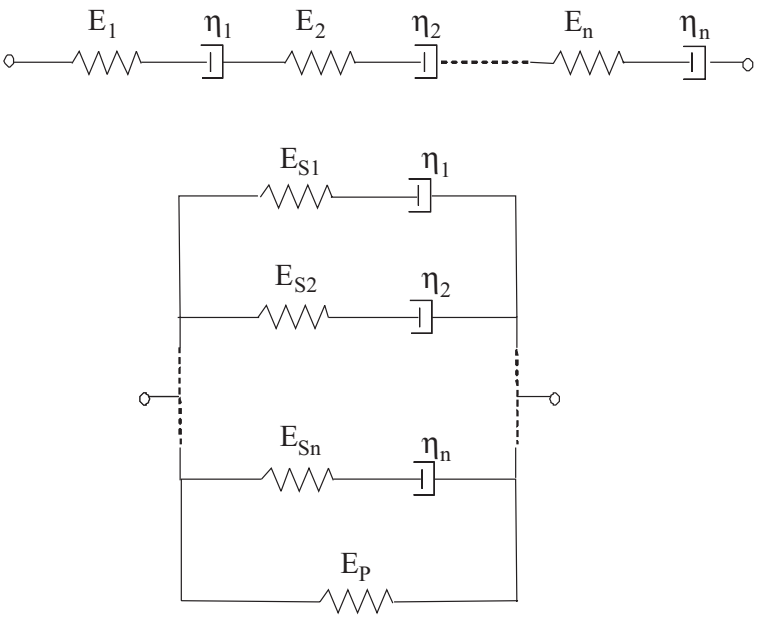

Fig. 8.E.1: Maxwell models in series and parallel.

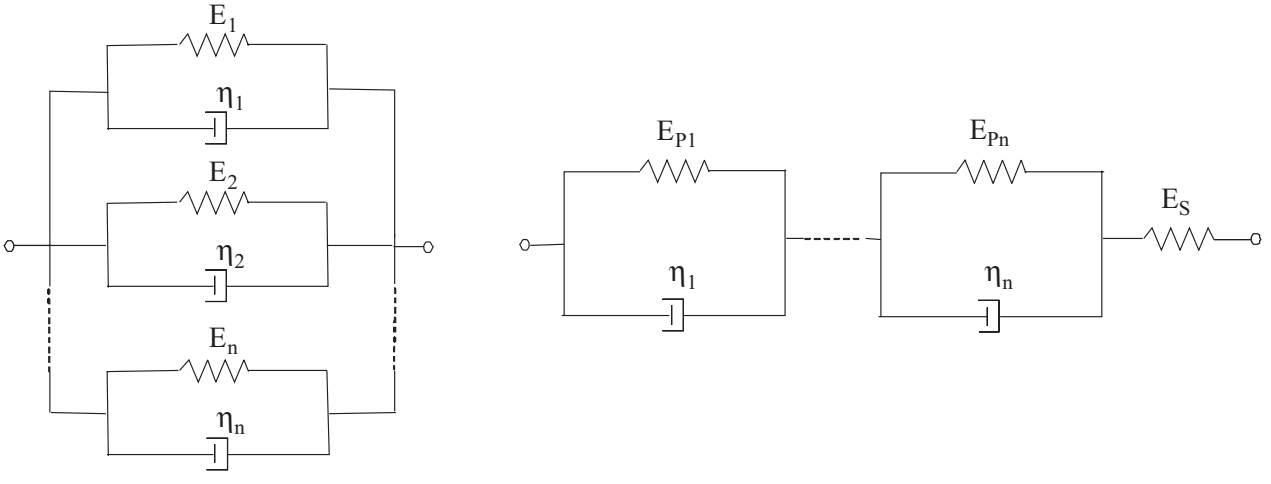

Fig. 8.E.2: Kelvin models in parallel and in series.

Exercise 8.2 Complex modulus of series and parallel groups of Kelvin models

The set of Kelvin models (E_k, η_k), $k \in [1, n]$, assembled in parallel shown on the left side of Fig. 8.E.2 is still a Kelvin model with modulus E and viscosity η such that $E = \sum_{k=1}^{n} E_k$ and $\eta = \sum_{k=1}^{n} \eta_k$. The complex modulus is given by (8.3.40).

Below we address the series assembly of viscoelastic elements shown on the right side of Fig. 8.E.2.

1. Consider a viscoelastic model composed by n models of Kelvin defined by the elastic moduli E_{Pk} and viscosities η_k, $k \in [1, n]$, in series with a spring E_S. Write the differential equation governing the response of this model.

Answer: Let Q be the stress and $q = Q/E_S + \sum_{k=1}^{n} q_k$ be the strain at the boundaries of the model. Let

$$K_k = \eta_k \frac{d}{dt} + E_{Pk}, \quad k \in [1, n]\,, \tag{8.E.10}$$

be the differential operator associated with the Kelvin model k. Then,

$$
\begin{aligned}
&Q = K_k\, q_k, \quad k \in [1,n],\\
&\prod_{j=1,j\neq k}^{n} K_j\, Q = (\prod_{j=1}^{n} K_j)\, q_k, \quad k \in [1,n],\\
&\sum_{k=1}^{n} \prod_{j=1,j\neq k}^{n} K_j\; Q = (\prod_{j=1}^{n} K_j)\, \Big(\sum_{k=1}^{n} q_k\Big)\,,
\end{aligned}
\tag{8.E.11}
$$

and the differential equation of order n that governs the model response can be cast in the form,

$$
\sum_{k=1}^{n} \prod_{j=1,j\neq k}^{n} K_j\; Q = (\prod_{j=1}^{n} K_j)\;\; (q - \frac{Q}{E_S})\,,
\tag{8.E.12}
$$

or

$$
\Big(\sum_{k=1}^{n} \prod_{j=1,j\neq k}^{n} K_j\Big)\, Q + \Big(\prod_{j=1}^{n} K_j\Big)\; \frac{Q}{E_S} = \Big(\prod_{j=1}^{n} K_j\Big)\; q\,.
\tag{8.E.13}
$$

For $n = 1$, the relation (8.E.12) is interpreted as

$$
Q = K_1\;\; (q - \frac{Q}{E_S})\,.
\tag{8.E.14}
$$

2. Obtain the complex compliance $J^*(i\,\omega)$ of this model and the creep function $J(t)$.

Answer: For a harmonic strain with pulsation ω, the complex modulus is obtained from (8.E.13) as defined by (8.3.3),

$$
E_S\, J^*(i\,\omega) = 1 + \sum_{k=1}^{n} \frac{1}{P_k\, t_{qk}}\; \frac{1}{i\,\omega + \dfrac{1}{t_{qk}}}\,,
\tag{8.E.15}
$$

where $P_k = E_{Pk}/E_S$ and $t_{qk} = \eta_k/E_{Pk}$ is the relaxation time associated with the model k, $k \in [1,n]$.

If the above expression is interpreted as a Laplace-Carson transform at $p = i\,\omega$, then its inverse is

$$
E_S\;\, J(t) = 1 + \sum_{k=1}^{n} \frac{1}{P_k}\, (1 - e^{-t/t_{qk}})\,.
\tag{8.E.16}
$$

Exercise 8.3 Governing equation of a model with a spring in parallel with two Kelvin models in series

Deduce the governing equation of the viscoelastic model of Fig. 8.7.1.

Answer:

Let Q_S ad Q_P be the stresses in the spring and Kelvin branches, respectively. The strain in the parallel branch is the sum of the strains in the Kelvin models, say q_a and q_b. Then

$$
\begin{aligned}
&Q = Q_S + Q_P,\\
&Q_S = E_S\, q,\\
&Q_P = E_a\, q_a + \eta_a\, \frac{dq_a}{dt} = E_b\, q_b + \eta_b\, \frac{dq_b}{dt},\\
&q = q_a + q_b\,.
\end{aligned}
\tag{8.E.17}
$$

The strain q_b may be eliminated from $(8.E.17)_{3,4}$,

$$
(E_a + E_b)\, q_a + (\eta_a + \eta_b)\, \frac{dq_a}{dt} = E_b\, q + \eta_b\, \frac{dq}{dt}\,.
\tag{8.E.18}
$$

Next dq_a/dt and dq_b/dt can be calculated from $(8.E.17)_3$,

$$
\frac{dq_a}{dt} = \frac{Q_P}{\eta_a} - \frac{E_a}{\eta_a}\, q_a, \quad \frac{dq_b}{dt} = \frac{Q_P}{\eta_b} - \frac{E_b}{\eta_b}\, q_b\,.
\tag{8.E.19}
$$

Summing up and using $(8.E.17)_4$ yields

$$
(\frac{E_a}{\eta_a} - \frac{E_b}{\eta_b})\, q_a = (\frac{1}{\eta_a} + \frac{1}{\eta_b})\, Q_P - \frac{E_b}{\eta_b}\, q - \frac{dq}{dt}\,.
\tag{8.E.20}
$$

Back-substituting in (8.E.18) with $Q_P = Q - E_S\, q$ yields the governing equation (8.7.1).

Chapter 9

Thermoelasticity and thermo-poroelasticity

This chapter addresses first thermoelastic constitutive equations of a solid. The analysis is next extended to include thermo-poroelasticity which involves three independent fields, namely the displacement of the solid, the pressure of the fluid and the temperature. In formulations which account for dynamic effects, the fluid pressure is substituted by the fluid velocity. The solid and porous medium under consideration here are in local thermal equilibrium, namely the temperature is identical over all species. Local thermal nonequilibrium is considered in Chapter 10.

Here are a few motivations for a thermal analysis of biological tissues:

- detection of unusual physical activities. Vessels and tissue exchange both mass (blood) and heat. Maintenance of an acceptable temperature is a main function of the central nervous system. In that sense, the consequences of deviations wrt the standard conditions are of interest. In particular, the difference in energy consumption between normal and tumor tissues may be used to detect tumors;
- cure of tumors through cryotherapy (use of a cold source) or conversely through a localized heat source (hyperthermia). For thermal models of hyperthermia, see e.g., Atkinson [1979]; for a review on cryosurgery, cryotherapy and cryopreservation, see Stánczyk and Telega [2002,2003];
- thermal ablation techniques like short pulse laser ablation. Ablation takes place at much shorter times than the thermal relaxation time (which is about 10 to 20 s for flesh, see below) so that thermal expansion has no time to develop and ablation takes place at constant volume. The photomechanical effect plays a major role: the photoenergy is used to create tension and to damage the tissue;
- analysis of thermal injury processes such as burns and frostbites, e.g., Moritz and Henriques [1947];
- temporary cooling of brain tissue following brain ischemia due to traumatic injury, stroke or cardiac arrest. Fast moderate cooling and slow re-heating requires careful protocols to be favorable, Diller and Zhu [2009];
- applications including food preservation, fertility programs and medical device implants, e.g., Polge et al [1949], Whittingham et al. [1972];
- application of cryo-protective agents in tissue preservation. Preservation of organs between extraction and transplant requires the knowledge of the physiological response of the tissues under hypothermal conditions;
- change of thermal conductivity of tissues with respect to temperature, zones of reversibility, Bhattacharya and Mahajan [2003].

9.1 Thermomechanical properties of elastic solids

Since $\boldsymbol{\sigma} : d\boldsymbol{\epsilon} - S\, dT$ is the differential of the free energy E, Table 9.1.1, then

$$\boldsymbol{\sigma} = \frac{\partial E}{\partial \boldsymbol{\epsilon}}_{|T}, \quad S = -\frac{\partial E}{\partial T}_{|\boldsymbol{\epsilon}}, \tag{9.1.1}$$

and

$$\frac{\partial \boldsymbol{\sigma}}{\partial T}_{|\boldsymbol{\epsilon}} = -\frac{\partial S}{\partial \boldsymbol{\epsilon}}_{|T}. \tag{9.1.2}$$

In view of (9.1.1), the knowledge of the free energy provides the other thermodynamic functions.

Table 9.1.1: Thermodynamical measures per unit (reference or current) volume [unit : Pa = J/m^3] of the state of a solid endowed with stress $\boldsymbol{\sigma}$, strain $\boldsymbol{\epsilon}$ and temperature T.

Measure	Variables	Arbitrary Increment
Internal energy	$U = U(\boldsymbol{\epsilon}, S)$	$dU = \boldsymbol{\sigma} : d\boldsymbol{\epsilon} + T\, dS$
Free energy	$E = E(\boldsymbol{\epsilon}, T) = U - T\, S$	$dE = \boldsymbol{\sigma} : d\boldsymbol{\epsilon} - S\, dT$
Enthalpy	$H = H(\boldsymbol{\sigma}, S) = U - \boldsymbol{\sigma} : \boldsymbol{\epsilon}$	$dH = -\boldsymbol{\epsilon} : d\boldsymbol{\sigma} + T\, dS$
Free enthalpy	$G = G(\boldsymbol{\sigma}, T) = H - T\, S$	$dG = -\boldsymbol{\epsilon} : d\boldsymbol{\sigma} - S\, dT$

9.1.1 Isothermal and isentropic moduli

An expression of the thermodynamic functions is obtained through an expansion up to order two in terms of the primary variables, e.g., Mandel [1974], p. 115. If the primary variables are strain $\boldsymbol{\epsilon}$ and temperature change $T - T_0$, then the free energy,

$$E = E_0 + \boldsymbol{\sigma}_0 : \boldsymbol{\epsilon} - (S_0 + \boldsymbol{\epsilon} : \mathbb{E} : \mathbf{c}_{\mathrm{T}})\,(T - T_0) + \frac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - \frac{1}{2}\,\frac{C_{0\epsilon}}{T_0}\,(T - T_0)^2\,, \tag{9.1.3}$$

expresses in terms of

- the symmetric fourth order isothermal elastic stiffness $\mathbb{E}$ [unit : Pa];
- the symmetric second order tensor of thermal expansion $\mathbf{c}_{\mathrm{T}}$ [unit : 1/K];
- the heat capacity per unit volume at constant strain $C_{0\epsilon}$ [unit : kg/m/s^2/K].

The subscript 0 indicates a reference value corresponding to vanishing primary variables $\boldsymbol{\epsilon} = \mathbf{0}$, $T - T_0 = 0$. The thermodynamic functions follow from (9.1.1) and the definitions shown in Table 9.1.1,

$$\begin{aligned}
S &= S_0 + \mathbf{c}_{\mathrm{T}} : \mathbb{E} : \boldsymbol{\epsilon} + \frac{C_{0\epsilon}}{T_0}\,(T - T_0);\\
U &= E_0 + T_0\, S_0 + (\boldsymbol{\sigma}_0 + \mathbb{E} : \mathbf{c}_{\mathrm{T}}\, T_0) : \boldsymbol{\epsilon} + \frac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} + \frac{1}{2}\,\frac{C_{0\epsilon}}{T_0}\,(T^2 - T_0^2);\\
H &= E_0 + T_0\, S_0 + \boldsymbol{\epsilon} : \mathbb{E} : \mathbf{c}_{\mathrm{T}}\, T - \frac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} + \frac{1}{2}\,\frac{C_{0\epsilon}}{T_0}\,(T^2 - T_0^2);\\
G &= E_0 - \frac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - (T - T_0)\, S_0 - \frac{1}{2}\,\frac{C_{0\epsilon}}{T_0}\,(T - T_0)^2\,.
\end{aligned} \tag{9.1.4}$$

The thermoelastic constitutive equations (9.1.1) can be cast in the matrix form,

$$\begin{bmatrix} \boldsymbol{\sigma} - \boldsymbol{\sigma}_0 \\ -(S - S_0) \end{bmatrix} = \begin{bmatrix} \mathbb{E} & -\mathbb{E} : \mathbf{c}_{\mathrm{T}} \\ -\mathbf{c}_{\mathrm{T}} : \mathbb{E} & -C_{0\epsilon}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ T - T_0 \end{bmatrix}. \tag{9.1.5}$$

A partial inversion of these relations,

$$\begin{bmatrix} \boldsymbol{\sigma} - \boldsymbol{\sigma}_0 \\ T - T_0 \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\mathrm{isEn}} & -\mathbb{E} : \mathbf{c}_{\mathrm{T}}\,(T_0/C_{0\epsilon}) \\ -(T_0/C_{0\epsilon})\mathbf{c}_{\mathrm{T}} : \mathbb{E} & T_0/C_{0\epsilon} \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ S - S_0 \end{bmatrix}, \tag{9.1.6}$$

displays the *isentropic* (or *adiabatic*) elastic tensor moduli $\mathbb{E}^{\mathrm{isEn}} = (\partial^2 U/\partial\boldsymbol{\epsilon}\,\partial\boldsymbol{\epsilon})_{|S}$,

$$\mathbb{E}^{\mathrm{isEn}} = \mathbb{E} + \mathbf{c}_{\mathrm{T}} : \mathbb{E} \otimes \mathbb{E} : \mathbf{c}_{\mathrm{T}}\,\frac{T_0}{C_{0\epsilon}}\,, \tag{9.1.7}$$

rather than the *isothermal* elastic tensor moduli $\mathbb{E} = (\partial^2 E/\partial\boldsymbol{\epsilon}\partial\boldsymbol{\epsilon})_{|T}$

The alternative partial inversion,

$$\begin{bmatrix} \boldsymbol{\epsilon} \\ S - S_0 \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{-1} & \mathbf{c}_{\mathrm{T}} \\ \mathbf{c}_{\mathrm{T}} & C_{0\sigma}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\sigma} - \boldsymbol{\sigma}_0 \\ T - T_0 \end{bmatrix}, \tag{9.1.8}$$

displays the heat capacity per unit volume at *constant stress*,

$$C_{0\sigma} = C_{0\epsilon} + \mathbf{c}_{\mathrm{T}} : \mathbb{E} : \mathbf{c}_{\mathrm{T}}\, T_0\,, \tag{9.1.9}$$

rather than the heat capacity per unit volume at *constant strain* $C_{0\epsilon}$.

For an isotropic material, both the isothermal and isentropic tensor moduli are endowed with the standard structure,

$$\mathbb{E} = \lambda\, \mathbf{I} \otimes \mathbf{I} + 2\,\mu\, \mathbf{I}\, \underline{\overline{\otimes}}\, \mathbf{I}, \quad \mathbb{E}^{\mathrm{isEn}} = \lambda^{\mathrm{isEn}}\, \mathbf{I} \otimes \mathbf{I} + 2\,\mu^{\mathrm{isEn}}\, \mathbf{I}\, \underline{\overline{\otimes}}\, \mathbf{I}\,. \tag{9.1.10}$$

With the isothermal Lamé moduli λ and μ, and bulk modulus $K = \lambda + 2\,\mu/3$, are associated the isentropic counterparts,

$$\lambda^{\mathrm{isEn}} = \lambda + K^2\, (\mathrm{tr}\, \mathbf{c}_{\mathrm{T}})^2\, \frac{T_0}{C_{0\epsilon}}, \quad \mu^{\mathrm{isEn}} = \mu, \quad K^{\mathrm{isEn}} = K + K^2\, (\mathrm{tr}\, \mathbf{c}_{\mathrm{T}})^2\, \frac{T_0}{C_{0\epsilon}}\,, \tag{9.1.11}$$

and the heat capacities at constant strain and constant stress obey the relation,

$$C_{0\sigma} = C_{0\epsilon} + K\, (\mathrm{tr}\, \mathbf{c}_{\mathrm{T}})^2\, T_0\,. \tag{9.1.12}$$

Stability of equilibrium requires the heat capacity at constant strain $C_{0\epsilon}$ to be positive and the isothermal elastic moduli to be positive definite, Mandel [1974], p. 115, and these conditions in turn imply the heat capacity at constant stress to be positive and the isentropic elastic moduli to be positive definite,

$$C_{0\sigma} \geq C_{0\epsilon} > 0, \quad \mathbb{E}^{\mathrm{isEn}} \ \text{ P.D.}, \quad \mathbb{E}^{\mathrm{isEn}} - \mathbb{E} \ \text{ P.sD.} \tag{9.1.13}$$

Actual values of the isothermal and isentropic moduli differ little. Typically, for rocks or cortical bones, the bulk modulus has magnitude 10^9 Pa, the coefficient of thermal expansion 10^{-4} /K, the heat capacity per unit volume 10^6 Pa/K, so that the relative difference of isothermal and isentropic moduli is not larger than 10^{-3}.

An analogy between linear poroelasticity and thermoelasticity can be observed through the correspondences between entropy and fluid mass content on one side and between temperature and pressure on the other side. The point is elaborated and used to cross-check macroscopic properties for spatially heterogeneous materials in Norris [1992].

9.1.2 Temperature dependence of heat capacity

Mimicking the formalism introduced for fluids by (3.3.3), let

$$T\, dS = \rho\, \mathcal{L} : d\boldsymbol{\epsilon} + C_\epsilon\, dT\,, \tag{9.1.14}$$

with

- $\mathcal{L}$ second order symmetric tensor of latent heat of deformation per unit mass [unit : J/kg];
- C_ϵ heat capacity per unit volume at constant strain [unit : J/m^3/K].

Both entities appear linear in absolute temperature,

$$\rho\, \mathcal{L} = \mathbb{E} : \mathbf{c}_{\mathrm{T}}\, T, \quad C_\epsilon = \frac{T}{T_0}\, C_{0\epsilon}\,. \tag{9.1.15}$$

Relations similar to (3.3.17) can be obtained for a thermoelastic solid,

$$T\, dS = \rho\, \mathcal{L} : d\boldsymbol{\epsilon} + C_\epsilon\, dT = \boldsymbol{\xi} : d\boldsymbol{\sigma} + C_\sigma\, dT = \boldsymbol{\zeta} : d\boldsymbol{\epsilon} + \boldsymbol{\eta} : d\boldsymbol{\sigma}\,. \tag{9.1.16}$$

In that vein, the four thermodynamic state functions U, E, H and G, may be expressed in terms of the four pairs of variables, $(\boldsymbol{\epsilon}, T)$, $(\boldsymbol{\sigma}, T)$, $(\boldsymbol{\epsilon}, S)$ and $(\boldsymbol{\sigma}, S)$. A method proposed in Lubarda [2004]b uses the equality of cross derivatives and alleviates lengthy algebraic derivations.

If one insists that the heat capacity should be a constant, $C_\epsilon = C_{0\epsilon}$, then the free energy should be modified, e.g., Chadwick [1960], p. 275,

$$E = E_0 + \boldsymbol{\sigma}_0 : \boldsymbol{\epsilon} - (S_0 + \boldsymbol{\epsilon} : \mathbb{E} : \mathbf{c}_{\mathrm{T}})\, (T - T_0) + \frac{1}{2}\, \boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} + C_{0\epsilon}\, (T - T_0) - C_{0\epsilon}\, T\, \mathrm{Ln}\, \frac{T}{T_0}\,, \tag{9.1.17}$$

and then,

$$\begin{aligned} S &= S_0 + \mathbf{c}_{\scriptscriptstyle T} : \mathbb{E} : \boldsymbol{\epsilon} + C_{0\epsilon} \operatorname{Ln} \frac{T}{T_0}; \\ U &= E_0 + S_0\, T_0 + (\boldsymbol{\sigma}_0 + \mathbb{E} : \mathbf{c}_{\scriptscriptstyle T}\, T_0) : \boldsymbol{\epsilon} + \frac{1}{2}\, \boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} + C_{0\epsilon}\, (T - T_0); \\ H &= E_0 + S_0\, T_0 + \boldsymbol{\epsilon} : \mathbb{E} : \mathbf{c}_{\scriptscriptstyle T}\, T - \frac{1}{2}\, \boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} + C_{0\epsilon}\, (T - T_0); \\ G &= E_0 - \frac{1}{2}\, \boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - S_0\, (T - T_0) + C_{0\epsilon}\, (T - T_0) - C_{0\epsilon}\, T \operatorname{Ln} \frac{T}{T_0}\,. \end{aligned} \tag{9.1.18}$$

It is useful to record the expansion to second order,

$$T - T_0 - T \operatorname{Ln} \frac{T}{T_0} = -\frac{1}{2\, T_0}\, (T - T_0)^2\,. \tag{9.1.19}$$

9.1.3 The energy equation of thermoelasticity

The constitutive equations (9.1.1) have been obtained assuming the linearized mechanical entropy production (4.7.28),

$$T \hat{S}_{(\mathrm{i},1)} = -\frac{dE}{dt} + \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} - S\, \frac{dT}{dt}\,, \tag{9.1.20}$$

to vanish,

$$T \hat{S}_{(\mathrm{i},1)} = 0\,. \tag{9.1.21}$$

Eliminating the rate of work $\boldsymbol{\sigma} : d\boldsymbol{\epsilon}/dt$ from the entropy production (9.1.20) and from the linearized balance of energy (4.6.22),

$$\frac{dU}{dt} - \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} + \operatorname{div}\, \mathbf{Q} - \Theta = 0\,, \tag{9.1.22}$$

where $\mathbf{Q}$ is the heat flux [unit : $\mathrm{W/m^2}$=$\mathrm{kg/m/s^3}$] and Θ is a heat source per unit volume [unit : $\mathrm{W/m^3}$ = $\mathrm{kg/m^2/s^3}$], yields in view of (9.1.21),

$$T \hat{S}_{(\mathrm{i},1)} = T\, \frac{dS}{dt} + \operatorname{div}\, \mathbf{Q} - \Theta = 0\,. \tag{9.1.23}$$

Fourier's law, expressing the heat flux $\mathbf{Q}$ in terms of the temperature gradient $\boldsymbol{\nabla} T$ via the symmetric positive (semi-)definite second order tensor of thermal conductivity $\mathbf{k}_{\scriptscriptstyle T}$ [unit : $\mathrm{W/m/K}$],

$$\mathbf{Q} = -\mathbf{k}_{\scriptscriptstyle T} \cdot \boldsymbol{\nabla} T\,, \tag{9.1.24}$$

implies the thermal contribution to the internal entropy production $T \hat{S}_{(\mathrm{i},3)} = -\mathbf{Q} \cdot \boldsymbol{\nabla} T / T$ to be nonnegative.

The energy equation (9.1.23) can then be phrased in terms of primary variables, say strain and temperature, in the format,

$$\underbrace{T\, \mathbf{c}_{\scriptscriptstyle T} : \mathbb{E} : \frac{d\boldsymbol{\epsilon}}{dt}}_{\substack{\text{thermoelastic} \\ \text{heat}}} + \underbrace{C_\epsilon\, \frac{dT}{dt}}_{\substack{\text{purely thermal} \\ \text{contribution}}} - \underbrace{\operatorname{div}\, (\mathbf{k}_{\scriptscriptstyle T} \cdot \boldsymbol{\nabla} T)}_{\substack{\text{conductive} \\ \text{heat flux}}} - \underbrace{\Theta}_{\substack{\text{heat} \\ \text{source}}} = 0\,, \tag{9.1.25}$$

which holds whether the heat capacity is variable, Eqn (9.1.4), or constant, Eqn (9.1.18).

The thermoelastic coupling term in the energy equation can be neglected under the conditions indicated in the following proposition:

Proposition 9.1 on the thermoelastic decoupling of the energy equation.

As indicated by Fig. 1.8.1 and Table 9.1.2, for many solids, the entities involved have the following orders of magnitude,

$$T = O(10^2)\, \mathrm{K}, \quad \mathbf{c}_{\scriptscriptstyle T} = O(10^{-4})\, \mathrm{K^{-1}}, \quad \mathbb{E} \leq O(10^9)\, \mathrm{Pa}, \quad C_\epsilon = O(10^6)\, \mathrm{J\, m^{-3}\, K^{-1}}\,. \tag{9.1.26}$$

Moreover, the total strain rate $d\boldsymbol{\epsilon}/dt$ and the thermal contribution $\mathbf{c}_{\scriptscriptstyle T}\, dT/dt$ to the strain rate may be assumed to be of the same order of magnitude. Therefore the ratio of the thermoelastic and purely thermal contributions is quite small,

$$\frac{T}{C_\epsilon}\, \mathbf{c}_{\scriptscriptstyle T} : \mathbb{E} : \mathbf{c}_{\scriptscriptstyle T} \leq O(10^{-3})\,. \tag{9.1.27}$$

Further in absence of heat source, and if the thermal conductivity is spatially homogeneous, the energy equation reduces to the canonical form of a parabolic equation,

$$\Big(\frac{\partial}{\partial t} - D_{\rm T}\,\frac{\partial^2}{\partial x^2}\Big)\,T = 0\,, \tag{9.1.28}$$

where the coefficient $D_{\rm T} = k_{\rm T}/C_\epsilon$ [unit : m^2/s] is called *thermal diffusivity*.

The same parabolic operator appears in many physical problems. In particular, for fluid flow across a porous medium governed by Darcy's law, it stems from the balance of mass: the coefficient $D = D_{\rm H}$ is then called *hydraulic diffusivity* and the unknown is a pressure or volumetric strain.

While thermal diffusivity involves thermal conductivity and heat capacity, hydraulic diffusivity of deformable tissues involves hydraulic permeability and elastic moduli. The time scale for equilibrium under seepage is equal to $L^2/D_{\rm H}$, L seepage distance, $D_{\rm H} = k_{\rm H}\,(\lambda + 2\,\mu)$ diffusivity, $k_{\rm H}$ hydraulic permeability, λ and μ Lamé moduli. Modifications of hydraulic diffusivity are indicators of modifications of the latter properties. In tumors, the ECM volume fraction is larger than in sound tissues, so that the bulk modulus is expected to be smaller and the shear modulus larger than normal. Detection of tumors by palpation is indeed based on spatially heterogeneous shear moduli. Secomb and El-Kareh [2001] suggest the following values: 1st Lamé modulus $\lambda = 4 \times 10^3\,\mathrm{Pa}$, shear modulus $\mu = 0.17 \times 10^3\,\mathrm{Pa}$, $k_{\rm H} = 3.1 \times 10^{-14}\,\mathrm{m}^2/\mathrm{Pa/s}$ leading to a diffusivity $D_{\rm H} = 1.4 \times 10^{-10}\,\mathrm{m}^2/\mathrm{s}$. For $L = 100\,\mu\mathrm{m}$ (typical spacing of micro-vessels), fluid seepage should be accounted for after about 71 s. For brain white matter, the hydraulic conductivity $k_{\rm H} = 750 \times 10^{-14}\,\mathrm{m}^2/\mathrm{Pa/s}$ is larger by two orders of magnitude, yielding a diffusivity $D_{\rm H} = 330 \times 10^{-10}\,\mathrm{m}^2/\mathrm{s}$ so that the characteristic time of diffusion over $100\,\mu\mathrm{m}$ falls down to a third of a second.

A parabolic operator governs also the diffusion of a chemical dissolved in a fluid which may itself be at rest or may move through a porous medium. Section 15.3 presents a comparative introduction to heat diffusion in a solid and to diffusion of a chemical convected by a fluid through a porous medium. A detailed example of chemical diffusion through a poroelastic medium is worked out in Section 13.13.

It might be worth to enlarge slightly the perspective and mention that diffusion may be seen as a transmission mode where the information moves at infinite speed. While the point of view is quite relevant to describe the physical aspects of the examples listed above, a more accurate description is desirable in particular circumstances, and especially when the dynamic response is of interest. Models along that vein are briefly introduced in Section 9.1.4.

Typical values of hydraulic and thermal diffusivities are displayed in Tables 7.3.1 and 9.1.2. The values listed in these tables are indicative only. Indeed, some properties may vary with temperature and display anisotropy. For example, thermal conductivity is larger across muscle fibers than along fibers. For a measurement technique based on pulse-decay method, the reader may consult M.M. Chen et al. [1981].

The thermal conductivities of a number of biological tissues have been collected by K.R. Holmes and posted on the website `http://users.ece.utexas.edu/~valvano/research/Thermal.pdf` (last visit: May 13, 2015). The mass density of soft tissues is often approximated to $1050\,\mathrm{kg/m}^3$ and their specific heat capacities c can be considered to increase linearly with their water content $w \in [0, 1]$, namely

$$c = 4.18 \times (0.40 + 0.60\,w) \quad [\text{unit : kJ/kg/K}]\,, \tag{9.1.29}$$

at physiological temperature.

The heat capacity per unit volume of a porous medium which is in local thermal equilibrium is equal to the spatial average of its counterparts over the constituents, say for a solid and a fluid,

$$C = n^{\rm s}\,C_{\rm s} + n^{\rm w}\,C_{\rm w}\,. \tag{9.1.30}$$

The thermal conductivity of the porous medium $k_{\rm T}$,

$$k_{\rm T} = \sum_{k=\rm s,w} n^k\,k_{{\rm T}k}\,, \tag{9.1.31}$$

is usually taken as the volume average of the thermal conductivities $k_{{\rm T}k}$ of the constituents. This arithmetic average assumes that heat flows in parallel in the constituents and the heat fluxes sum up. Still, the effective thermal conductivity is bounded by the arithmetic mean and the harmonic mean over constituents,

$$\sum_{k=\rm s,w} n^k\,k_{{\rm T}k} \geq \prod_{k=\rm s,w} (k_{{\rm T}k})^{n^k} \geq \frac{1}{\displaystyle\sum_{k=\rm s,w} \frac{n^k}{k_{{\rm T}k}}}\,. \tag{9.1.32}$$

Table 9.1.2: Indicative thermal properties at ambient (20 °C) or physiological (37.5 °C) temperature of some biological tissues, biomaterials, geomaterials and metals.

• Liquids have a higher coefficient of thermal expansion than solids, $\sim 10^{-3}$/K versus $\sim 10^{-5}$/K;
• Water has the next largest heat capacity among liquids, after ammonia. The energy necessary to increase by 1 °C the temperature of 1 kg of water is equivalent to the energy delivered by gravity when this mass falls by 416 m. Water is a poor conductor of heat or equivalently, it is a good insulator. Average heat capacity of human body is about[(4)] $c = 3.470 \times 10^3$ J/kg/K.
• The negative coefficient of thermal expansion of cornea is attributed to the fact that chloride binding decreases with temperature, which implies a decreases of swelling pressure, see Section 19.2.2.
• The water content of human soft tissues listed here ranges from 70 to 85%, except for fat, where it does not exceed 15 to 20%.

Material	Density [kg/m^3]	Heat Capacity C[10^6 J/m^3/K] c[10^3 J/kg/K]	Volumetric Thermal Expansion Coeff. [10^{-3}/K]	Thermal Conductivity [W/m/K]	Thermal Diffusivity [10^{-6} m^2/s]

In the harmonic mean, the constituents are thermally in series, while the geometric mean correspond to an intermediate constituent distribution.

The thermal conductivity k_{Ts} of most tissues is not far from the thermal conductivity k_{Tw} of water. The thermal conductivity of most solid constituents is one to five times that of water. On the other hand, the heat capacity of water is the next largest among liquids after ammonia. The averaging relations (9.1.30) and (9.1.31) are in strong contrast with Proposition 9.4 that implies the thermal expansion of the porous *skeleton* to be equal to its counterpart in the solid constituent, irrespective of the volume fractions.

Characteristic diffusion times (9.5.14) are inversely proportional to the diffusivity. Therefore typical diffusion processes in water and soft tissues take place in identical time windows, while they are about an order of magnitude faster in bones and geological materials, and about two to three orders of magnitude faster in metals.

9.1.4 Cattaneo's heat conductor

The energy equation for a heat conductor obeying Fourier's law is of a parabolic type, that is, temperature propagates at infinite speed. The thermoelastic models of Cattaneo [1948,1949,1958] and Green and Laws [1972] aim at describing temperature propagation at finite speed. Fundamental differences between partial differential equations of parabolic and hyperbolic types are exposed in Chapter 15.

Green and Laws [1972] formulate the entropy inequality with help of a dependent variable that is required to be equal to the temperature only at equilibrium. For a conductor, Fourier's heat law remains formally untouched but the thermal conductivity depends on both the temperature and its rate. The idea has been used by Green and Lindsay [1972] to formulate a thermoelastic model, whose dynamic response in a finite element framework has been examined by Prévost and Tao [1983].

In Cattaneo's model on the other hand, Fourier's law is modified so as to include a relaxation time. The short presentation below is a simple extension to deformable anisotropic solids of the formulation presented in Bowen [1989], p. 195, which was restricted to rigid conductors. According to the original idea of Müller [1967], to the set of state variables, namely strain $\boldsymbol{\epsilon}$ and temperature T, are added the temperature gradient $\mathbf{G} = \boldsymbol{\nabla} T$ and the heat flux $\mathbf{Q}$. The total entropy production,

$$\begin{aligned} T\hat{S}_{(\mathrm{i})} &= -\frac{dE}{dt} + \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} - S\,\frac{dT}{dt} - \mathbf{Q}\cdot\frac{\mathbf{G}}{T} \\ &= (\boldsymbol{\sigma} - \frac{\partial E}{\partial \boldsymbol{\epsilon}}) : \frac{d\boldsymbol{\epsilon}}{dt} - (S + \frac{\partial E}{\partial T})\,\frac{dT}{dt} - \frac{\partial E}{\partial \mathbf{G}}\cdot\frac{d\mathbf{G}}{dt} - \frac{\partial E}{\partial \mathbf{Q}}\cdot\frac{d\mathbf{Q}}{dt} - \mathbf{Q}\cdot\frac{\mathbf{G}}{T} \geq 0\,, \end{aligned} \tag{9.1.33}$$

should be positive. The constitutive equations (9.1.1) for the stress and entropy dispose of the first two terms on the left hand side of the above inequality. The free energy is assumed to be independent of the temperature gradient, but it depends on strain and temperature as in (9.1.3) or (9.1.17), and it also depends quadratically on the heat flux via a symmetric second order tensor $\mathbf{A}_{\mathrm{Cat}}$,

$$E(\boldsymbol{\epsilon}, T, \mathbf{Q}) = E_1(\boldsymbol{\epsilon}, T) + \frac{1}{2}\,\mathbf{Q}\cdot\mathbf{A}_{\mathrm{Cat}}\cdot\mathbf{Q}\,. \tag{9.1.34}$$

Moreover in this approach, the rate of thermal flux is a dependent variable, for which a constitutive equation is required, say

$$t_{\mathrm{Cat}}\,\frac{d\mathbf{Q}}{dt} + \mathbf{Q} = -\mathbf{k}_{\mathrm{T}}\cdot\mathbf{G}\,, \tag{9.1.35}$$

with t_{Cat} [unit : s] a characteristic relaxation time and $\mathbf{k}_{\mathrm{T}}$ [unit : W/m/K] the positive definite thermal conductivity tensor. Clearly Fourier's heat law appears as a limit case of (9.1.35), namely for $t_{\mathrm{Cat}} = 0$. Then the reduced entropy production,

$$T\hat{S}_{(\mathrm{i})} = \frac{1}{t_{\mathrm{Cat}}}\,\mathbf{Q}\cdot\mathbf{A}_{\mathrm{Cat}}\cdot\mathbf{Q} + \mathbf{Q}\cdot\big(\mathbf{A}_{\mathrm{Cat}} - \frac{t_{\mathrm{Cat}}}{T}\,\mathbf{k}_{\mathrm{T}}^{-1}\big)\cdot\frac{\mathbf{k}_{\mathrm{T}}}{t_{\mathrm{Cat}}}\cdot\mathbf{G} \geq 0\,, \tag{9.1.36}$$

is satisfied by setting $\mathbf{A}_{\mathrm{Cat}} = t_{\mathrm{Cat}}\,(T\,\mathbf{k}_{\mathrm{T}})^{-1}$ which is indeed positive definite.

The thermoelastic constitutive equation (9.1.5) for the stress is not modified while an additional nonlinear term contributes to the entropy,

$$\begin{bmatrix} \boldsymbol{\sigma} - \boldsymbol{\sigma}_0 \\ -(S - S_0) \end{bmatrix} = \begin{bmatrix} \mathbb{E} & -\mathbb{E} : \mathbf{c}_{\mathrm{T}} \\ -\mathbf{c}_{\mathrm{T}} : \mathbb{E} & -C_{0\epsilon}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ T - T_0 \end{bmatrix} - \frac{t_{\mathrm{Cat}}}{2\,T^2}\,\mathbf{Q}\cdot\mathbf{k}_{\mathrm{T}}^{-1}\cdot\mathbf{Q}\begin{bmatrix} 0 \\ 1 \end{bmatrix}. \tag{9.1.37}$$

A linearized energy equation is obtained by adding the production of mechanical entropy (9.1.23) and its time derivative multiplied by the relaxation time t_{Cat}, yielding with help of (9.1.35),

$$T\,\mathbf{c}_{\mathrm{T}} : \mathbb{E} : \Big(t_{\mathrm{Cat}}\,\frac{\partial^2\boldsymbol{\epsilon}}{\partial t^2} + \frac{\partial\boldsymbol{\epsilon}}{\partial t}\Big) + C_\epsilon\Big(t_{\mathrm{Cat}}\,\frac{\partial^2 T}{\partial t^2} + \frac{\partial T}{\partial t}\Big) - \mathrm{div}\,(\mathbf{k}_{\mathrm{T}}\cdot\boldsymbol{\nabla} T) - t_{\mathrm{Cat}}\,\frac{\partial\Theta}{\partial t} - \Theta = 0\,, \tag{9.1.38}$$

which, for $t_{\mathrm{Cat}} > 0$ and a positive definite thermal conductivity $\mathbf{k}_{\mathrm{T}}$, is recognized as a hyperbolic equation for the thermal field. The issue is considered in Section 11.3: the relaxation time t_{Cat} is shown to be linked to the speed of heat propagation and thermal diffusivity, Eqn (11.3.10).

9.1.5 Cauchy stress versus Eshelby stress

Thermo-(hyper)elastic constitutive equations are built starting from a vanishing mechanical dissipation (4.7.28), which for a solid takes the form

$$T\hat{S}_{(\mathrm{i},1)} = -\frac{dE}{dt} + \boldsymbol{\sigma}^{\mathrm{E}} : \frac{d\boldsymbol{\epsilon}}{dt} - S\,\frac{dT}{dt} = 0\,, \tag{9.1.39}$$

where $\boldsymbol{\sigma}^{\mathrm{E}} = \boldsymbol{\sigma} - E\,\mathbf{I}$ is Eshelby stress and the free energy per unit volume E is a function of strain $\boldsymbol{\epsilon}$ and temperature T. The point here is to explore the consequences of not neglecting the difference between Cauchy and Eshelby stresses.

Consider the quadratic free energy,

$$E = E_0 + \boldsymbol{\sigma}^{\mathrm{E}}_0 : \boldsymbol{\epsilon} - (S_0 + \boldsymbol{\epsilon} : \mathbb{E} : \mathbf{c}_{\mathrm{T}})\,(T - T_0) + \frac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - \frac{1}{2}\,\frac{C_{0\epsilon}}{T_0}\,(T - T_0)^2\,. \tag{9.1.40}$$

The constitutive equations for Eshelby stress and entropy in terms of the primary variables can be cast in the matrix form,

$$\begin{bmatrix} \boldsymbol{\sigma}^{\mathrm{E}} - \boldsymbol{\sigma}^{\mathrm{E}}_0 \\ -(S - S_0) \end{bmatrix} = \begin{bmatrix} \mathbb{E} & -\mathbb{E} : \mathbf{c}_{\mathrm{T}} \\ -\mathbf{c}_{\mathrm{T}} : \mathbb{E} & -C_{0\epsilon}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ T - T_0 \end{bmatrix}. \tag{9.1.41}$$

Since the free energy is quadratic with respect to the primary variables, Eshelby stress and entropy are affine functions of the latter. On the other hand, unlike Eshelby stress, Cauchy stress $\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\mathrm{E}} + E\,\mathbf{I}$ is quadratic with respect to the primary variables.

The energy equation differs from the linearized analysis of Section 9.1.3. Indeed, the balance of energy,

$$\frac{dU}{dt} + U\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt} - \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} + \operatorname{div}\,\mathbf{Q} - \Theta = 0\,, \tag{9.1.42}$$

and the dissipation,

$$\begin{aligned} T\hat{S}_{(\mathrm{i},1)} &= -\frac{dE}{dt} - E\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt} + \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} - S\,\frac{dT}{dt} \\ &= T\,\frac{dS}{dt} + TS\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt} + \operatorname{div}\,\mathbf{Q} - \Theta\,, \end{aligned} \tag{9.1.43}$$

include an additional term so that the energy equation becomes

$$\underbrace{T\,\mathbf{c}_{\mathrm{T}} : \mathbb{E} : \frac{d\boldsymbol{\epsilon}}{dt}}_{\substack{\text{thermoelastic}\\ \text{heat}}} + \underbrace{C_\epsilon\,\frac{dT}{dt}}_{\substack{\text{purely thermal}\\ \text{contribution}}} + \underbrace{TS\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt}}_{\substack{\text{nonlinear}\\ \text{term}}} - \underbrace{\operatorname{div}\,(\mathbf{k}_{\mathrm{T}} \cdot \boldsymbol{\nabla} T)}_{\substack{\text{conductive}\\ \text{heat flux}}} - \underbrace{\Theta}_{\substack{\text{heat}\\ \text{source}}} = 0\,. \tag{9.1.44}$$

9.1.6 Free energy versus Massieu function

Let us recall again the expression of mechanical dissipation (4.7.28) for a solid, namely

$$T\hat{S}_{(\mathrm{i},1)} = -\frac{dE}{dt} + (\boldsymbol{\sigma} - E\,\mathbf{I}) : \frac{d\boldsymbol{\epsilon}}{dt} - S\,\frac{dT}{dt} = 0\,, \tag{9.1.45}$$

where the free energy per unit volume E is a function of strain $\boldsymbol{\epsilon}$ and temperature T. Constitutive equations result from the expression (9.1.45), namely

$$\boldsymbol{\sigma} - E\,\mathbf{I} = \frac{\partial E}{\partial \boldsymbol{\epsilon}}, \quad S = -\frac{\partial E}{\partial T}, \quad U = E - T\,\frac{\partial E}{\partial T}\,. \tag{9.1.46}$$

Partial or total Legendre transforms allow to change the set of primary (independent) variables. Examples are given in Section 14.8.

The issue discussed in this section circles on the use of either $T\,\hat{S}_{(\mathrm{i},1)} \geq 0$ or $\hat{S}_{(\mathrm{i},1)} \geq 0$ to ensure the mechanical entropy production to be non negative. The difference seems a priori harmless for solids, or for mixtures which are in local thermal equilibrium. On the other hand, the question will be more acute for mixtures which are *not* in local

thermal equilibrium. Indeed, the entropy production of the mixture is the sum of the individual contributions and not the sum of coldness weighted contributions.

If the entropy production is not multiplied by T, the potential that naturally appears is the Massieu function associated with free energy, Bowen and Garcia [1970],

$$\Xi = -\frac{E}{T} = S - \frac{U}{T}\,, \tag{9.1.47}$$

which depends on strain and coldness $\nu = 1/T$. Indeed,

$$\hat{S}_{(\mathrm{i},1)} = \frac{d\Xi}{dt} + (\nu\,\boldsymbol{\sigma} + \Xi\,\mathbf{I}) : \frac{d\boldsymbol{\epsilon}}{dt} + U\,\frac{d\nu}{dt} = 0\,, \tag{9.1.48}$$

which yields the stress, internal energy U and entropy S, namely

$$\boldsymbol{\sigma} = -\frac{\Xi}{\nu}\,\mathbf{I} - \frac{1}{\nu}\,\frac{\partial \Xi}{\partial \boldsymbol{\epsilon}}, \quad U = -\frac{\partial \Xi}{\partial \nu}, \quad S = \Xi - \nu\frac{\partial \Xi}{\partial \nu}\,. \tag{9.1.49}$$

For example, an expansion to second order in terms of strain $\boldsymbol{\epsilon}$ and coldness $\Delta\nu = \nu - \nu_0$ starting from the reference $\boldsymbol{\epsilon} = \mathbf{0}$ and $\nu = \nu_0$,

$$\Xi = \Xi_0 - \alpha_\mathrm{s}\,\Delta\nu - \sigma_\mathrm{s}\,\nu_0\,\mathrm{tr}\,\boldsymbol{\epsilon} + \frac{1}{2}\,v_\mathrm{s}\,\frac{(\Delta\nu)^2}{\nu_0} + \tau_\mathrm{s}\,\Delta\nu\,\mathrm{tr}\,\boldsymbol{\epsilon} - \frac{\nu_0}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon}\,, \tag{9.1.50}$$

with α_s, v_s, σ_s and τ_s [unit : Pa] material constants, yields

$$\begin{aligned} U &= \alpha_\mathrm{s} - v_\mathrm{s}\,\frac{\Delta\nu}{\nu_0} - \tau_\mathrm{s}\,\mathrm{tr}\,\boldsymbol{\epsilon}\,, \\ S &= \Xi_0 + \alpha_\mathrm{s}\,\nu_0 - \nu_0\,(\tau_\mathrm{s} + \sigma_\mathrm{s})\,\mathrm{tr}\,\boldsymbol{\epsilon} - \frac{1}{2}\,\frac{v_\mathrm{s}}{\nu_0}\,(\nu^2 - \nu_0^2) - \frac{\nu_0}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon}\,. \end{aligned} \tag{9.1.51}$$

The heat capacity at constant strain and latent heat of deformation may be deduced from the resulting expression,

$$T\,dS = \frac{v_\mathrm{s}}{\nu_0}\,\frac{dT}{T^2} - \frac{T}{T_0}\,\big(\mathbb{E} : \boldsymbol{\epsilon} + (\tau_\mathrm{s} + \sigma_\mathrm{s})\,\mathbf{I}\big) : d\boldsymbol{\epsilon}\,. \tag{9.1.52}$$

A 2nd order expansion of the stress results as,

$$\begin{aligned} \boldsymbol{\sigma} &= \frac{\nu_0}{\nu}\,\Big(\big(\underbrace{\sigma_\mathrm{s} - \frac{\Xi_0}{\nu_0}}_{\sigma_0}\big)\,\mathbf{I} + \mathbb{E} : \boldsymbol{\epsilon} + \sigma_\mathrm{s}\,\mathrm{tr}\,\boldsymbol{\epsilon}\,\mathbf{I} + \frac{\Delta\nu}{\nu_0}\,(\alpha_\mathrm{s} - \tau_\mathrm{s})\,\mathbf{I} \\ &\quad + \big(\tfrac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - \tfrac{1}{2}\,v_\mathrm{s}\,\tfrac{(\Delta\nu)^2}{\nu_0^2} - \tau_\mathrm{s}\,\tfrac{\Delta\nu}{\nu_0}\,\mathrm{tr}\,\boldsymbol{\epsilon}\big)\,\mathbf{I}\Big) \\ &= \sigma_0\,\mathbf{I} + \mathbb{E} : \boldsymbol{\epsilon} + \sigma_\mathrm{s}\,\mathrm{tr}\,\boldsymbol{\epsilon}\,\mathbf{I} + \frac{\Delta\nu}{\nu_0}\,(\alpha_\mathrm{s} - \tau_\mathrm{s} - \sigma_0)\,\mathbf{I} \\ &\quad + \Big(\tfrac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - \big(\alpha_\mathrm{s} - \tau_\mathrm{s} + \tfrac{1}{2}\,v_\mathrm{s}\big)\,\frac{(\Delta\nu)^2}{\nu_0^2}\Big)\,\mathbf{I} - \frac{\Delta\nu}{\nu_0}\,\big(\mathbb{E} : \boldsymbol{\epsilon} + (\tau_\mathrm{s} + \sigma_\mathrm{s})\,\mathrm{tr}\,\boldsymbol{\epsilon}\,\mathbf{I}\big)\,. \end{aligned} \tag{9.1.53}$$

Clearly, the structure of the thermodynamic functions and stress have quite different features than when the starting potential is the free energy.

9.2 Thermoelastic heat, stored energy and dissipated energy

The notions of external, thermoelastic and inelastic heats, plastic work and recoverable and irrecoverable stored energies are illustrated through a one-dimensional thermomechanical model.

9.2.1 A thermomechanical model including an internal variable

The model below developed by Rosakis et al. [2000] assumes small strains and it is one-dimensional. Let E and S be the free energy and entropy per unit current or reference volume. The state variables are the elastic strain $\epsilon^{\rm e}$, an internal variable ξ that describes some physical property of the material and the temperature T,

$$\mathcal{V} = \{\epsilon^{\rm e},\, \xi,\, T\}\,. \tag{9.2.1}$$

The exact interpretation of the elastic strain, as opposed to the total strain, need not to be specified here. Suffices to say for now that it is the entity that is involved in the stress-strain relation. Then, as a consequence of Clausius-Duhem inequality (4.7.28),

$$\sigma = \frac{\partial E}{\partial \epsilon^{\rm e}}, \quad S = -\frac{\partial E}{\partial T}\,. \tag{9.2.2}$$

The specific heat capacity at constant strain and internal variable is therefore equal to,

$$C_v = C_v(\mathcal{V}) = -T\,\frac{\partial^2 E}{\partial T^2}\,. \tag{9.2.3}$$

Three assumptions are adopted in order to obtain a minimal framework:

Assumption 9.1: the heat capacity C_v is independent of the internal variable ξ.

Then

$$\frac{\partial C_v}{\partial \xi} = 0 \Rightarrow \frac{\partial E}{\partial \xi} = a(\epsilon^{\rm e}, \xi)\,T + b(\epsilon^{\rm e}, \xi)\,, \tag{9.2.4}$$

where $a(\epsilon^{\rm e}, \xi)$ and $b(\epsilon^{\rm e}, \xi)$ are arbitrary functions of their arguments.

Assumption 9.2: the elastic moduli are independent of the internal variable ξ, i.e. $\partial\sigma/\partial\xi = 0$.

Since $\partial\sigma/\partial\xi = \partial(\partial E/\partial\epsilon^{\rm e})/\partial\xi = \partial(\partial E/\partial\xi)/\partial\epsilon^{\rm e}$, then, with help of (9.2.2), $\partial E/\partial\xi$ is independent of $\epsilon^{\rm e}$. This condition restricts (9.2.4) further:

$$\frac{\partial \sigma}{\partial \xi} = 0 \Rightarrow \frac{\partial E}{\partial \xi} = a(\xi)\,T + b(\xi)\,. \tag{9.2.5}$$

Thus

$$E(\mathcal{V}) = E_1(\epsilon^{\rm e}, T) + \overbrace{U_0(\xi) - T\,S_0(\xi)}^{\substack{\text{stored free energy}\\ \text{of cold work}}}\,, \quad S(\mathcal{V}) = -\frac{\partial E_1}{\partial T}(\epsilon^{\rm e}, T) + S_0(\xi)\,. \tag{9.2.6}$$

Rosakis et al. [2000] provide experimental determination of the energy of cold work for two metals in terms of an internal variable, taken as the plastic strain.

Assumption 9.3: as a further restriction, the heat capacity C_v is constant and the stress depends linearly on the strain.

Then

$$E(\mathcal{V}) = U_0(\xi) - T_0\,S_0(\xi) - (S_0(\xi) + \mu\,\epsilon^{\rm e} c_{\rm T}\,)\,(T - T_0) + \frac{\mu}{2}\,(\epsilon^{\rm e})^2 + C_v\,(T - T_0) - C_v\,T\,{\rm Ln}\,\frac{T}{T_0}\,, \tag{9.2.7}$$

from which follows

$$\sigma = \mu\,\big(\epsilon^{\rm e} - c_{\rm T}\,(T - T_0)\big)\,, \tag{9.2.8}$$

and

$$S(\mathcal{V}) = S_0(\xi) + \mu\,c_{\rm T}\epsilon^{\rm e} + C_v\,{\rm Ln}\,\frac{T}{T_0}, \quad U(\mathcal{V}) = U_0(\xi) + \mu\,c_{\rm T}\,T_0\,\epsilon^{\rm e} + \frac{\mu}{2}\,(\epsilon^{\rm e})^2 + C_v\,(T - T_0)\,, \tag{9.2.9}$$

with μ the constant elastic modulus and $c_{\rm T}$ the constant coefficient of thermal expansion.

9.2.2 Plastic work and inelastic heat

The strain is decomposed into an elastic and a plastic part, $\boldsymbol{\epsilon} = \boldsymbol{\epsilon}^{\mathrm{e}} + \boldsymbol{\epsilon}^{\mathrm{p}}$. From the mechanical part of the linearized internal entropy production (the contributions due to diffusion and mass transfer are excluded here),

$$T\,\hat{S}_{(\mathrm{i},1)} = -\frac{dE}{dt} + \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} - S\,\frac{dT}{dt} \geq 0\,, \tag{9.2.10}$$

follow the constitutive equations,

$$\boldsymbol{\sigma} = \frac{\partial E}{\partial \boldsymbol{\epsilon}^{\mathrm{e}}}, \quad S = -\frac{\partial E}{\partial T}\,, \tag{9.2.11}$$

and the reduced inequality,

$$T\,\hat{S}_{(\mathrm{i},1)} = \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}^{\mathrm{p}}}{dt} - \frac{dE}{d\xi}\,\frac{d\xi}{dt}\,. \tag{9.2.12}$$

The linearized balance of energy may be expressed in terms of the internal energy per unit volume U, heat flux $\mathbf{Q}$ and heat source Θ,

$$\frac{dU}{dt} - \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} + \mathrm{div}\ \mathbf{Q} - \Theta = 0\,. \tag{9.2.13}$$

The energy equation may also be phrased in terms of the free energy $E = U - T\,S$, and the resulting expression of $-dE/dt + \boldsymbol{\sigma} : d\boldsymbol{\epsilon}/dt$ inserted in (9.2.10) yields an alternative form of the dissipation,

$$T\,\hat{S}_{(\mathrm{i},1)} = T\,\frac{dS}{dt} + \mathrm{div}\ \mathbf{Q} - \Theta\,. \tag{9.2.14}$$

Comparison with (9.2.12) results in the relation,

$$-\,\mathrm{div}\ \mathbf{Q} + \Theta + \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}^{\mathrm{p}}}{dt} - \frac{dE}{d\xi}\,\frac{d\xi}{dt} \;=\; T\,\frac{dS}{dt}\,, \tag{9.2.15}$$

that, using (9.2.11), can be split in physically meaningful parts,

$$C_v\,\frac{dT}{dt} = \overbrace{-\mathrm{div}\ \mathbf{Q} + \Theta}^{\text{external heat}} + \overbrace{\underbrace{\boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}^{\mathrm{p}}}{dt}}_{\substack{\text{plastic}\\ \text{power } dW^{\mathrm{pl}}/dt}} + (T\,\frac{\partial^2 E}{\partial T \partial \xi} - \frac{\partial E}{\partial \xi})\,\frac{d\xi}{dt}}^{\text{inelastic heat } dQ^{\mathrm{pl}}/dt} + \overbrace{T\,\frac{\partial \boldsymbol{\sigma}}{\partial T} : \frac{d\boldsymbol{\epsilon}^{\mathrm{e}}}{dt}}^{\text{thermoelastic heat}}\,. \tag{9.2.16}$$

For the free energy (9.2.7), this expression becomes, Rosakis et al. [2000],

$$C_v\,\frac{dT}{dt} \;=\; \overbrace{-\mathrm{div}\ \mathbf{Q} + \Theta}^{\text{external heat}} + \overbrace{\underbrace{\boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}^{\mathrm{p}}}{dt}}_{\substack{\text{plastic}\\ \text{power } dW^{\mathrm{pl}}/dt}} - \frac{\partial U_0}{\partial \xi}\,\frac{d\xi}{dt}}^{\text{inelastic heat } dQ^{\mathrm{pl}}/dt} + \overbrace{T\,\frac{\partial \boldsymbol{\sigma}}{\partial T} : \frac{d\boldsymbol{\epsilon}^{\mathrm{e}}}{dt}}^{\text{thermoelastic heat}}\,. \tag{9.2.17}$$

For many metals, the thermoelastic heat is negligible with respect to the inelastic heat. With $\xi = \boldsymbol{\epsilon}^{\mathrm{p}}$, Rosakis et al. [2000] provide measurements of the ratio $\beta = dQ^{\mathrm{pl}}/dW^{\mathrm{pl}}$ of inelastic versus plastic heats: they find β around 0.5 for alumina and 0.8-0.9 for α-titanium. For more recent measurements using infrared thermography, see Badulescu et al. [2011].

Another viewpoint:

Another perspective consists in viewing the rate of internal entropy as dissipated power, e.g., by introducing a potential of dissipation $\Omega \geq 0$. The work done by the plastic strain rate is then the sum of the dissipated heat and a contribution due to the stored energy,

$$\boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}^{\mathrm{p}}}{dt} = \overbrace{\Omega}^{\geq 0} + \overbrace{\frac{dE}{d\xi}\,\frac{d\xi}{dt}}^{\geq 0 \text{ or } \leq 0}\,. \tag{9.2.18}$$

This point of view is ambiguous when one assumes for example $\xi = \boldsymbol{\epsilon}^{\mathrm{p}}$, because the plastic strain rate appears on both the lhs and rhs. However, the models below precise the recoverable nature of the stored energy and give a physical illustration of the internal variables ξ.

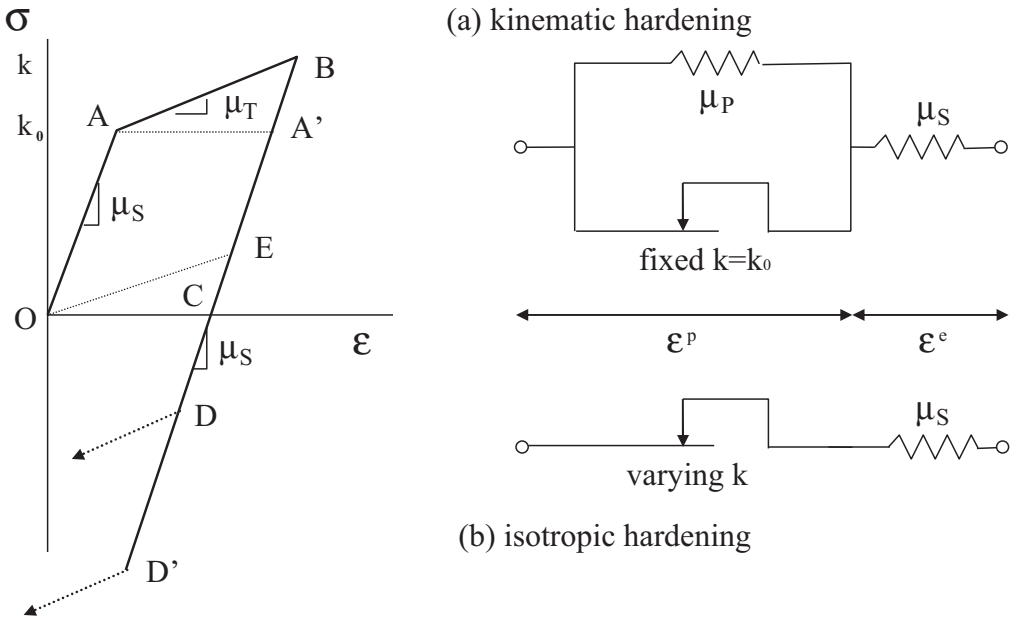

Fig. 9.2.1: Kinematic and isotropic hardenings. Stored energy AA'B=OCE, plastic work OEBA.

9.2.3 Plastic work, recoverable and irrecoverable stored energies

The issues below disregard temperature effects on the mechanical behavior and are one-dimensional. They consider elastic-plastic models, where $\epsilon = \epsilon^{\rm e} + \epsilon^{\rm p}$.

9.2.3.1 Kinematic hardening

Here $\xi = \epsilon^{\rm p}$. Let

$$E = \overbrace{\tfrac{1}{2}\,\mu_S\,(\epsilon^{\rm e})^2}^{\text{elastic energy}} + \overbrace{\tfrac{1}{2}\,\mu_P\,(\epsilon^{\rm p})^2}^{\text{recoverable stored energy}}\,, \tag{9.2.19}$$

where $\mu_S > 0$ and $\mu_P \geq 0$ are the constant elastic modulus and plastic hardening modulus. Thus,

$$\sigma = \frac{\partial E}{\partial \epsilon^{\rm e}} = \mu_S\,\epsilon^{\rm e}, \quad \hat{S}_{\rm (i)} = \sigma\,\frac{d\epsilon^{\rm p}}{dt} - \frac{\partial E}{\partial \xi}\,\frac{d\xi}{dt} = (\sigma - \mu_P\,\epsilon^{\rm p})\,\frac{d\epsilon^{\rm p}}{dt} \geq 0\,. \tag{9.2.20}$$

In the framework of the generalized normality rule, Chapter 22, the inequality above is ensured by the existence of a convex function $f = f(\sigma - \mu_P\,\epsilon^{\rm p})$ defined on a domain that contains the origin $\sigma - \mu_P\,\epsilon^{\rm p} = 0$ if

$$\frac{d\boldsymbol{\epsilon}^{\rm p}}{dt} = \frac{d\lambda}{dt}\,\frac{\partial f}{\partial(\sigma - \mu_P\,\epsilon^{\rm p})} = \frac{d\lambda}{dt}\,\frac{\partial f}{\partial \sigma}, \quad \frac{d\lambda}{dt} \geq 0\,, \tag{9.2.21}$$

the derivative being estimated at the current point $\sigma - \mu_P\,\epsilon^{\rm p}$. Let

$$f(\sigma - \mu_P\,\epsilon^{\rm p}) = |\sigma - \mu_P\,\epsilon^{\rm p}| - k_0 \leq 0\,, \tag{9.2.22}$$

be the convex of plasticity, with k_0 the constant plastic threshold.

In order to interpret the energies, let us consider the scheme shown in Fig. 9.2.1. The material is subjected to a load cycle controlled in stress. For simplicity of explanation, the unloading point B is assumed to be such that unloading from B to C occurs elastically. The plastic strain at point B, or C, is denoted by $\epsilon^{\rm p}$.

The following relations are easily obtained:

- stress-strain relation:

$$\epsilon = \epsilon^{\rm e} + \epsilon^{\rm p}; \quad \frac{d\epsilon^{\rm e}}{d\sigma} = \frac{1}{\mu_S}; \quad \frac{d\epsilon^{\rm p}}{d\sigma} = \frac{1}{\mu_P}; \quad \frac{d\epsilon}{d\sigma} = \frac{1}{\mu_T} = \frac{1}{\mu_S} + \frac{1}{\mu_P} \quad \text{on AB}\,; \tag{9.2.23}$$

$$d\epsilon = \frac{d\epsilon}{d\sigma}\,\frac{d\sigma}{d\epsilon^{\rm p}} \quad \Rightarrow \quad \epsilon = \epsilon_A + (1+\frac{\mu_P}{\mu_S})\,\epsilon^{\rm p} \quad \text{on AB}\,; \tag{9.2.24}$$

- work done by the spring $\mu_{\rm P}$: area AA′B = OCE :

$$W_{\rm r} = \int_0^{\epsilon^{\rm p}} (\sigma - k_0)\, d\epsilon^{\rm p} = \int_0^{\epsilon^{\rm p}} \mu_T\,(\epsilon - \epsilon_A)\, d\epsilon^{\rm p} = \int_0^{\epsilon^{\rm p}} \mu_P\,\epsilon^{\rm p}\, d\epsilon^{\rm p} = \frac{1}{2}\,\mu_P\,(\epsilon^{\rm p})^2\,; \tag{9.2.25}$$

- work done by the slider : area OEBA = OCA′A :

$$W_{\rm nr} = \int_0^{\epsilon^{\rm p}} k_0\, d\epsilon^{\rm p} = k_0\,\epsilon^{\rm p}\,. \tag{9.2.26}$$

Thus the stored energy is the work done by the spring μ_P. It begins to be recovered upon unloading when the path hits the plastic limit at E, with $|\sigma_E - \sigma_B| = 2\,k_0$.

9.2.3.2 Isotropic hardening

Let

$$E = \overbrace{\tfrac{1}{2}\,\mu_S\,(\epsilon^{\rm e})^2}^{\text{elastic energy}} + \overbrace{E_h(\xi)}^{\substack{\text{irrecoverable}\\ \text{stored energy}}}\,, \tag{9.2.27}$$

where $\mu_S > 0$ is the constant elastic modulus. Thus,

$$\sigma = \frac{\partial E}{\partial \epsilon^{\rm e}} = \mu_S\,\epsilon^{\rm e}, \quad \hat{S}_{\rm (i)} = \sigma\,\frac{d\epsilon^{\rm p}}{dt} - \frac{\partial E}{\partial \xi}\,\frac{d\xi}{dt} = \sigma\,\frac{d\epsilon^{\rm p}}{dt} + A\,\frac{d\xi}{dt} \geq 0, \quad A = -\frac{\partial E_h}{\partial \xi}\,. \tag{9.2.28}$$

Again, the inequality above is ensured by the existence of a convex function $f = f(\sigma,\,\xi)$ defined on a domain that contains the origin $\sigma = 0$,

$$f(\sigma,\xi) = |\sigma| - k \leq 0, \quad k = k_0 - A\,, \tag{9.2.29}$$

with k_0 the initial plastic threshold and k the current plastic threshold, if

$$\frac{d\epsilon^{\rm p}}{dt} = \frac{d\lambda}{dt}\,\frac{\partial f}{\partial \sigma}, \quad \frac{d\xi}{dt} = \frac{d\lambda}{dt}\,\frac{\partial f}{\partial A} = \frac{d\lambda}{dt}, \quad \frac{d\lambda}{dt} \geq 0\,, \tag{9.2.30}$$

the derivative being estimated at the current point (σ, ξ). Thus

$$\frac{d\epsilon^{\rm p}}{dt} = \frac{d\lambda}{dt}\,\frac{\partial f}{\partial \sigma} = \frac{d\lambda}{dt}\,\frac{\sigma}{|\sigma|}, \quad \frac{d\xi}{dt} = \frac{d\lambda}{dt} \Rightarrow \xi = \int_0^{\epsilon^{\rm p}} d|\epsilon^{\rm p}|\,. \tag{9.2.31}$$

The interpretations of the stored energy and plastic work are identical to the kinematic model, as long as the points where the unloading path hits the plastic yield limit correspond both to stress of the same sign (negative if the loading involves traction, and conversely positive if the loading involves compression). The point D' at which plastic loading resumes upon unloading is still such that $|\sigma'_D - \sigma_B| = 2\,k$. But now k has increased, assuming the plastic modulus $\mu_P = d^2E_h/d\xi^2$ positive (plastic hardening) or zero (perfect plasticity) rather than negative (plastic softening). If μ_P is constant, then $E_h = \frac{1}{2}\mu_P\,\xi^2$.

However, there are differences with respect to kinematic hardening. There the stored energy was due to the strain in the spring μ_P, and, upon unloading, the stored energy could be recovered. Such is not the case for the isotropic model above, due to the fact that the threshold of the slider increases, for $\mu_P \geq 0$ constant. In other words, the stored energy is connected with modifications of the microstructure of the model. It can be recovered if the initial microstructure can be recovered as well.

9.3 Anisotropic thermo-poroelasticity: mechanics, transport, energy

This section considers a mixture composed of an anisotropic solid skeleton $k = \rm s$ circulated by one or several fluid species $k \in \mathcal{K}^{**}$. These species obey

Proposition 9.2 on local thermal equilibrium (LTE).

All species have identical temperature,

$$T_k = T, \quad k \in \mathcal{K}\,. \tag{9.3.1}$$

The property is referred to as *local* thermal equilibrium in order to emphasize the fact that it holds at the level of a representative elementary volume.

9.3.1 Thermodynamic derivation

For convenience, the mechanical entropy productions are now expressed in the reference configuration. The expression for the solid constituent $k = \mathrm{s}$ has the form $(7.2.28)_1$ but it does not involve the chemical potential term. Upon multiplication by $T \det \mathbf{F}$, the mechanical entropy productions $(7.2.28)_1$ are modified to

$$\begin{aligned} T\underline{\hat{S}}^{\mathrm{s}}_{(\mathrm{i},1)} &= -\frac{d}{dt}(m^{\mathrm{s}} e_{\mathrm{s}}) + \boldsymbol{\tau}^{\mathrm{s}} : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} - m^{\mathrm{s}} s_{\mathrm{s}} \frac{dT}{dt}\,, \\ T\underline{\hat{S}}^{k}_{(\mathrm{i},1)} &= -\frac{d}{dt}(m^{k} e_{k}) + \boldsymbol{\tau}^{k} : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} + \mu_k \frac{dm^k}{dt} - m^k s_k \frac{dT}{dt}\,. \end{aligned} \tag{9.3.2}$$

The mechanical entropy production of the mixture,

$$T\underline{\hat{S}}_{(\mathrm{i},1)} = -\frac{d\underline{E}}{dt} + \boldsymbol{\tau} : \boldsymbol{\nabla}\mathbf{v}_{\mathrm{s}} + \sum_{k\in\mathcal{K}^{**}} \mu_k \frac{dm^k}{dt} - \underline{S}\,\frac{dT}{dt}\,, \tag{9.3.3}$$

expressed in terms of the free energy per reference volume of the mixture,

$$\underline{E} = \underline{E}(\boldsymbol{\epsilon},\ \cup_{k\,\in\,\mathcal{K}^{**}}\ m^k,\ T) = \sum_{k\,\in\,\mathcal{K}} m^k\, e_k\,, \tag{9.3.4}$$

is set to zero. Constitutive equations result for the Kirchhoff stress $\boldsymbol{\tau}$, the chemical potentials μ_k of the fluid species, and the entropy of the mixture $\underline{S}$,

$$\boldsymbol{\tau} = \boldsymbol{\tau}^{\mathrm{s}} + \sum_{k\in\mathcal{K}^{**}} \boldsymbol{\tau}^k = \frac{\partial \underline{E}}{\partial \boldsymbol{\epsilon}}\,; \quad \mu_k = \frac{\partial \underline{E}}{\partial m^k}, \quad k \in \mathcal{K}^{**}; \quad \underline{S} = \sum_{k\,\in\,\mathcal{K}} m^k\, s_k = -\frac{\partial \underline{E}}{\partial T}\,. \tag{9.3.5}$$

If one wishes to change the primary variables, one can

- either perform a partial or total Legendre transform at the mixture level by changing the strain energy function,
- or perform the corresponding manipulations directly on the mechanical entropy production of each species.

For example, in order to recover the stress and fluid pressures as primary variables, the appropriate Legendre transform reads,

$$\underline{E} \longrightarrow \underline{\mathcal{W}} = -\underline{E} + \sum_{k\in\mathcal{K}} \boldsymbol{\tau}^k : \boldsymbol{\epsilon} + \sum_{k\in\mathcal{K}^{**}} \mu_k\, m^k\,. \tag{9.3.6}$$

The mechanical entropy productions (9.3.2) are modified to

$$\begin{aligned} T\underline{\hat{S}}^{\mathrm{s}}_{(\mathrm{i},1)} &= \frac{d}{dt}(-m^{\mathrm{s}} e_{\mathrm{s}} + \boldsymbol{\tau}^{\mathrm{s}} : \boldsymbol{\epsilon}) \qquad -\frac{d\boldsymbol{\tau}^{\mathrm{s}}}{dt} : \boldsymbol{\epsilon} - m^{\mathrm{s}} s_{\mathrm{s}} \frac{dT}{dt}\,, \\ T\underline{\hat{S}}^{k}_{(\mathrm{i},1)} &= \frac{d}{dt}(-m^k e_k + \boldsymbol{\tau}^k : \boldsymbol{\epsilon} + \mu_k\, m^k) \quad -\frac{d\boldsymbol{\tau}^{k}}{dt} : \boldsymbol{\epsilon} - v^k \frac{dp_k}{dt}, \quad k \in \mathcal{K}^{**}\,. \end{aligned} \tag{9.3.7}$$

Summing up these contributions and setting the resulting mechanical entropy production of the mixture to zero provides constitutive equations in the format,

$$\boldsymbol{\epsilon} = \frac{\partial \underline{\mathcal{W}}}{\partial \boldsymbol{\tau}}\,; \quad v^k = \frac{\partial \underline{\mathcal{W}}}{\partial p_k}, \quad k \in \mathcal{K}^{**}; \quad \underline{S}^{\mathrm{s}} = m^{\mathrm{s}} s_{\mathrm{s}} = \frac{\partial \underline{\mathcal{W}}}{\partial T}\,. \tag{9.3.8}$$

9.3.2 Linear thermo-poroelasticity

The analysis is now restricted to linear thermo-poroelastic materials, with a single fluid constituent. The current configuration is taken as reference. The poroelastic part of the constitutive equations is given by (7.4.11), with however a slight modification indicated by (7.4.8) due to the fact that the strain measure is now the volume content, and not the (dimensionless) mass content. The thermo-poroelastic constitutive equations can be cast in the matrix form,

$$\begin{bmatrix} \boldsymbol{\epsilon} \\ v^{\mathrm{w}} - v^{\mathrm{w}}_0 \\ S^{\mathrm{s}} - S^{\mathrm{s}}_0 \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{-1} & \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\mathrm{w}} & \mathbf{c}_{\mathrm{T}} \\ \boldsymbol{\alpha}_{\mathrm{w}} : \mathbb{E}^{-1} & \mathbf{I} : \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\mathrm{w}}/S - n^{\mathrm{w}}/K_{\mathrm{w}} & n^{\mathrm{w}}\,\mathbf{I} : \mathbf{c}_{\mathrm{T}} \\ \mathbf{c}_{\mathrm{T}} & n^{\mathrm{w}}\,\mathbf{I} : \mathbf{c}_{\mathrm{T}} & C^{\mathrm{s}}_{\sigma p}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\sigma} \\ p_{\mathrm{w}} \\ T - T_0 \end{bmatrix}. \tag{9.3.9}$$

Here $\mathbf{c}_{\mathrm{T}}$ [unit : K^{-1}] denotes the thermal expansion tensor of the drained porous medium, and $C^{\mathrm{s}}_{\sigma p}$ [unit : $\mathrm{J/m^3/K}$] is the *apparent heat capacity* of the solid, at constant stress and fluid pressure, per unit volume of porous medium, i.e., heat capacity times volume fraction of the solid.

The first line of the matrix form is motivated by the effective stress introduced in (9.3.10), the strain coming into picture now being the elastic strain, that is, the total strain minus the thermal expansion,

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\mathrm{w}}\,\boldsymbol{\alpha}_{\mathrm{w}} = \mathbb{E} : \big(\boldsymbol{\epsilon} - \mathbf{c}_{\mathrm{T}}\,(T - T_0)\big)\,, \tag{9.3.10}$$

with $\boldsymbol{\alpha}_{\mathrm{w}}$ defined by (7.4.14).

The format and notations used to cast the thermo-poroelastic constitutive coefficients appearing in the third line and column of the matrix are now justified. The identification procedure uses the following property:

Proposition 9.3 on homogeneous deformation under purely thermal loading.

For a purely thermal loading, i.e. $\Delta T \neq 0$ while the total stress and pressures vanish, $\boldsymbol{\sigma} = \mathbf{0}$, $p_k = 0$, $k \in \mathcal{K}^{**}$, the deformation should be homogeneous throughout the phases: the contribution of each phase is proportional to its volume fraction, $\Delta v^k = n^k \operatorname{tr} \boldsymbol{\epsilon}$, $k \in \mathcal{K}$.

The above proposition does not violate the strain averaging proposition 7.1. In fact, since the deformation is homogeneous, the strain in all species is equal to the strain of the solid skeleton, i.e. $\operatorname{tr} \boldsymbol{\epsilon}_k = \operatorname{tr} \boldsymbol{\epsilon}$, and the strain averaging relation trivially follows from the constraint (7.1.1). In addition, the identification of the thermal expansion tensor of the solid skeleton uses the property epitomized by Proposition 9.4 below. Indeed, under the above purely thermal loading, i.e. all intrinsic and apparent stresses and pressures vanish, the effective strain of the solid constituent given by (7.2.14) and (7.2.15) vanishes, namely $\boldsymbol{\epsilon}_{\mathrm{s}} = \mathbf{c}_{\mathrm{Ts}}\,\Delta T$, while the strain of the porous medium follows from (9.3.9) as $\boldsymbol{\epsilon} = \mathbf{c}_{\mathrm{T}}\,\Delta T$. The proposition follows from the fact that, for purely thermal loading, the strains are homogeneous:

Proposition 9.4 on tensors of thermal expansion of the solid and of the solid skeleton.

The tensors of thermal expansion of the solid skeleton $\mathbf{c}_{\mathrm{T}}$ and of the solid constituent $\mathbf{c}_{\mathrm{Ts}}$ are identical:

$$\mathbf{c}_{\mathrm{T}} = \mathbf{c}_{\mathrm{Ts}}\,. \tag{9.3.11}$$

The variation of fluid mass expresses in terms of the variations of fluid volume content, fluid pressure and temperature via (7.2.9). Then it appears that the major symmetry property is *not* conserved when the constitutive equations express the 'strain' triplet ($\boldsymbol{\epsilon}$, ζ^{w}, S^{s}) in terms of the 'stress' triplet ($\boldsymbol{\sigma}$, p_{w}, T). On the other hand, the major symmetry property is conserved for the triplet ($\boldsymbol{\epsilon}$, ζ^{w}, S), S being the entropy of the mixture per unit volume,

$$\begin{bmatrix} \boldsymbol{\epsilon} \\ \zeta^{\mathrm{w}} \\ S - S_0 \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{-1} & \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\mathrm{w}} & \mathbf{c}_{\mathrm{T}} \\ \boldsymbol{\alpha}_{\mathrm{w}} : \mathbb{E}^{-1} & \mathbf{I} : \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\mathrm{w}}/S & n^{\mathrm{w}}\,(\mathbf{I} : \mathbf{c}_{\mathrm{T}} - c_{\mathrm{Tw}}) \\ \mathbf{c}_{\mathrm{T}} & n^{\mathrm{w}}\,(\mathbf{I} : \mathbf{c}_{\mathrm{T}} - c_{\mathrm{Tw}}) & C_{\sigma p}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\sigma} \\ p_{\mathrm{w}} \\ T - T_0 \end{bmatrix}, \tag{9.3.12}$$

where $C_{\sigma p}$ [unit : $\mathrm{J/m^3/K}$] is the *apparent heat capacity* of the porous medium at constant stress and pressure per unit volume of porous medium. In fact,

$$\begin{aligned} C_{\sigma p} &= C^{\mathrm{s}}_{\sigma p} + C^{\mathrm{w}}_{\sigma p} \\ &= n^{\mathrm{s}}\,C_{\sigma p,\mathrm{s}} + n^{\mathrm{w}}\,C_{\sigma p,\mathrm{w}} \\ &= n^{\mathrm{s}}\,\rho_{\mathrm{s}}\,c_{\sigma p,\mathrm{s}} + n^{\mathrm{w}}\,\rho_{\mathrm{w}}\,c_{\sigma p,\mathrm{w}}\,, \end{aligned} \tag{9.3.13}$$

with $C^k_{\sigma p}$ [unit : $\mathrm{J/m^3/K}$] being the *apparent heat capacity* of the species k, at constant stress and fluid pressure, per unit volume of porous medium, and $c_{\sigma p,k}$ [unit : $\mathrm{J/kg/K}$] the *heat capacity* of the species k, at constant stress and fluid pressure as well but per unit mass of species k.

Thermal loading $T - T_0 > 0$ implies a volume expansion of the solid skeleton, and a proportional expansion of the pore space. The change of fluid mass under purely thermal loading can now be interpreted:

Proposition 9.5 on influx and efflux of fluid mass due to thermal loading.

The change of fluid mass in a porous medium in local thermal equilibrium due to a change of temperature, at constant stress and fluid pressure, is governed by the difference of the coefficients of thermal expansion of the solid and fluid constituents. Table 9.1.2 displays values for a few solids and liquids.

If the strain, instead of the total stress, is considered as a primary variable, then (9.3.12) becomes,

$$\begin{bmatrix} -\boldsymbol{\sigma} \\ \zeta^{\mathrm{w}} \\ S - S_0 \end{bmatrix} = \begin{bmatrix} -\mathbb{E} & \boldsymbol{\alpha}_{\mathrm{w}} & \mathbb{E} : \mathbf{c}_{\mathrm{T}} \\ \boldsymbol{\alpha}_{\mathrm{w}} & 1/M & n^{\mathrm{w}} \left(\mathbf{I} : \mathbf{c}_{\mathrm{T}} - c_{\mathrm{Tw}} \right) - \boldsymbol{\alpha}_{\mathrm{w}} : \mathbf{c}_{\mathrm{T}} \\ \mathbb{E} : \mathbf{c}_{\mathrm{T}} & n^{\mathrm{w}} \left(\mathbf{I} : \mathbf{c}_{\mathrm{T}} - c_{\mathrm{Tw}} \right) - \boldsymbol{\alpha}_{\mathrm{w}} : \mathbf{c}_{\mathrm{T}} & C_{\epsilon p}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ p_{\mathrm{w}} \\ T - T_0 \end{bmatrix}, \tag{9.3.14}$$

where the scalar modulus M has been defined by (7.4.19), and $C_{\epsilon p}$ [unit : J/m^3/K] is the apparent heat capacity of the porous medium at constant strain and fluid pressure,

$$C_{\sigma p} = C_{\epsilon p} + T_0 \, \mathbf{c}_{\mathrm{T}} : \mathbb{E} : \mathbf{c}_{\mathrm{T}} \, . \tag{9.3.15}$$

One may further use the fluid mass content as primary variable instead of the fluid pressure. The constitutive relations then involve the undrained tensor of thermal expansion $\mathbf{c}_{\mathrm{T}}^{\mathrm{U}}$,

$$\mathbf{c}_{\mathrm{T}}^{\mathrm{U}} = \mathbf{c}_{\mathrm{T}} + n^{\mathrm{w}} \left(c_{\mathrm{Tw}} - \mathbf{I} : \mathbf{c}_{\mathrm{T}} \right) \mathbf{S} \, , \tag{9.3.16}$$

where the Skempton tensor $\mathbf{S}$ defined by (7.4.20) satisfies the relation (7.4.30). Moreover, with help of (7.4.22) and (7.4.30), the following relation may be obtained,

$$\left(n^{\mathrm{w}} \left(\mathbf{I} : \mathbf{c}_{\mathrm{T}} - c_{\mathrm{Tw}} \right) - \boldsymbol{\alpha}_{\mathrm{w}} : \mathbf{c}_{\mathrm{T}} \right) M \, \boldsymbol{\alpha}_{\mathrm{w}} = \mathbf{c}_{\mathrm{T}} : \mathbb{E} - \mathbf{c}_{\mathrm{T}}^{\mathrm{U}} : \mathbb{E}^{\mathrm{U}} \, . \tag{9.3.17}$$

With repeated use of (7.4.30), the constitutive equations can be cast in a sort of *undrained* format,

$$\begin{bmatrix} \boldsymbol{\sigma} \\ p_{\mathrm{w}} \\ -(S - S_0) \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\mathrm{U}} & -\mathbb{E}^{\mathrm{U}} : \mathbf{S} & -\mathbb{E}^{\mathrm{U}} : \mathbf{c}_{\mathrm{T}}^{\mathrm{U}} \\ -\mathbf{S} : \mathbb{E}^{\mathrm{U}} & M & -(\mathbf{c}_{\mathrm{T}} : \mathbb{E} - \mathbf{c}_{\mathrm{T}}^{\mathrm{U}} : \mathbb{E}^{\mathrm{U}}) : \boldsymbol{\alpha}_{\mathrm{w}}^{-1} \\ -\mathbf{c}_{\mathrm{T}}^{\mathrm{U}} : \mathbb{E}^{\mathrm{U}} & -(\mathbf{c}_{\mathrm{T}} : \mathbb{E} - \mathbf{c}_{\mathrm{T}}^{\mathrm{U}} : \mathbb{E}^{\mathrm{U}}) : \boldsymbol{\alpha}_{\mathrm{w}}^{-1} & -C_{\epsilon\zeta}^{\mathrm{U}}/T_0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ \zeta^{\mathrm{w}} \\ T - T_0 \end{bmatrix}, \tag{9.3.18}$$

which involves the heat capacity of the porous medium at constant strain and fluid mass,

$$C_{\epsilon\zeta}^{\mathrm{U}} = C_{\epsilon p} - \left((\mathbf{c}_{\mathrm{T}} : \mathbb{E} - \mathbf{c}_{\mathrm{T}}^{\mathrm{U}} : \mathbb{E}^{\mathrm{U}}) : \boldsymbol{\alpha}_{\mathrm{w}}^{-1} \right)^2 \frac{T_0}{M} \, , \tag{9.3.19}$$

with M given by one of the expressions proposed in Section 7.4.2, for example (7.4.32).

These constitutive equations are a generalization to anisotropic materials of the equations derived by McTigue [1986]. Yet, McTigue [1986] contains two additional qualitative features, which are nevertheless not quantified:

- he does not adopt neither Proposition 9.3 nor Proposition 9.4. According to (7.2.21), the change of the volume fraction of the solid constituent Δn^{s} is equal to $\mathrm{tr}\, \boldsymbol{\epsilon}_{\mathrm{s}} - \mathrm{tr}\, \boldsymbol{\epsilon}$, which, for a purely thermal loading, becomes $\Delta n^{\mathrm{s}} = n^{\mathrm{s}} \, \mathbf{I} : (\mathbf{c}_{\mathrm{Ts}} - \mathbf{c}_{\mathrm{T}}) \, \Delta T$. Propositions 9.3 and 9.4 amount to set this change of volume fraction to zero;
- he assumes that under uniform pressure loading, the volume change Δv is controlled by a second tensor moduli $\mathbb{E}_{\mathrm{s}}^{''}$ different from the tensor of the solid constituent $\mathbb{E}_{\mathrm{s}}$. Then $\boldsymbol{\alpha}_{\mathrm{w}}$, Eqn (7.4.14), remains unchanged but the Skempton coefficient (7.4.15) becomes,

$$\frac{1}{S} = 1 + n^{\mathrm{w}} \left(\frac{1}{K_{\mathrm{w}}} - \frac{1}{K_{\mathrm{s}}^{''}} \right) \left(\frac{1}{K} - \frac{1}{K_{\mathrm{s}}} \right)^{-1} , \tag{9.3.20}$$

  where $1/K_{\mathrm{s}}^{''} \equiv \mathbf{I} : (\mathbb{E}_{\mathrm{s}}^{''})^{-1} : \mathbf{I}$.

These two features are highlighted in the change of volume fraction $\Delta n^{\mathrm{w}} = \Delta v^{\mathrm{w}} - n^{\mathrm{w}} \, \mathrm{tr}\, \boldsymbol{\epsilon}$. Indeed, with insertion of (7.4.14) and (9.3.20) in (9.3.9), the change of volume fraction becomes,

$$n^{\mathrm{w}} - n_0^{\mathrm{w}} = (\boldsymbol{\alpha}_{\mathrm{w}} - n^{\mathrm{w}} \, \mathbf{I}) : \mathbb{E}^{-1} : (\boldsymbol{\sigma} + p_{\mathrm{w}} \, \mathbf{I}) + \left(\frac{n^{\mathrm{w}}}{K_{\mathrm{s}}} - \frac{n^{\mathrm{w}}}{K_{\mathrm{s}}^{''}} \right) p_{\mathrm{w}} + n^{\mathrm{w}} \, \mathbf{I} : (\mathbf{c}_{\mathrm{Ts}} - \mathbf{c}_{\mathrm{T}}) \, \Delta T \, . \tag{9.3.21}$$

By contrast, two effective stresses epitomize the model developed in this section:

Proposition 9.6 on effective stresses.

While the thermoelastic strain is driven by the Nur-Byerlee effective stress,

$$\boldsymbol{\epsilon} - \mathbf{c}_{\mathrm{T}}\,(T - T_0) \quad = \quad \mathbb{E}^{-1} : \overbrace{(\boldsymbol{\sigma} + p_{\mathrm{w}}\,\boldsymbol{\alpha}_{\mathrm{w}})}^{\text{Nur}-\text{Byerlee stress}} \;, \tag{9.3.22}$$

the volume fractions are governed by Terzaghi's effective stress, e.g., for the fluid volume fraction,

$$n^{\mathrm{w}} - n^{\mathrm{w}}_0 \quad = \quad (\boldsymbol{\alpha}_{\mathrm{w}} - n^{\mathrm{w}}\,\mathbf{I}) : \mathbb{E}^{-1} : \overbrace{(\boldsymbol{\sigma} + p_{\mathrm{w}}\,\mathbf{I})}^{\text{Terzaghi's stress}} \;. \tag{9.3.23}$$

If the solid constituent is incompressible[9.1], then $\boldsymbol{\alpha}_{\mathrm{w}} = \mathbf{I}$. Using (9.3.22), the latter relation (9.3.23) becomes $n^{\mathrm{w}} - n^{\mathrm{w}}_0 = n^{\mathrm{s}}\,\mathrm{tr}\,(\boldsymbol{\epsilon} - \mathbf{c}_{\mathrm{T}}\,\Delta T)$ as it should. Indeed then $n^{\mathrm{s}} = V_{\mathrm{s}}/V$, and $n^{\mathrm{s}} - n^{\mathrm{s}}_0 = -n^{\mathrm{s}}\,\mathrm{tr}\,(\boldsymbol{\epsilon} - \mathbf{c}_{\mathrm{Ts}}\,\Delta T)$. The changes of the two volume fractions are opposite, as they should, due to Proposition 9.4.

9.3.3 Coupled flows: thermoosmosis

Let us consider a porous medium saturated by water to be in contact with two reservoirs in which the temperature and the pressure are controlled. The interface between the porous medium and the baths can be permeable or impermeable to water flow and/or heat flow.

The thermoosmotic properties are assumed to be isotropic, so as to simplify the exposition. Neglecting acceleration and body force in (7.2.32), the internal dissipation associated with the diffusion of water and heat expresses in terms of the heat flux $\mathbf{Q}$ [unit : $\mathrm{W/m^2}$=$\mathrm{kg/s^3}$], volume hydraulic flux $\mathbf{J}_{\mathrm{w}}$ [unit : m/s], and gradients of the temperature T [unit : K], and of the pressure p_{w} [unit : Pa],

$$T\,\hat{S}_{(\mathrm{i},3)} = -\mathbf{Q}\cdot\frac{\boldsymbol{\nabla} T}{T} - \mathbf{J}_{\mathrm{w}}\cdot\boldsymbol{\nabla} p_{\mathrm{w}} \geq 0\,. \tag{9.3.24}$$

By choosing the fluxes $\mathcal{J}$ to be linearly related to the gradients $\mathcal{F}$ through a positive (semi-)definite thermoosmotic matrix $\mathcal{K}$,

$$\mathcal{J} = -\mathcal{K}\,\mathcal{F}, \qquad \begin{bmatrix} \mathbf{J}_{\mathrm{w}} \\ \mathbf{Q} \end{bmatrix} = -\begin{bmatrix} k_{\mathrm{H}} & k_{\mathrm{TO}} \\ k_{\mathrm{MC}} & T\,k_{\mathrm{T}} \end{bmatrix} \begin{bmatrix} \boldsymbol{\nabla} p_{\mathrm{w}} \\ \boldsymbol{\nabla} T/T \end{bmatrix} \;, \tag{9.3.25}$$

the dissipation inequality can be satisfied. The actual dissipation depends only on the symmetric part of the matrix, Exercise 9.1. This observation is used as an argument to assume the matrix to be symmetric. The symmetry property is conserved by consistent scalings of the fluxes and driving gradients, Exercise 16.1. On the other hand, there is no argument why the fluxes themselves should display a symmetric coupling: while, in many cases, symmetry is used mainly as a starting convenient assumption, it should *in fine* be verified, or disproved experimentally.

Thus if the thermoosmotic matrix is symmetric, $k_{\mathrm{MC}} = k_{\mathrm{TO}}$, the conditions of positive definiteness become,

$$k_{\mathrm{H}} > 0, \quad k_{\mathrm{T}} > 0, \quad \sqrt{T\,k_{\mathrm{T}}\,k_{\mathrm{H}}} \geq k_{\mathrm{TO}} \geq -\sqrt{T\,k_{\mathrm{T}}\,k_{\mathrm{H}}}\,. \tag{9.3.26}$$

Indeed,

$$\begin{aligned} \mathcal{F}^{\mathrm{T}}\mathcal{K}\,\mathcal{F} \quad &= \quad k_{\mathrm{H}}\,\mathcal{F}_{\mathrm{w}}^2 + 2\,k_{\mathrm{TO}}\,\mathcal{F}_{\mathrm{w}}\cdot\mathcal{F}_{\mathrm{T}} + T\,k_{\mathrm{T}}\,\mathcal{F}_{\mathrm{T}}^2, \\ &= \quad k_{\mathrm{H}}\,(\mathcal{F}_{\mathrm{w}} + \frac{k_{\mathrm{TO}}}{k_{\mathrm{H}}}\mathcal{F}_{\mathrm{T}})^2 + (T\,k_{\mathrm{T}} - \frac{k_{\mathrm{TO}}^2}{k_{\mathrm{H}}})\,\mathcal{F}_{\mathrm{T}}^2\,. \end{aligned} \tag{9.3.27}$$

If the matrix is not symmetric, just replace k_{TO} by $(k_{\mathrm{TO}} + k_{\mathrm{MC}})/2$ in (9.3.26) and (9.3.27).

Let us record the units of the coefficients of the thermoosmotic matrix:

$$\text{units:} \quad k_{\mathrm{H}}\text{: } \mathrm{m^3\times s/kg}; \quad k_{\mathrm{TO}},\, k_{\mathrm{MC}}\text{: } \mathrm{m^2/s}; \quad k_{\mathrm{T}}\text{: } \mathrm{kg\times m/s^3/K}.$$

[9.1] Actually, we have seen in Section 3.3.2 that incompressibility is accompanied by thermal inextensibility.

9.3.3.1 Experimental identification of the thermoosmotic coefficients

Since the flows are coupled, the experiments to be used to identify the diffusion coefficients need to be described accurately. A similar issue is encountered for electroosmosis in Section 16.2.5. Indeed,

(1) isothermal flow $\boldsymbol{\nabla} T = \mathbf{0}$:

Then the transfer of matter is accompanied with a transfer of heat. If vaporization takes place, the proportionality coefficient is the latent heat of vaporization $\mathcal{L}_{\rm vap}$ [unit : $\mathrm{m}^2/\mathrm{s}^2$],

$$\mathbf{J}_{\rm w} = -k_{\rm H} \cdot \boldsymbol{\nabla} p_{\rm w}, \quad \mathbf{Q} = -k_{\rm MC} \cdot \boldsymbol{\nabla} p_{\rm w} \;\Rightarrow\; \mathbf{Q} = \rho_{\rm w}\, \mathcal{L}_{\rm vap}\, \mathbf{J}_{\rm w}, \quad \rho_{\rm w}\, \mathcal{L}_{\rm vap} = \frac{k_{\rm MC}}{k_{\rm H}}\,. \tag{9.3.28}$$

According to Spanner [1964], p. 246, at 35 °C, $\mathcal{L}_{\rm vap} = 2.417\,\mathrm{MJ/kg}$, $\rho_{\rm w} = 994\,\mathrm{kg/m^3}$, so that $k_{\rm MC}/k_{\rm H} = 2403 \times 10^6\,\mathrm{kg/m/s^2}$.

(2) thermally insulated flow $\mathbf{Q} = \mathbf{0}$:

Measurement of hydraulic permeability in absence of heat flux provides the 'thermally insulated' hydraulic permeability

$$\boldsymbol{\nabla} T = -\frac{k_{\rm MC}}{k_{\rm T}}\, \boldsymbol{\nabla} p_{\rm w}, \quad \mathbf{J}_{\rm w} = -\underbrace{(k_{\rm H} - \frac{k_{\rm TO}\, k_{\rm MC}}{T\, k_{\rm T}})}_{\substack{\text{'thermally insulated'} \\ \text{hydraulic permeability} \geq 0}} \boldsymbol{\nabla} p_{\rm w}\,. \tag{9.3.29}$$

(3) thermoosmotic pressure in absence of water flow $\mathbf{J}_{\rm w} = \mathbf{0}$:

Measurement of thermal conductivity in absence of water flux provides the 'hydraulically open circuit' thermal conductivity

$$\boldsymbol{\nabla} p_{\rm w} = -\frac{k_{\rm TO}}{k_{\rm H}}\, \frac{\boldsymbol{\nabla} T}{T}, \quad \mathbf{Q} = -\underbrace{(k_{\rm T} - \frac{k_{\rm MC}\, k_{\rm TO}}{T\, k_{\rm H}})}_{\substack{\text{'hydraulically open circuit'} \\ \text{thermal conductivity} \geq 0}} \boldsymbol{\nabla} T\,. \tag{9.3.30}$$

Thus at 35°C, assuming $k_{\rm MC} = k_{\rm TO}$, a gradient of temperature of 1°C gives rise to a gradient of pressure equal to -7.8 MPa: note that the signs of the gradients are opposite.

9.3.3.2 The sign of the thermoosmotic coefficient

Whether in membranes, biomaterials or geomaterials, thermoosmosis is strongly related to the presence of a fixed electrical charge. For positively charged (hydrophobic) membranes, the thermoosmotic coefficient is negative so that the thermoosmotic flow is from the cold side to the hot side. For negatively charged membranes, like Nafion®, endowed with hydrophilic sulfonic groups, and for negatively charged geomaterials, experimental measurements seem to depend on the properties of the electrolyte and, in particular, of the counterions. Both positive and negative thermoosmotic coefficients are reported.

Constitutive equations of generalized diffusion with thermal effects in an electrolyte are developed in Section 16.5.

9.3.4 Energy equation of a porous medium in local thermal equilibrium

Since the two species have identical temperature, a single energy equation associated with the whole mixture is needed. The following simplifying assumptions are adopted:

- no exchange of mass between the fluid and solid constituents takes place;
- no supply of mass, momentum and internal energy emanates from the surroundings.

In a small strain context, the energy equation (4.6.22) reduces to

$$\frac{dU}{dt} + U\, \mathrm{div}\, \mathbf{v}_{\rm s} + \mathrm{div}\, (h_{\rm w}\, \mathbf{M}_{\rm w}) + \mathbf{M}_{\rm w} \cdot (\frac{d^{\rm w}\mathbf{v}_{\rm w}}{dt} - \mathbf{b}_{\rm w}) - \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} + \mathrm{div}\ \mathbf{Q} - \Theta = 0\,, \tag{9.3.31}$$

where U [unit : Pa] is the internal energy of the porous medium per unit volume, and Θ [unit : W/m^3] a heat source per unit volume. The mechanical entropy production (4.7.28) simplifies to,

$$T\hat{S}_{(\mathrm{i},1)} = -\frac{dE}{dt} - E\,\mathrm{div}\,\mathbf{v}_\mathrm{s} + \boldsymbol{\sigma} : \frac{d\boldsymbol{\epsilon}}{dt} - S\,\frac{dT}{dt} + \mu_\mathrm{w}\,\frac{dm^\mathrm{w}}{dt}\,. \tag{9.3.32}$$

It vanishes by construction of the thermoelastic constitutive equations. Upon elimination of the rate of work $\boldsymbol{\sigma} : d\boldsymbol{\epsilon}/dt$, the energy equation can be phrased in terms of the entropy of the porous medium,

$$T\hat{S}_{(\mathrm{i},1)} = T\,\frac{dS}{dt} + TS\,\mathrm{div}\,\mathbf{v}_\mathrm{s} + \mu_\mathrm{w}\,\frac{dm^\mathrm{w}}{dt} + \mathrm{div}\,(\mathbf{Q} + h_\mathrm{w}\,\mathbf{M}_\mathrm{w}) + \mathbf{M}_\mathrm{w}\cdot(\frac{d^\mathrm{w}\mathbf{v}_\mathrm{w}}{dt} - \mathbf{b}_\mathrm{w}) - \Theta = 0\,. \tag{9.3.33}$$

With the entropy now given by the constitutive equations (9.3.18), the energy equation becomes,

$$\begin{aligned} &\underbrace{T\,\mathbf{c}_\mathrm{T}^\mathrm{U} : \mathbb{E}^\mathrm{U} : \frac{d\boldsymbol{\epsilon}}{dt} + T\,(\mathbf{c}_\mathrm{T} : \mathbb{E} - \mathbf{c}_\mathrm{T}^\mathrm{U} : \mathbb{E}^\mathrm{U}) : \boldsymbol{\alpha}_\mathrm{w}^{-1}\,\frac{d\zeta^\mathrm{w}}{dt}}_{\substack{\text{thermoelastic}\\ \text{heat}}} \quad + \quad \underbrace{\frac{T}{T_0}\,C^\mathrm{U}_{\epsilon\zeta}\,\frac{dT}{dt}}_{\substack{\text{purely thermal}\\ \text{contribution}}} \\ &+ \quad \underbrace{TS\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt} + \rho_\mathrm{w}\mu_\mathrm{w}\,\frac{d\zeta^\mathrm{w}}{dt}}_{\text{nonlinear terms}} + \underbrace{\mathrm{div}\,(\mathbf{Q} + h_\mathrm{w}\,\mathbf{M}_\mathrm{w})}_{\substack{\text{conductive+convective}\\ \text{heat fluxes}}} + \mathbf{M}_\mathrm{w}\cdot(\frac{d^\mathrm{w}\mathbf{v}_\mathrm{w}}{dt} - \mathbf{b}_\mathrm{w}) - \underbrace{\Theta}_{\substack{\text{heat}\\ \text{source}}} = 0\,. \end{aligned} \tag{9.3.34}$$

The specific entropy and specific enthalpy of water, s_w and h_w respectively, are given in explicit form in terms of pressure and temperature in Section 3.3.3.

The orders of magnitude of the various terms may be estimated as indicated by Proposition 9.1. Fluid mechanics and diffusion models introduce dimensionless numbers, e.g., Péclet, Reynolds and Prandtl numbers, that indicate the relative weights of various physical phenomena: examples are shown in Sections 15.3.4 and 15.6.

It thus appears that the heat transported by the porous medium is composed of

- *the conductive heat* $\mathbf{Q}$ and of
- *the heat* $h_\mathrm{w}\,\mathbf{M}_\mathrm{w}$ *convected by the fluid.*

With help of the relation (4.4.9), an alternative format would display the convective contribution in the form of a product of a flux times a gradient of a scalar entity (pressure, thermodynamic function $\cdots$), for example,

$$\begin{aligned} &\underbrace{T\,\mathbf{c}_\mathrm{T}^\mathrm{U} : \mathbb{E}^\mathrm{U} : \frac{d\boldsymbol{\epsilon}}{dt} + T\,(\mathbf{c}_\mathrm{T} : \mathbb{E} - \mathbf{c}_\mathrm{T}^\mathrm{U} : \mathbb{E}^\mathrm{U}) : \boldsymbol{\alpha}_\mathrm{w}^{-1}\,\frac{d\zeta^\mathrm{w}}{dt}}_{\substack{\text{thermoelastic}\\ \text{heat}}} \quad + \quad \underbrace{\frac{T}{T_0}\,C^\mathrm{U}_{\epsilon\zeta}\,\frac{dT}{dt}}_{\substack{\text{purely thermal}\\ \text{contribution}}} \quad + \quad \underbrace{\mathbf{M}_\mathrm{w}\cdot\boldsymbol{\nabla} h_\mathrm{w}}_{\substack{\text{convective}\\ \text{term}}} \\ &+ \quad \underbrace{TS\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt} - T\rho_\mathrm{w} s_\mathrm{w}\,\frac{d\zeta^\mathrm{w}}{dt}}_{\substack{\text{nonlinear}\\ \text{terms}}} \quad + \quad \underbrace{\mathrm{div}\,\mathbf{Q}}_{\substack{\text{conductive}\\ \text{heat flux}}} \quad + \mathbf{M}_\mathrm{w}\cdot(\frac{d^\mathrm{w}\mathbf{v}_\mathrm{w}}{dt} - \mathbf{b}_\mathrm{w}) \quad - \quad \underbrace{\Theta}_{\substack{\text{heat}\\ \text{source}}} = 0\,. \end{aligned} \tag{9.3.35}$$

This form is more appropriate to the case where the flux is either a datum or strongly constrained, like for forced convection. The current exposition is more in line with free convection: the hydraulic and thermal fluxes are not considered as primary variables, but rather as dependent variables given by the constitutive equations of generalized diffusion. In a finite element perspective, prescribing the hydraulic flux at arbitrary points within the body requires that this flux, or the velocities it is built on, is a primary variable. As an example, the finite element scheme used in a dynamic context by Loret and Prévost [1991] makes use of solid and fluid displacements as primary variables. The associated constitutive framework is exposed in Section 7.3.6. By contrast, the approach adopted in the other sections of this chapter is in line with a *mixed* finite element method with the solid displacement, fluid pressure and temperature as primary variables.

9.4 Generalized compatibility conditions for the stress

The compatibility conditions for infinitesimal strains (21.8.12),

$$\begin{aligned} \mathbf{A} &\equiv \overrightarrow{\boldsymbol{\nabla}}^2\,\mathrm{tr}\,\boldsymbol{\epsilon} - \overrightarrow{\boldsymbol{\nabla}}(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon}) - \big(\overrightarrow{\boldsymbol{\nabla}}(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon})\big)^\mathrm{T} + \Delta\boldsymbol{\epsilon} = \mathbf{0}\,, \\ B &\equiv \Delta\mathrm{tr}\,\boldsymbol{\epsilon} - \overrightarrow{\boldsymbol{\nabla}}\cdot(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon}) = 0\,, \end{aligned} \tag{9.4.1}$$

may be phrased in terms of the stress. The resulting restrictions are useful if a solution to a boundary value problem is sought in terms of stress, rather than strain.

9.4.1 Compatibility conditions for the stress for linear isotropic elasticity

For isotropic elasticity, introduction of the strain $E\,\boldsymbol{\epsilon} = -\nu\,\mathrm{tr}\,\boldsymbol{\sigma}\,\mathbf{I} + (1+\nu)\,\boldsymbol{\sigma}$ in the above relations yields the two conditions,

$$\begin{aligned} \mathbf{A} \equiv \frac{1}{E}\,\overrightarrow{\boldsymbol{\nabla}}^2\,\mathrm{tr}\,\boldsymbol{\sigma} - \frac{\nu}{E}\,\Delta\mathrm{tr}\,\boldsymbol{\sigma}\,\mathbf{I} - \frac{1+\nu}{E}\,\Big(\,\overrightarrow{\boldsymbol{\nabla}}\,(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}) + \big(\big(\,\overrightarrow{\boldsymbol{\nabla}}\,(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma})\big)^{\mathrm{T}}\Big) + \frac{1+\nu}{E}\,\Delta\boldsymbol{\sigma} = \mathbf{0}\,, \\ B \equiv \frac{1-\nu}{E}\,\Delta\mathrm{tr}\,\boldsymbol{\sigma} - \frac{1+\nu}{E}\;\overrightarrow{\boldsymbol{\nabla}}\cdot(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}) = 0\,, \end{aligned} \tag{9.4.2}$$

which are combined to $\mathbf{A}+\nu/(1-\nu)\,B\,\mathbf{I} = \mathbf{0}$. Together with the three equations of balance of momentum $\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}+\mathbf{f} = \mathbf{0}$, $\sigma_{ij,i} + f_j = 0$, with body force $\mathbf{f}$, the six compatibility conditions,

$$\begin{aligned} &\frac{1}{E}\,\overrightarrow{\boldsymbol{\nabla}}^2\,\mathrm{tr}\,\boldsymbol{\sigma} + \frac{1+\nu}{E}\,\Delta\boldsymbol{\sigma} + \frac{\nu}{E}\,\frac{1+\nu}{1-\nu}\;\overrightarrow{\boldsymbol{\nabla}}\cdot\mathbf{f}\,\mathbf{I} + \frac{1+\nu}{E}\,\big(\,\overrightarrow{\boldsymbol{\nabla}}\,\mathbf{f} + \mathbf{f}\,\overleftarrow{\boldsymbol{\nabla}}\,\big) = \mathbf{0}\,, \\ &\frac{1}{E}\,\sigma_{kk,ij} + \frac{1+\nu}{E}\,\sigma_{ij,kk} + \frac{\nu}{E}\,\frac{1+\nu}{1-\nu}\,f_{k,k}\,I_{ij} + \frac{1+\nu}{E}\,\big(f_{j,i} + f_{i,j}\big) = 0\,, \end{aligned} \tag{9.4.3}$$

require nine equations to be satisfied by the six stress components, and therefore represent three functionally independent constraints. They are referred to as Beltrami-Mitchell compatibility equations.

Special case: body force deriving from a harmonic potential

As a special case, consider a body force that derives from a harmonic potential,

$$\mathbf{f} = -\,\overrightarrow{\boldsymbol{\nabla}}\,F, \quad \Delta F = 0\,. \tag{9.4.4}$$

Then, the compatibility equations simplify to,

$$\begin{aligned} &\frac{1}{E}\,\overrightarrow{\boldsymbol{\nabla}}^2\,\mathrm{tr}\,\boldsymbol{\sigma} + \frac{1+\nu}{E}\,\Delta\boldsymbol{\sigma} - 2\,\frac{1+\nu}{E}\,\overrightarrow{\boldsymbol{\nabla}}^2 F = \mathbf{0}\,, \\ &\frac{1}{E}\,\sigma_{kk,ij} + \frac{1+\nu}{E}\,\sigma_{ij,kk} - 2\,\frac{1+\nu}{E}\,F_{,ij} = 0\,. \end{aligned} \tag{9.4.5}$$

The trace of these relations implies (since $2+\nu \neq 0$) that the first invariant of the stress $\mathrm{tr}\,\boldsymbol{\sigma}$ is harmonic,

$$\Delta\mathrm{tr}\,\boldsymbol{\sigma} = 0\,. \tag{9.4.6}$$

Therefore, if it vanishes on the boundary of a simply connected body, it vanishes within the body. Moreover, applying the Laplacian operator to the compatibility relations, and accounting for the fact that both $\mathrm{tr}\,\boldsymbol{\sigma}$ and the potential F are harmonic implies that the stress is biharmonic,

$$\Delta\Delta\boldsymbol{\sigma} = 0, \quad \boldsymbol{\sigma}_{ij,kkll} = 0\,. \tag{9.4.7}$$

9.4.2 Compatibility conditions for the stress in presence of an inelastic strain

Assume now that the strain contains an inelastic component $\boldsymbol{\epsilon}^*$,

$$\boldsymbol{\epsilon} = -\frac{\nu}{E}\,\mathrm{tr}\,\boldsymbol{\sigma}\,\mathbf{I} + \frac{1+\nu}{E}\,\boldsymbol{\sigma} + \boldsymbol{\epsilon}^*\,. \tag{9.4.8}$$

The inelastic strain $\boldsymbol{\epsilon}^*$ may have various origins, e.g., it can represent a thermal strain or a growth strain. The inelastic strain $\boldsymbol{\epsilon}^*$ corresponding to an anisotropic linear thermo-poroelastic material with a single porosity can be read from (9.3.9). The special case where both the elastic and the thermal properties are isotropic is given by (9.5.2).

Then the following terms should be added to the lhs of the compatibility relations (9.4.3),

$$\begin{aligned} &\overrightarrow{\boldsymbol{\nabla}}^2\,\mathrm{tr}\,\boldsymbol{\epsilon}^* - \overrightarrow{\boldsymbol{\nabla}}\,(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon}^*) - \big(\,\overrightarrow{\boldsymbol{\nabla}}\,(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon}^*)\big)^{\mathrm{T}} + \Delta\boldsymbol{\epsilon}^* + \frac{\nu}{1-\nu}\,(\Delta\mathrm{tr}\,\boldsymbol{\epsilon}^* - \overrightarrow{\boldsymbol{\nabla}}\cdot(\overrightarrow{\boldsymbol{\nabla}}\cdot\boldsymbol{\epsilon}^*))\,\mathbf{I}\,, \\ &\epsilon^*_{kk,ij} - \epsilon^*_{ik,jk} - \epsilon^*_{jk,ik} + \epsilon^*_{ij,kk} + \frac{\nu}{1-\nu}\,(\epsilon^*_{mm,kk} - \epsilon^*_{km,km})\,I_{ij}\,. \end{aligned} \tag{9.4.9}$$

If the inelastic strain is isotropic, the above terms simplify to

$$\begin{array}{l} \dfrac{1}{3}\,\vec{\boldsymbol{\nabla}}^{2}\,\mathrm{tr}\,\boldsymbol{\epsilon}^{*} + \dfrac{1}{3}\dfrac{1+\nu}{1-\nu}\,\Delta \mathrm{tr}\,\boldsymbol{\epsilon}^{*}\,\mathbf{I}\,, \\ \dfrac{1}{3}\,\epsilon^{*}_{kk,ij} \quad + \dfrac{1}{3}\dfrac{1+\nu}{1-\nu}\,\epsilon^{*}_{kk,mm}\,I_{ij}\,. \end{array} \tag{9.4.10}$$

Taking the trace of the compatibility relations yields, up to a multiplicative factor $(2+\nu)/E \neq 0$,

$$\Delta \mathrm{tr}\,\boldsymbol{\sigma} + \frac{1+\nu}{1-\nu}\;\vec{\boldsymbol{\nabla}}\cdot\mathbf{f} + 2\,\frac{E}{3\,(1-\nu)}\Delta \mathrm{tr}\,\boldsymbol{\epsilon}^{*} = 0\,. \tag{9.4.11}$$

As indicated above, the inelastic strain may include a pressure contribution associated with the fluid pressure p_{w}, a thermal contribution associated with the isotropic thermal expansion tensor $\frac{1}{3}\,\mathrm{tr}\,\mathbf{c}_{\mathrm{T}}\,\mathbf{I}$ and temperature change $T-T_0$, an isotropic growth contribution $\frac{1}{3}\,\mathrm{tr}\,\boldsymbol{\epsilon}^{\mathrm{g}}\,\mathbf{I}$,

$$2\,\frac{E}{3\,(1-\nu)}\,\mathrm{tr}\,\boldsymbol{\epsilon}^{*} = 2\,\frac{1-2\nu}{1-\nu}\,\Big(\big(1-\frac{K}{K_{\mathrm{s}}}\big)\,p_{\mathrm{w}} + K\,\mathrm{tr}\,\mathbf{c}_{\mathrm{T}}\,(T-T_0) + K\,\mathrm{tr}\,\boldsymbol{\epsilon}^{\mathrm{g}}\Big)\,, \tag{9.4.12}$$

and possibly other effects. The pressure coefficient in (9.4.12) has been rewritten using (7.4.42) and (7.4.45).

The results (9.4.6) and (9.4.7) hold if the body force derives from a harmonic potential and if the trace of the inelastic strain is harmonic.

9.4.3 Compatibility conditions for spherical problems with radial symmetry

The particular situation where the displacement of the solid constituent of a linear isotropic poroelastic mixture is radial and subjected to a radial body force $\mathbf{f} = f_r\,\hat{\mathbf{e}}_r$ is detailed using the spherical coordinates (r,θ,ϕ) and the associated unit axes $(\hat{\mathbf{e}}_r,\hat{\mathbf{e}}_\theta,\hat{\mathbf{e}}_\phi)$. The required definitions are exposed in Section 2.4.3.1.

The stress and the strain tensors are principal in these axes, and $\sigma_{\theta\theta}=\sigma_{\phi\phi}$, $\epsilon_{\theta\theta}=\epsilon_{\phi\phi}$, so that

$$\boldsymbol{\sigma} = \sigma_{rr}\,\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r + \sigma_{\theta\theta}\,(\mathbf{I}-\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r), \quad \boldsymbol{\epsilon} = \epsilon_{rr}\,\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r + \epsilon_{\theta\theta}\,(\mathbf{I}-\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r)\,. \tag{9.4.13}$$

A number of preliminary differential relations are needed, namely

$$\begin{aligned}
\vec{\boldsymbol{\nabla}}\,\mathrm{tr}\,\boldsymbol{\sigma} &= \frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\vec{\partial}\,\mathrm{tr}\,\boldsymbol{\sigma}}{\partial x_k} = \frac{d\mathrm{tr}\,\boldsymbol{\sigma}}{dr}\,\hat{\mathbf{e}}_r, \\
\vec{\boldsymbol{\nabla}}\,(\vec{\boldsymbol{\nabla}}\,\mathrm{tr}\,\boldsymbol{\sigma}) &= \frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\vec{\partial}}{\partial x_k}\big((\vec{\boldsymbol{\nabla}}\,\mathrm{tr}\,\boldsymbol{\sigma})\big) = \frac{d^2\mathrm{tr}\,\boldsymbol{\sigma}}{dr^2}\,\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r + \frac{1}{r}\,\frac{d\mathrm{tr}\,\boldsymbol{\sigma}}{dr}\,(\mathbf{I}-\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r), \\
\vec{\boldsymbol{\nabla}}\,\boldsymbol{\sigma} &= \frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\vec{\partial}\,\boldsymbol{\sigma}}{\partial x_k} \\
&= \Big(\frac{d}{dr}(\sigma_{rr}-\sigma_{\theta\theta}) - \frac{\sigma_{rr}-\sigma_{\theta\theta}}{r}\Big)\,\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r \\
&+ \frac{d\sigma_{\theta\theta}}{dr}\hat{\mathbf{e}}_r\otimes\mathbf{I} + \frac{\sigma_{rr}-\sigma_{\theta\theta}}{r}\,\mathbf{I}\otimes\hat{\mathbf{e}}_r + \frac{\sigma_{rr}-\sigma_{\theta\theta}}{r}\,(\hat{\mathbf{e}}_\theta\otimes\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_\theta + \hat{\mathbf{e}}_\phi\otimes\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_\phi), \\
\boldsymbol{\Delta\sigma} &= \vec{\boldsymbol{\nabla}}\cdot(\vec{\boldsymbol{\nabla}}\,\boldsymbol{\sigma}) = \frac{\hat{\mathbf{e}}_k}{h_k}\,\frac{\vec{\partial}}{\partial x_k}\cdot(\vec{\boldsymbol{\nabla}}\,\boldsymbol{\sigma}) \\
&= \Big(\frac{d^2}{dr^2}(\sigma_{rr}-\sigma_{\theta\theta}) + \frac{2}{r}\,\frac{d}{dr}(\sigma_{rr}-\sigma_{\theta\theta}) - \frac{6}{r^2}(\sigma_{rr}-\sigma_{\theta\theta})\Big)\,\hat{\mathbf{e}}_r\otimes\hat{\mathbf{e}}_r \\
&+ \Big(\frac{d^2\sigma_{\theta\theta}}{dr^2} + \frac{2}{r}\,\frac{d\sigma_{\theta\theta}}{dr} + \frac{2}{r^2}(\sigma_{rr}-\sigma_{\theta\theta})\Big)\,\mathbf{I}\,.
\end{aligned} \tag{9.4.14}$$

Collecting the above relations, the compatibility relations can be cast in the format,

$$\begin{aligned}
&\hat{\mathbf{e}}_r \otimes \hat{\mathbf{e}}_r \Big[\frac{1}{E} \Big(\frac{d^2 \mathrm{tr}\, \boldsymbol{\sigma}}{dr^2} - \frac{1}{r} \frac{d \mathrm{tr}\, \boldsymbol{\sigma}}{dr} \Big) \\
&+ \frac{1+\nu}{E} \Big(\frac{d^2}{dr^2}(\sigma_{rr} - \sigma_{\theta\theta}) + \frac{2}{r} \frac{d}{dr}(\sigma_{rr} - \sigma_{\theta\theta}) - \frac{6}{r^2}(\sigma_{rr} - \sigma_{\theta\theta}) \Big) \\
&+ 2 \frac{1+\nu}{E} \big(\frac{df_r}{dr} - \frac{f_r}{r} \big) + \frac{1}{3} \frac{d^2 \mathrm{tr}\, \boldsymbol{\epsilon}^*}{dr^2} - \frac{1}{3} \frac{1}{r} \frac{d \mathrm{tr}\, \boldsymbol{\epsilon}^*}{dr} \Big] \\
&+ \mathbf{I} \Big[\frac{1}{E} \Big(\frac{1}{r} \frac{d \mathrm{tr}\, \boldsymbol{\sigma}}{dr} \Big) + \frac{1+\nu}{E} \Big(\frac{d^2 \sigma_{\theta\theta}}{dr^2} + \frac{2}{r} \frac{d\sigma_{\theta\theta}}{dr} + \frac{2}{r^2}(\sigma_{rr} - \sigma_{\theta\theta}) \Big) + \frac{\nu}{E} \frac{1+\nu}{1-\nu} \big(\frac{df_r}{dr} + 2 \frac{f_r}{r} \big) \\
&+ 2 \frac{1+\nu}{E} \frac{f_r}{r} + \frac{1}{3} \frac{1}{r} \frac{d \mathrm{tr}\, \boldsymbol{\epsilon}^*}{dr} + \frac{1}{3} \frac{1+\nu}{1-\nu} \big(\frac{d^2 \mathrm{tr}\, \boldsymbol{\epsilon}^*}{dr^2} + \frac{2}{r} \frac{d \mathrm{tr}\, \boldsymbol{\epsilon}^*}{dr} \big) \Big] = \mathbf{0} \,.
\end{aligned} \tag{9.4.15}$$

Of course, the trace of the left hand-side is a particular case of (9.4.11).

9.5 Heating a thermo-poroelastic medium

A porous half-space is heated uniformly over its surface and the only non zero component of the strain tensor is the strain along the depth of the half-space of axis x. The medium is saturated by a fluid, and both the solid constituent and the fluid are compressible. The initial and boundary value problem exposed below in Sections 9.5.1 to 9.5.8 draws from McTigue [1986]. A number of simplifications are adopted to obtain a tractable analytical solution. The simulations highlight the influence of the ratio of the hydraulic and thermal diffusivities on the thermo-hydromechanical response. Stronger thermohydraulic interactions are expected when this ratio is close to one.

9.5.1 Thermo-poroelastic field and constitutive equations

The linearized field equations governing the thermo-poroelastic problem addressed here consist of

$$\begin{aligned}
&\text{the balance of momentum of the porous medium} \quad \mathrm{div}\, \boldsymbol{\sigma} = \mathbf{0} \,, \\
&\text{the balance of mass of fluid} \quad \frac{dm^{\mathrm{w}}}{dt} + \mathrm{div}\, \mathbf{M}_{\mathrm{w}} = 0 \,, \\
&\text{the energy equation of the porous medium} \quad T \frac{dS_{\mathrm{pm}}}{dt} + \mathrm{div}\, \mathbf{Q} = 0 \,.
\end{aligned} \tag{9.5.1}$$

These equations justify as follows:

- the quasi-static balance of momentum phrased in terms of the total stress $\boldsymbol{\sigma}$ assumes a zero body force;
- unlike in some other models, like the double porosity model of Section 10.6 or the models of Section 24.8, there are no internal mass transfers. Therefore the mass balance of fluid indicates that the rate of change of the fluid mass content m^{w} is compensated by the exchange of mass with the surroundings represented by the mass flux $\mathbf{M}_{\mathrm{w}}$;
- the energy equation assumes a zero heat source and neglects the convective and nonlinear terms: the sole contributions due to the rate of change of entropy S_{pm} of the porous medium and heat flux $\mathbf{Q}$ survive from (9.3.33).

The porous medium under consideration is isotropic in its elastic, flow and thermal properties. Thus the tensor of elastic moduli is a fourth order isotropic tensor defined by two material parameters, while the tensors providing the heat and fluid fluxes in terms of the gradients of temperature and fluid pressure respectively, and the tensor of thermal expansion are second order isotropic tensors, each of them being defined by a single material parameter.

The thermo-poroelastic constitutive equations (9.3.12) for the strain and dimensionless fluid mass may be recast, with help of (7.4.42), in the format,

$$\begin{aligned}
\boldsymbol{\epsilon} &= \frac{1}{2\mu} \Big(\boldsymbol{\sigma} - \frac{\nu}{1+\nu} \mathrm{tr}\, \boldsymbol{\sigma}\, \mathbf{I} \Big) + \frac{3}{2\mu} \frac{1}{S} \frac{\nu^{\mathrm{U}} - \nu}{(1+\nu)(1+\nu^{\mathrm{U}})} p_{\mathrm{w}}\, \mathbf{I} + \frac{1}{3} \mathrm{tr}\, \mathbf{c}_{\mathrm{T}}\, \theta\, \mathbf{I}, \\
\zeta^{\mathrm{w}} &= \frac{3}{2\mu} \frac{1}{S} \frac{\nu^{\mathrm{U}} - \nu}{(1+\nu)(1+\nu^{\mathrm{U}})} \Big(\mathrm{tr}\, \boldsymbol{\sigma} + \frac{3}{S} p_{\mathrm{w}} \Big) + n^{\mathrm{w}} \left(\mathrm{tr}\, \mathbf{c}_{\mathrm{T}} - c_{\mathrm{Tw}} \right) \theta \,.
\end{aligned} \tag{9.5.2}$$

The constitutive expression (9.3.18) for the entropy has been introduced in the energy equation (9.3.33) to yield the differential equation (9.3.34). For this energy equation to become a partial differential equation for the sole temperature field $\theta(x,t) = T(x,t) - T_0$, where T_0 is a reference uniform temperature, the thermoelastic heat should be neglected. Thermoosmosis, considered in Section 9.3.3, should also be neglected, in such a way that the volume fluid flux $\mathbf{J}_{\rm w}$ [unit : m/s] and heat flux $\mathbf{Q}$ [unit : W/m^2] are uncoupled,

$$\mathbf{J}_{\rm w} = -k_{\rm H}\,\boldsymbol{\nabla}\,p_{\rm w}, \quad \mathbf{Q} = -k_{\rm T}\,\boldsymbol{\nabla}\,\theta\,, \tag{9.5.3}$$

with $k_{\rm H} > 0$ hydraulic permeability [unit : m^2/Pa/s], and $k_{\rm T} > 0$ thermal conductivity [unit : W/m/K]. The energy equation (9.3.34) then simplifies to

$$\frac{\partial\theta}{\partial t} - D_{\rm T}\,\Delta\theta = 0\,, \tag{9.5.4}$$

where the thermal diffusivity $D_{\rm T}$ [unit : m^2/s],

$$D_{\rm T} = \frac{k_{\rm T}}{C^{\rm U}_{\epsilon\zeta}}\,, \tag{9.5.5}$$

is built from the thermal conductivity $k_{\rm T}$ and the heat capacity of the porous medium at constant strain and fluid mass defined by (9.3.19). In fact, consistent with the linearization of the energy equation, all three heat capacities appearing in the constitutive expressions (9.3.12), (9.3.14) and (9.3.18) should be close. As indicated by (9.1.30), the thermal conductivity of a porous medium which is in local thermal equilibrium is equal to the spatial average of the thermal conductivities of its constituents.

Since the stress components will be calculated first, the compatibility conditions in terms of stress derived in Section 9.4 with the thermo-poroelastic strain $\boldsymbol{\epsilon}^*$ given by (9.5.2),

$$\overrightarrow{\boldsymbol{\nabla}}^2\,\mathrm{tr}\,\boldsymbol{\sigma} + (1+\nu)\,\Delta\boldsymbol{\sigma} + \frac{3}{S}\frac{\nu^{\rm U}-\nu}{1+\nu^{\rm U}}\Big(\overrightarrow{\boldsymbol{\nabla}}^2 p_{\rm w} + \frac{1+\nu}{1-\nu}\,\Delta p_{\rm w}\,\mathbf{I}\Big) + \frac{2}{3}\,\mu\,(1+\nu)\,\mathrm{tr}\,\mathbf{c}_{\rm T}\Big(\overrightarrow{\boldsymbol{\nabla}}^2\theta + \frac{1+\nu}{1-\nu}\,\Delta\theta\,\mathbf{I}\Big) = \mathbf{0}\,, \tag{9.5.6}$$

should be satisfied. Use will be made of the trace of this tensorial relation, which, factoring out the coefficient $(2+\nu)\,(1+\nu)/(1-\nu)$, can be cast in the format,

$$\frac{1-\nu}{1+\nu}\Delta\Big(\mathrm{tr}\,\boldsymbol{\sigma} + \frac{3}{S}\,p_{\rm w}\Big) - \frac{3}{S}\frac{1-\nu^{\rm U}}{1+\nu^{\rm U}}\,\Delta p_{\rm w} + \frac{4}{3}\,\mu\,\mathrm{tr}\,\mathbf{c}_{\rm T}\,\Delta\theta = 0\,. \tag{9.5.7}$$

Upon linearization, the balance of fluid mass becomes $\partial\zeta^{\rm w}/\partial t + \mathrm{div}\,\mathbf{J}_{\rm w} = 0$. Insertion of the elastic constitutive equation and flow equation and elimination of the Laplacians of pressure and temperature via (9.5.4) and (9.5.7), respectively, yield an inhomogeneous equation of diffusion type phrased in terms of a hydraulic (Darcy's) diffusivity $D_{\rm H}$ [unit : m^2/s],

$$D_{\rm H} = \frac{2}{9}S^2\frac{(1+\nu^{\rm U})^2(1-\nu)}{(\nu^{\rm U}-\nu)(1-\nu^{\rm U})}\,\mu\,k_{\rm H}\,, \tag{9.5.8}$$

for $\mathrm{tr}\,\boldsymbol{\sigma} + (3/S)\,p_{\rm w}$, namely

$$\Big(\frac{\partial}{\partial t} - D_{\rm H}\,\frac{\partial^2}{\partial x^2}\Big)\Big(\mathrm{tr}\,\boldsymbol{\sigma} + \frac{3}{S}\,p_{\rm w}\Big) = \frac{4}{3}\,\mu\,\frac{1+\nu}{1-\nu}\Big(\big(\frac{D_{\rm H}}{D_{\rm T}} - 1\big)\,\mathrm{tr}\,\mathbf{c}_{\rm T} + \frac{9}{4S}\,\frac{b_1}{\mu}\,\frac{1-\nu^{\rm U}}{1+\nu^{\rm U}}\Big)\frac{\partial\theta}{\partial t}\,, \tag{9.5.9}$$

or, via (9.5.2), for the dimensionless mass content $\zeta^{\rm w}$,

$$\Big(\frac{\partial}{\partial t} - D_{\rm H}\,\frac{\partial^2}{\partial x^2}\Big)\zeta^{\rm w} = \frac{D_{\rm H}}{D_{\rm T}}b_2\,\frac{\partial\theta}{\partial t}\,. \tag{9.5.10}$$

The two positive coefficients b_1 [unit : Pa/K] and b_2 [unit : 1/K],

$$\begin{aligned} &b_1\,k_{\rm H} = b_2\,D_{\rm H}\,,\\ &\frac{b_1}{b_0} = \frac{4}{9}\,\mu\,\frac{1+\nu^{\rm U}}{1-\nu^{\rm U}}\,S\,, \quad \frac{b_2}{b_0} = \frac{2}{S}\,\frac{\nu^{\rm U}-\nu}{(1+\nu^{\rm U})(1-\nu)}\,,\\ &b_0 = \mathrm{tr}\,\mathbf{c}_{\rm T} + \frac{S}{2}\frac{(1+\nu^{\rm U})(1-\nu)}{\nu^{\rm U}-\nu}\,n^{\rm w}\,(c_{\rm Tw} - \mathrm{tr}\,\mathbf{c}_{\rm T})\,, \end{aligned} \tag{9.5.11}$$

have been introduced so as to comment the results in terms of thermomechanical properties, and thermal and hydraulic diffusivities. It is also instrumental to introduce the ratio of the diffusivities,

$$\chi \equiv \frac{\sqrt{D_{\rm H}}}{\sqrt{D_{\rm T}}}\,, \tag{9.5.12}$$

and the dimensionless coordinates,

$$X_{\rm T} \equiv \frac{x}{2\sqrt{D_{\rm T}\,t}}, \quad X_{\rm H} \equiv \frac{x}{2\sqrt{D_{\rm H}\,t}}\,. \tag{9.5.13}$$

Even if the medium is semi-infinite, one may focus attention on the diffusion processes over a finite distance L. Then, $t_{\rm T}$ and $t_{\rm H}$, defined by

$$t_{\rm T} \equiv \frac{L^2}{D_{\rm T}}, \quad t_{\rm H} \equiv \frac{L^2}{D_{\rm H}}\,, \tag{9.5.14}$$

appear as times characterizing respectively thermal diffusion and hydraulic diffusion.

9.5.2 Thermo-poroelastic field equations in a 1D context

In the one-dimensional context envisaged here, the only nonzero displacement component u_x is along the axis x, and all fields are independent of the lateral coordinates y and z. Therefore, the only nonzero component of the strain tensor $\boldsymbol{\epsilon}$ is the axial strain $\epsilon_{xx} = \partial u_x/\partial x$. The constraint $\epsilon_{yy} = \epsilon_{zz} = 0$ provides the lateral stresses $\sigma_{yy} = \sigma_{zz}$ in terms of σ_{xx}, $p_{\rm w}$ and θ. With help of the energy equation (9.5.4), the field equation (9.5.9) transforms to

$$\Big(\frac{\partial}{\partial t} - D_{\rm H}\,\frac{\partial^2}{\partial x^2}\Big)\Big(\frac{S}{3}\,\frac{1+\nu^{\rm U}}{1-\nu^{\rm U}}\,\sigma_{xx} + p_{\rm w}\Big) = b_1\,\frac{\partial \theta}{\partial t}\,. \tag{9.5.15}$$

In a one-dimensional context, the compatibility condition for the strain is automatically satisfied since there is a single nonzero strain component. In fact, the constitutive relations yield directly,

$$\frac{1-\nu}{1+\nu}\Big(\operatorname{tr}\boldsymbol{\sigma} + \frac{3}{S}\,p_{\rm w}\Big) - \sigma_{xx} - \frac{3}{S}\,\frac{1-\nu^{\rm U}}{1+\nu^{\rm U}}\,p_{\rm w} + \frac{4}{3}\,\mu\operatorname{tr}\mathbf{c}_{\rm T}\,\theta = 0\,. \tag{9.5.16}$$

To simplify the analysis, the mechanical loading is specified in terms of traction,

$$\begin{aligned}
&(\mathrm{FE})_{\rm M}\ \text{field equation} && \frac{\partial \sigma_{xx}}{\partial x} = 0, \quad t>0,\ x>0;\\
&(\mathrm{IC})_{\rm M}\ \text{initial condition} && \sigma_{xx}(x,0) = 0\,;\\
&(\mathrm{BC})_{\rm M}\ \text{boundary condition} && \sigma_{xx}(0,t) = \sigma^0_{xx}\,\mathcal{H}(t);\\
&(\mathrm{RC})_{\rm M}\ \text{radiation condition} && u_x(x\to\infty,t) = 0, \quad t>0\,.
\end{aligned} \tag{9.5.17}$$

Consequently the axial stress is uniform in both space and time, $\sigma_{xx}(x,t) = \sigma^0_{xx}\,\mathcal{H}(t)$. The field equation (9.5.15) becomes a decoupled equation for the fluid pressure. It would not be so if the displacement, rather than the traction, was prescribed at the boundary $x = 0$.

The scheme to obtain a complete analytical solution simplifies, due to the partial couplings:

1. the thermal problem is solved first;
2. the flow problem, driven by the thermal loading, can then be solved;
3. finally, the axial displacement and all components of stress follow.

The analytical treatment via the Laplace transform technique capitalizes upon the elementary solutions of diffusion problems worked out in Section 15.3.2.

The four thermo-hydromechanical boundary conditions at the left boundary $x = 0$ envisaged below are sketched in Fig. 9.5.1.

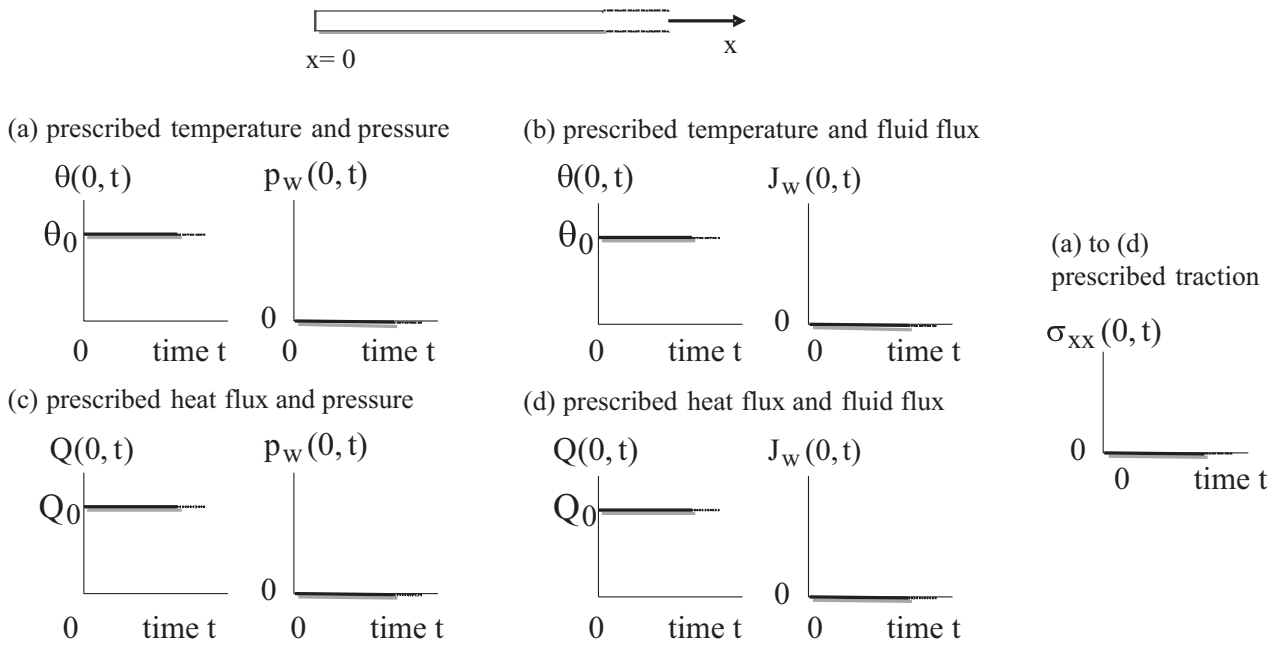

Fig. 9.5.1: Boundary conditions for the coupled heat diffusion problem, fluid diffusion problem and mechanical problem.

9.5.3 Prescribed temperature and drained boundary

The solution to the one-dimensional Initial and Boundary Value Problem (IBVP) for the temperature,

$$\begin{aligned}
&(\mathrm{FE})_{\mathrm{T}} \text{ field equation} && \frac{\partial \theta}{\partial t} - D_{\mathrm{T}} \frac{\partial^2 \theta}{\partial x^2} = 0, \quad t > 0,\ x > 0;\\
&(\mathrm{IC})_{\mathrm{T}} \text{ initial condition} && \theta(x,0) = 0\,;\\
&(\mathrm{BC})_{\mathrm{T}} \text{ boundary condition} && \theta(0,t) = \theta_0\, \mathcal{H}(t);\\
&(\mathrm{RC})_{\mathrm{T}} \text{ radiation condition} && -\infty < \theta(x \to \infty, t) < \infty, \quad t > 0\,,
\end{aligned} \tag{9.5.18}$$

is detailed in Section 15.3.2.1, and reads

$$\theta(x,t) = \theta_0 \operatorname{erfc}(X_{\mathrm{T}}), \quad Q(x,t) = -k_{\mathrm{T}} \frac{\partial \theta}{\partial x}(x,t) = \frac{k_{\mathrm{T}}\, \theta_0}{\sqrt{\pi D_{\mathrm{T}}\, t}} \exp(-X_{\mathrm{T}}^2)\,. \tag{9.5.19}$$

For any coefficient α,

$$\frac{\partial \theta}{\partial t} = D_{\mathrm{T}}\, \Delta\theta = \alpha \frac{\partial \theta}{\partial t} + (1-\alpha)\, D_{\mathrm{T}}\, \Delta\theta\,, \tag{9.5.20}$$

the field equation (9.5.15) may be transformed to,

$$\frac{\partial}{\partial t}\Big(p_{\mathrm{w}} - \alpha\, b_1\, \theta\Big) - D_{\mathrm{H}} \frac{\partial^2}{\partial x^2}\Big(p_{\mathrm{w}} + (1-\alpha)\, b_1 \frac{D_{\mathrm{T}}}{D_{\mathrm{H}}}\theta\Big) = 0\,. \tag{9.5.21}$$

Then, with

$$\alpha = \frac{1}{1-\chi^2}\,, \tag{9.5.22}$$

the IBVP for the fluid pressure may be conveniently cast in a format which is identical to the thermal IBVP,

$$\begin{aligned}
&(\mathrm{FE})_{\mathrm{H}} \text{ field equation} && \Big(\frac{\partial}{\partial t} - D_{\mathrm{H}} \frac{\partial^2}{\partial x^2}\Big)(p_{\mathrm{w}} - \alpha\, b_1\, \theta) = 0, \quad t > 0,\ x > 0;\\
&(\mathrm{IC})_{\mathrm{H}} \text{ initial condition} && (p_{\mathrm{w}} - \alpha\, b_1\, \theta)(x,0) = 0\,;\\
&(\mathrm{BC})_{\mathrm{H}} \text{ boundary condition} && (p_{\mathrm{w}} - \alpha\, b_1\, \theta)(0,t) = -\alpha\, b_1\, \theta_0\, \mathcal{H}(t);\\
&(\mathrm{RC})_{\mathrm{H}} \text{ radiation condition} && -\infty < (p_{\mathrm{w}} - \alpha\, b_1\, \theta)(x \to \infty, t) < \infty, \quad t > 0\,.
\end{aligned} \tag{9.5.23}$$

The solution for the pressure results readily,

$$p_{\rm w}(x,t) = \alpha\, b_1\, \theta_0 \left(\operatorname{erfc}(X_{\rm T}) - \operatorname{erfc}(X_{\rm H})\right). \tag{9.5.24}$$

Whether the thermal diffusivity is smaller or larger than the hydraulic diffusivity, namely $\chi > 1$ or $\chi < 1$, the pressure has a maximum for

$$X_{\rm H} = \frac{x}{2\sqrt{D_{\rm H}\, t}} = \sqrt{\frac{\operatorname{Ln}\chi}{\chi^2 - 1}}\,. \tag{9.5.25}$$

This maximum is a constant and its position moves inward. It is interesting to note that, even if it is triggered by a thermal boundary condition, the fluid flow may precede the thermal flow at some depth within the body, if the hydraulic diffusivity is larger than the thermal diffusivity.

The fluid flux,

$$J_{\rm w}(x,t) = -b_2\, \theta_0\, \frac{\sqrt{D_{\rm H}}\sqrt{D_{\rm T}}}{\sqrt{D_{\rm H}} + \sqrt{D_{\rm T}}}\, \frac{1}{\sqrt{\pi t}}\, \frac{\exp(-X_{\rm H}^2) - \chi \exp(-X_{\rm T}^2)}{1-\chi}\,, \tag{9.5.26}$$

has distinct sign on each side of the maximum of the pressure, and vanishes at large times. Its value at the boundary $x = 0$,

$$J_{\rm w}(0,t) = -b_2\, \theta_0\, \frac{\sqrt{D_{\rm H}}\sqrt{D_{\rm T}}}{\sqrt{D_{\rm H}} + \sqrt{D_{\rm T}}}\, \frac{1}{\sqrt{\pi t}}\,, \tag{9.5.27}$$

is controlled by the lowest of the thermal and hydraulic diffusivities. It has a sign opposite to the temperature change: if the temperature is increased, the flux at the boundary is directed outwards.

9.5.4 Prescribed temperature and impervious boundary

For this boundary condition, the only change in the IBVP defined by (9.5.23) reads,

$$(\mathrm{BC})_{\rm H} \text{ boundary condition} \quad \frac{\partial}{\partial x}(p_{\rm w} - \alpha\, b_1\, \theta)(0,t) = -\alpha\, b_1\, \frac{\partial \theta}{\partial x}(0,t)\,. \tag{9.5.28}$$

The solution is obtained by the Laplace transform technique with respect to time. The solution in the Laplace domain derives from the field equation, radiation condition and boundary condition,

$$\begin{aligned} &(\mathrm{FE})\ \mathcal{L}\{(p_{\rm w} - \alpha\, b_1\, \theta)(x,t)\}(p) = A(p)\, \exp\Big(-\sqrt{\frac{p}{D_{\rm H}}}\, x\Big) + \underbrace{B(p)\, \exp\Big(\sqrt{\frac{p}{D_{\rm H}}}\, x\Big)}_{B(p)=0,\ (\mathrm{RC})_{\rm H}} \\ &(\mathrm{BC})_{\rm H}\ A(p) = -\alpha\, b_1\, \frac{\sqrt{D_{\rm H}}}{\sqrt{p}}\, \mathcal{L}\Big\{\frac{\partial \theta}{\partial x}(0,t)\Big\}(p) = -\chi\, \alpha\, \frac{b_1\, \theta_0}{p}\,. \end{aligned} \tag{9.5.29}$$

The inverse transform is obtained by using Table 15.3.1, yielding finally,

$$p_{\rm w}(x,t) = b_1\, \theta_0\, \frac{\sqrt{D_{\rm T}}}{\sqrt{D_{\rm H}} + \sqrt{D_{\rm T}}}\, \frac{\operatorname{erfc}(X_{\rm T}) - \chi \operatorname{erfc}(X_{\rm H})}{1-\chi}\,. \tag{9.5.30}$$

Its value at the boundary $x = 0$,

$$p_{\rm w}(0,t) = b_1\, \theta_0\, \frac{\sqrt{D_{\rm T}}}{\sqrt{D_{\rm H}} + \sqrt{D_{\rm T}}}\,, \tag{9.5.31}$$

is constant in time. The fluid flux,

$$J_{\rm w}(x,t) = -\alpha\, b_2\, \theta_0\, \frac{D_{\rm H}}{\sqrt{D_{\rm T}}}\, \frac{1}{\sqrt{\pi t}} \left(\exp(-X_{\rm H}^2) - \exp(-X_{\rm T}^2)\right), \tag{9.5.32}$$

has the sign of the temperature change. It duly vanishes at the boundary $x = 0$. At any time $t > 0$, the flux is maximum at the position

$$X_{\rm H} = \frac{x}{2\sqrt{D_{\rm H}\, t}} = \sqrt{\frac{\operatorname{Ln}\chi^2}{\chi^2 - 1}}\,, \tag{9.5.33}$$

and the value of this maximum,

$$J_{\rm w}(x,t) = b_2\, D_{\rm T}\, \theta_0\, \frac{\exp(-X_{\rm H}^2)}{\sqrt{\pi D_{\rm T} t}} = b_2\, D_{\rm H}\, \theta_0\, \frac{\exp(-X_{\rm T}^2)}{\sqrt{\pi D_{\rm T} t}}\,, \tag{9.5.34}$$

is infinitely large at short times but decreases as time goes by. In fact, at large times, the pressure homogenizes and the flux vanishes.

9.5.5 Prescribed thermal flux and drained boundary

The solution to the IBVP corresponding to a sudden heat flux Q_0 [unit : W/m^2],

$$\begin{aligned}
&(\mathrm{FE})_{\mathrm{T}}\ \text{field equation} && \frac{\partial\theta}{\partial t} - D_{\mathrm{T}}\,\frac{\partial^2\theta}{\partial x^2} = 0, \quad t>0,\ x>0;\\
&(\mathrm{IC})_{\mathrm{T}}\ \text{initial condition} && \theta(x,0) = 0\,;\\
&(\mathrm{BC})_{\mathrm{T}}\ \text{boundary condition} && Q(0,t) = -k_{\mathrm{T}}\,\frac{\partial\theta}{\partial x}(0,t) = Q_0\,\mathcal{H}(t);\\
&(\mathrm{RC})_{\mathrm{T}}\ \text{radiation condition} && \theta(x\to\infty,t) < \infty, \quad t>0\,,
\end{aligned} \tag{9.5.35}$$

is detailed in Section 15.3.2.2, and reads

$$\theta(x,t) = 2\,\frac{Q_0}{k_{\mathrm{T}}}\,\sqrt{D_{\mathrm{T}}\,t}\,\mathrm{F}_1(X_{\mathrm{T}}), \quad Q(x,t) = Q_0\,\mathrm{erfc}\big(X_{\mathrm{T}}\big)\,, \tag{9.5.36}$$

where $\mathrm{F}_1(X) \equiv \exp(-X^2)/\sqrt{\pi} - X\,\mathrm{erfc}(X)$, and $\mathrm{F}_1(0) = 1/\sqrt{\pi}$. The heat flux tends to homogenize progressively in the body. On the other hand, the temperature increases to large values,

$$\theta(x=0,t) = \theta(x,t\to\infty) = 2\,\frac{Q_0}{k_{\mathrm{T}}}\,\sqrt{\frac{D_{\mathrm{T}}}{\pi}\,t}\,. \tag{9.5.37}$$

The IBVP for the fluid pressure is still given by (9.5.23) but with the temperature (9.5.36). It is solved once again through the Laplace transform,

$$\begin{aligned}
&(\mathrm{FE})\ \mathcal{L}\{(p_{\mathrm{w}} - \alpha\,b_1\,\theta)(x,t)\}(p) = A(p)\,\exp(-\sqrt{\frac{p}{D_{\mathrm{H}}}}\,x) + \overbrace{B(p)\,\exp(\sqrt{\frac{p}{D_{\mathrm{H}}}}\,x)}^{B(p)=0,\ (\mathrm{RC})_{\mathrm{H}}}\\
&(\mathrm{BC})_{\mathrm{H}}\ A(p) = -\alpha\,b_1\,\mathcal{L}\{\theta(0,t)\}(p) = -\alpha\,b_1\,\frac{Q_0}{k_{\mathrm{T}}}\,\frac{\sqrt{D_{\mathrm{T}}}}{p^{3/2}}\,,
\end{aligned} \tag{9.5.38}$$

yielding,

$$p_{\mathrm{w}}(x,t) = 2\,\alpha\,b_1\,\frac{Q_0}{k_{\mathrm{T}}}\,\sqrt{D_{\mathrm{T}}\,t}\,\Big(\,\mathrm{F}_1(X_{\mathrm{T}}) - \mathrm{F}_1(X_{\mathrm{H}})\,\Big)\,. \tag{9.5.39}$$

Therefore, the pressure vanishes at any point at times $t=0$ and $t=\infty$. It has a maximum for X_{H} solution of the equation $\chi\,\mathrm{erfc}(X_{\mathrm{T}}) = \mathrm{erfc}(X_{\mathrm{H}})$, and this maximum, which moves inward, increases in time like $t^{1/2}$. The fluid flux,

$$J_{\mathrm{w}}(x,t) = -\frac{Q_0}{k_{\mathrm{T}}}\,b_2\,\frac{\sqrt{D_{\mathrm{H}}}\,D_{\mathrm{T}}}{\sqrt{D_{\mathrm{H}}}+\sqrt{D_{\mathrm{T}}}}\,\frac{\mathrm{erfc}\big(X_{\mathrm{H}}\big) - \chi\,\mathrm{erfc}\big(X_{\mathrm{T}}\big)}{1-\chi}\,, \tag{9.5.40}$$

is finite and constant in time at the boundary, and tends to homogenize at large times,

$$J_{\mathrm{w}}(x=0,t) = J_{\mathrm{w}}(x,t\to\infty) = -\frac{Q_0}{k_{\mathrm{T}}}\,b_2\,\frac{\sqrt{D_{\mathrm{H}}}\,D_{\mathrm{T}}}{\sqrt{D_{\mathrm{H}}}+\sqrt{D_{\mathrm{T}}}}\,. \tag{9.5.41}$$

9.5.6 Prescribed thermal flux and impervious boundary

The IBVP is again defined by (9.5.23) and (9.5.28). The solution is obtained by the Laplace transform technique with respect to time. The solution in the Laplace domain derives from the field equation, radiation condition and boundary condition,

$$\begin{aligned}
&(\mathrm{FE})\ \mathcal{L}\{(p_{\mathrm{w}} - \alpha\,b_1\,\theta)(x,t)\}(p) = A(p)\,\exp(-\sqrt{\frac{p}{D_{\mathrm{H}}}}\,x) + \overbrace{B(p)\,\exp(\sqrt{\frac{p}{D_{\mathrm{H}}}}\,x)}^{B(p)=0,\ (\mathrm{RC})_{\mathrm{H}}}\,,\\
&(\mathrm{BC})_{\mathrm{H}}\ \mathcal{L}\Big\{\frac{\partial}{\partial x}(p_{\mathrm{w}} - \alpha\,b_1\,\theta)(0,t)\Big\}(p) = -\alpha\,b_1\,\mathcal{L}\Big\{\frac{\partial\theta}{\partial x}(0,t)\Big\}(p) = -A(p)\,\sqrt{\frac{p}{D_{\mathrm{H}}}}\,,\\
&\quad\Rightarrow\quad A(p) = -\alpha\,b_1\,\frac{Q_0}{k_{\mathrm{T}}}\,\frac{\sqrt{D_{\mathrm{H}}}}{p^{3/2}}\,.
\end{aligned} \tag{9.5.42}$$

The inverse transform is obtained by using Table 15.3.1, yielding finally,

$$p_{\rm w}(x,t) = 2\,b_1\,\frac{Q_0}{k_{\rm T}}\,\frac{D_{\rm T}\,\sqrt{t}}{\sqrt{D_{\rm H}}+\sqrt{D_{\rm T}}}\,\frac{{\rm F}_1(X_{\rm T})-\chi{\rm F}_1(X_{\rm H})}{1-\chi}\,, \tag{9.5.43}$$

and

$$p_{\rm w}(x=0,t) = p_{\rm w}(x,t\to\infty) = 2\,b_1\,\frac{Q_0}{k_{\rm T}}\,\frac{D_{\rm T}\,\sqrt{t}}{\sqrt{D_{\rm H}}+\sqrt{D_{\rm T}}}\,\frac{1}{\sqrt{\pi}}\,. \tag{9.5.44}$$

The fluid flux,

$$J_{\rm w}(x,t) = -\frac{Q_0}{k_{\rm T}}\,\alpha\,b_2\,D_{\rm H}\,\Big({\rm erfc}\big(X_{\rm H}\big)-{\rm erfc}\big(X_{\rm T}\big)\Big)\,, \tag{9.5.45}$$

has the sign of the prescribed heat flux. It tends to vanish at large times all over the body.

9.5.7 Mechanical output, strain, stress and displacement

Given the pressure and temperature fields, the lateral stresses and axial strain deduce from the vanishing lateral strain through the elastic constitutive equations (9.5.2),

$$\begin{aligned}
\sigma_{yy} = \sigma_{zz} &= \frac{\nu}{1-\nu}\,\sigma_{xx} - \frac{3}{S}\frac{\nu^{\rm U}-\nu}{(1+\nu^{\rm U})(1-\nu)}\,p_{\rm w} - \frac{2}{3}\,\mu\,\frac{1+\nu}{1-\nu}\,{\rm tr}\,\mathbf{c}_{\rm T}\;\theta,\\
\epsilon_{xx} &= \underbrace{\frac{1-2\nu}{1-\nu}}_{a_0}\,\frac{\sigma_{xx}}{2\mu} + \underbrace{\frac{3}{S}\frac{\nu^{\rm U}-\nu}{(1+\nu^{\rm U})(1-\nu)}}_{a_1>0}\,\frac{p_{\rm w}}{2\mu} + \underbrace{\frac{1}{3}\frac{1+\nu}{1-\nu}\,{\rm tr}\,\mathbf{c}_{\rm T}}_{a_2>0}\;\theta\,.
\end{aligned} \tag{9.5.46}$$

For the displacement to vanish at $x=\infty$, the prescribed traction σ^0_{xx} should itself vanish. The fact the total stress should be zero for the displacement at infinity to vanish is a one-dimensional feature. For two- and three-dimensional problems, the applied traction can spread over a surface or a volume and dies out quickly.

When the temperature is prescribed at the boundary $x=0$ which is drained, the displacement integrates to

$$u_x(x,t) = 2\,\sqrt{D_{\rm T}\,t}\,\theta_0\,\Big(a_1\,\frac{b_1}{2\mu}\,\frac{\chi\,{\rm ierfc}(X_{\rm H})-{\rm ierfc}(X_{\rm T})}{1-\chi^2} - a_2\,{\rm ierfc}(X_{\rm T})\Big)\,, \tag{9.5.47}$$

where the integral ierfc defined by (15.3.36) satisfies ierfc$(0)=1/\sqrt{\pi}$. The displacement at the boundary,

$$u_x(0,t) = -2\,\frac{\sqrt{D_{\rm T}\,t}}{\sqrt{\pi}}\,\theta_0\Big(a_1\,\frac{b_1}{2\mu}\,\frac{1}{1+\chi}+a_2\Big)\,, \tag{9.5.48}$$

varies in time like $t^{1/2}$, and has the sign opposite to the temperature change.

When the heat flux is prescribed at the boundary $x=0$ which is drained, the displacement integrates to

$$u_x(x,t) = 4\,\frac{Q_0}{k_{\rm T}}\,D_{\rm T}\,t\,\Big(a_1\,\frac{b_1}{2\mu}\,\frac{\chi\,{\rm i}^2{\rm erfc}(X_{\rm H})-{\rm i}^2{\rm erfc}(X_{\rm T})}{1-\chi^2} - a_2\,{\rm i}^2{\rm erfc}(X_{\rm T})\Big)\,. \tag{9.5.49}$$

The function i^{2}erfc defined by (15.3.36) is the integral of ierfc, that satisfies i^{2}erfc$(0)=1/4$, and, with help of the expansion (15.3.32), i^{2}erfc$(\infty)=0$. The following relations have been used, $\int_x^\infty {\rm ierfc}(X_{\rm A}(y))dy = 2\,\sqrt{D_A\,t}\,{\rm i}^2{\rm erfc}(X_{\rm A}(x))$, for $A=H,T$. The displacement $u_x(0,t)$ at the boundary,

$$u_x(0,t) = -\frac{Q_0}{k_{\rm T}}\,D_{\rm T}\,t\,\Big(a_1\,\frac{b_1}{2\mu}\,\frac{1}{1+\chi}+a_2\Big)\,, \tag{9.5.50}$$

varies linearly in time, and has the sign opposite to the heat flux.

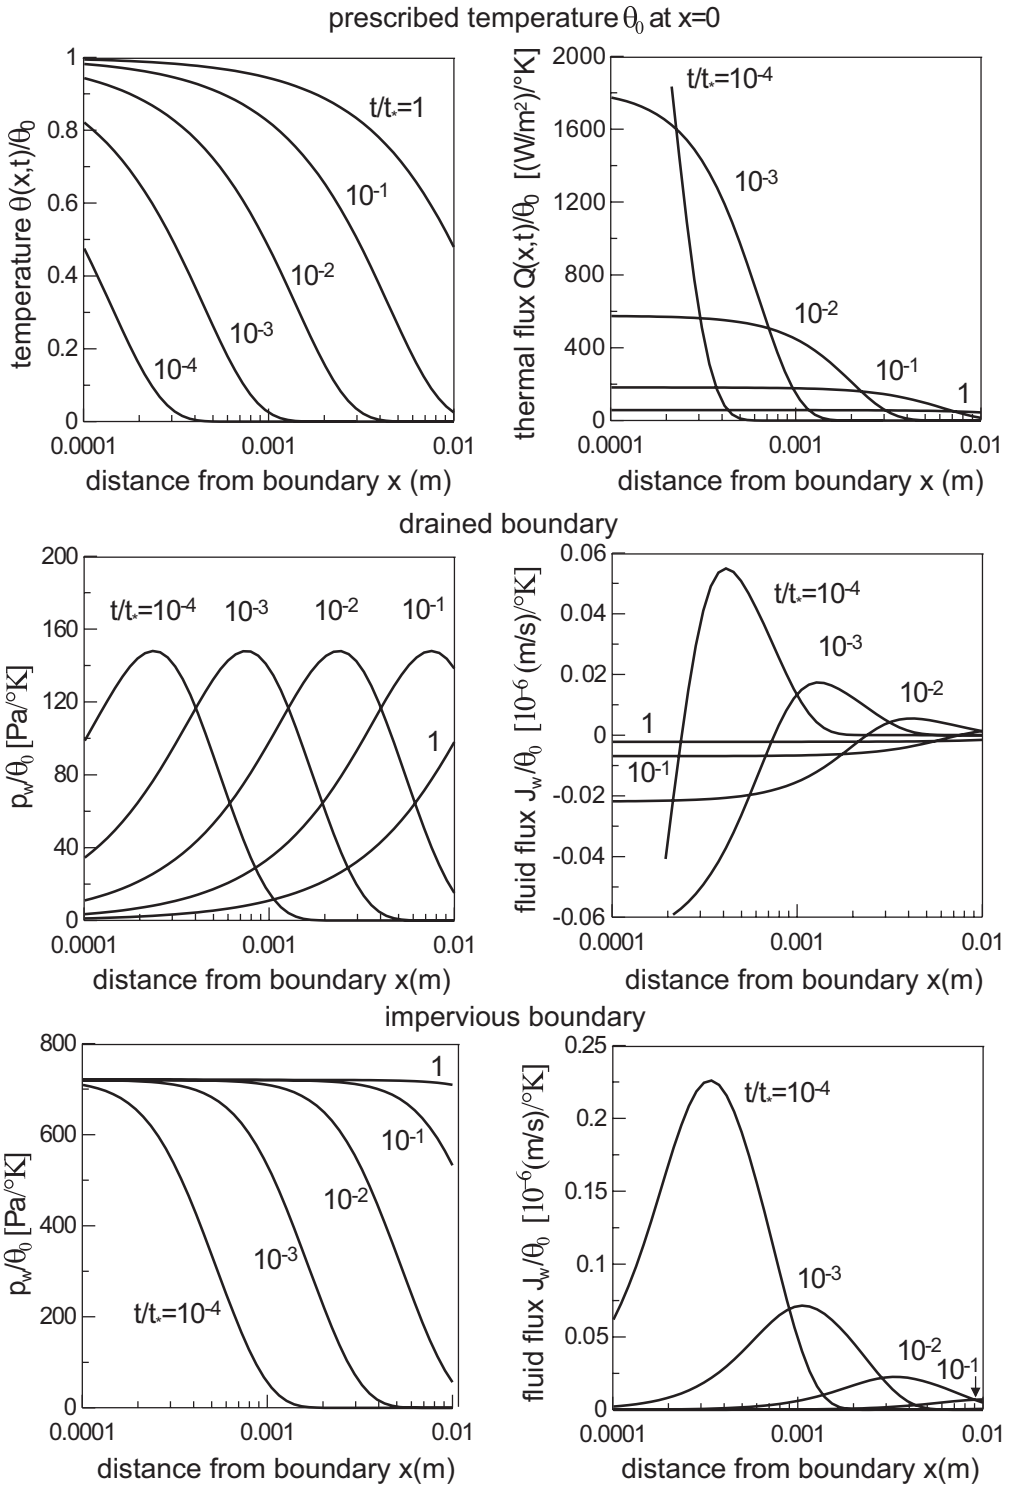

Fig. 9.5.2: One-dimensional poroelastic medium subjected to a prescribed temperature θ_0 at the left boundary $x = 0$. Temperature and thermal flux profiles in the neighborhood of this boundary over a depth $L = 10^{-2}$ m at selected times t/t_*. Thermal diffusion time $t_{\rm T} = L^2/D_{\rm T}$=384.3 s, hydraulic diffusion time $t_{\rm H} = L^2/D_{\rm H}$=27.8 s, and $t_* = \max(t_{\rm T}, t_{\rm H})$.

Fluid pressure and fluid flux for a drained boundary, and for an impervious boundary.

For a drained boundary, and for $\theta_0 > 0$, the pressure is positive, its maximum moves to the interior of the medium, and therefore water flows *out* close to the boundary (which is wet) but, deeper in the medium, it tends to flow *in*.

When the boundary is impervious, the pressure is again positive, and the water tends to move to the interior of the medium. As time goes by, the pressure tends to homogenize in space, and the water flux consequently dies out.

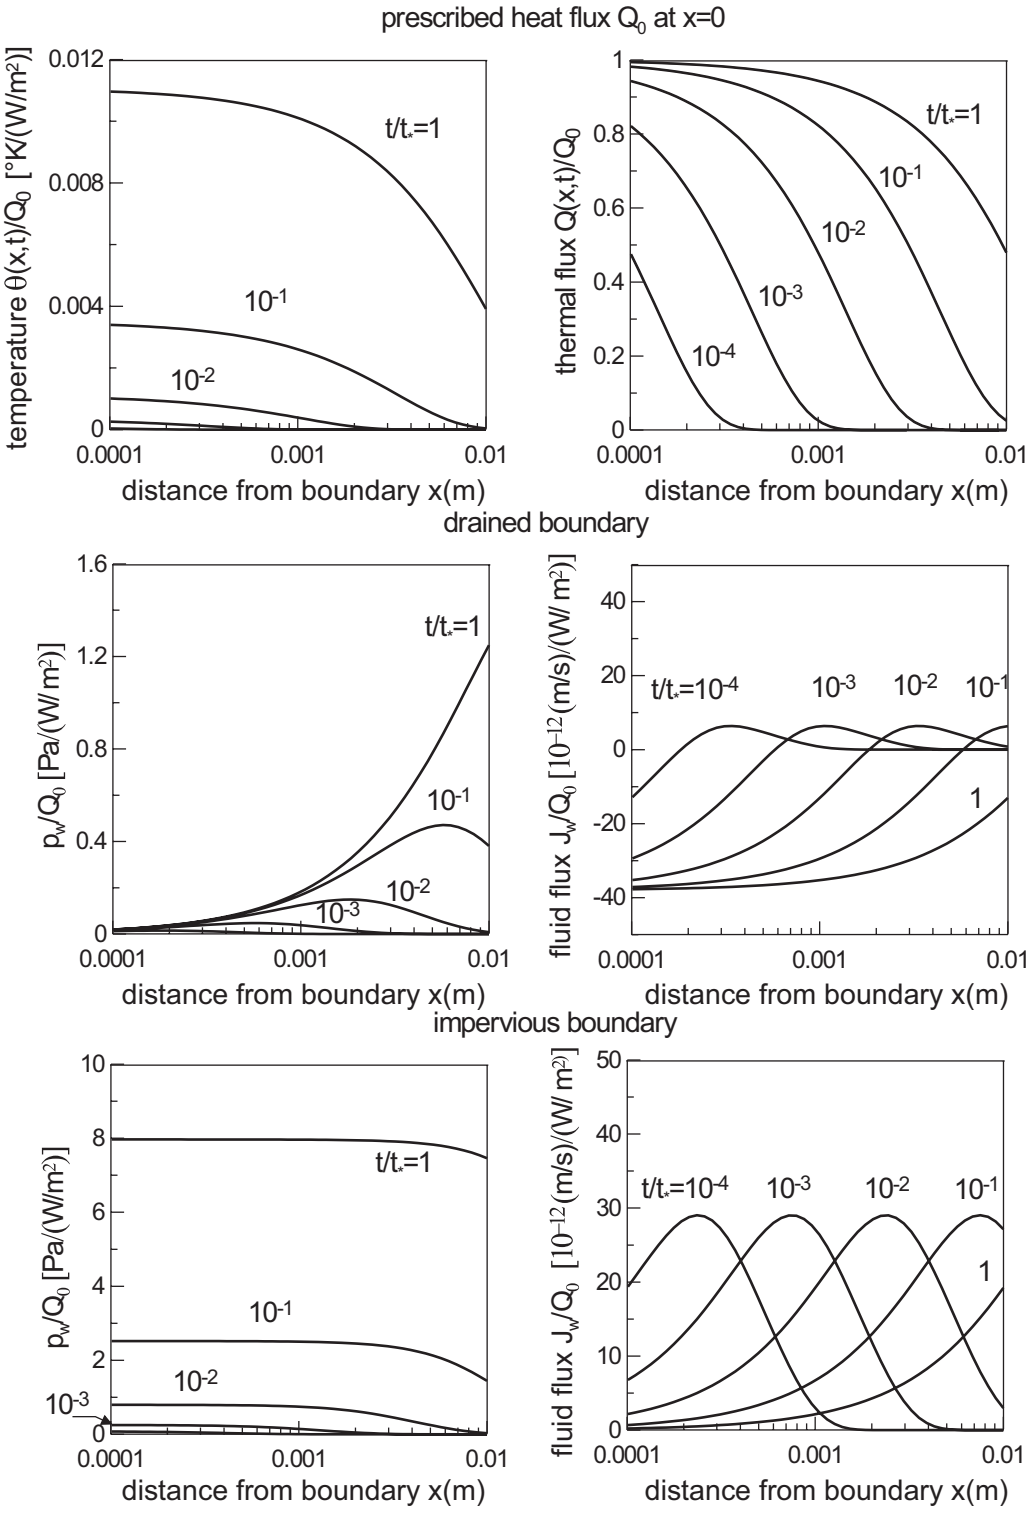

Fig. 9.5.3: Same as Fig. 9.5.2, but with heat flux Q_0 prescribed at the boundary $x = 0$. When the boundary is drained, it is wet for $Q_0 > 0$, and the flux tends to homogenize throughout the medium to its boundary value. When the boundary is impervious, water tends initially to move to the interior of the medium for $Q_0 > 0$, before coming to rest: the neighborhood of the boundary tends to dry out.

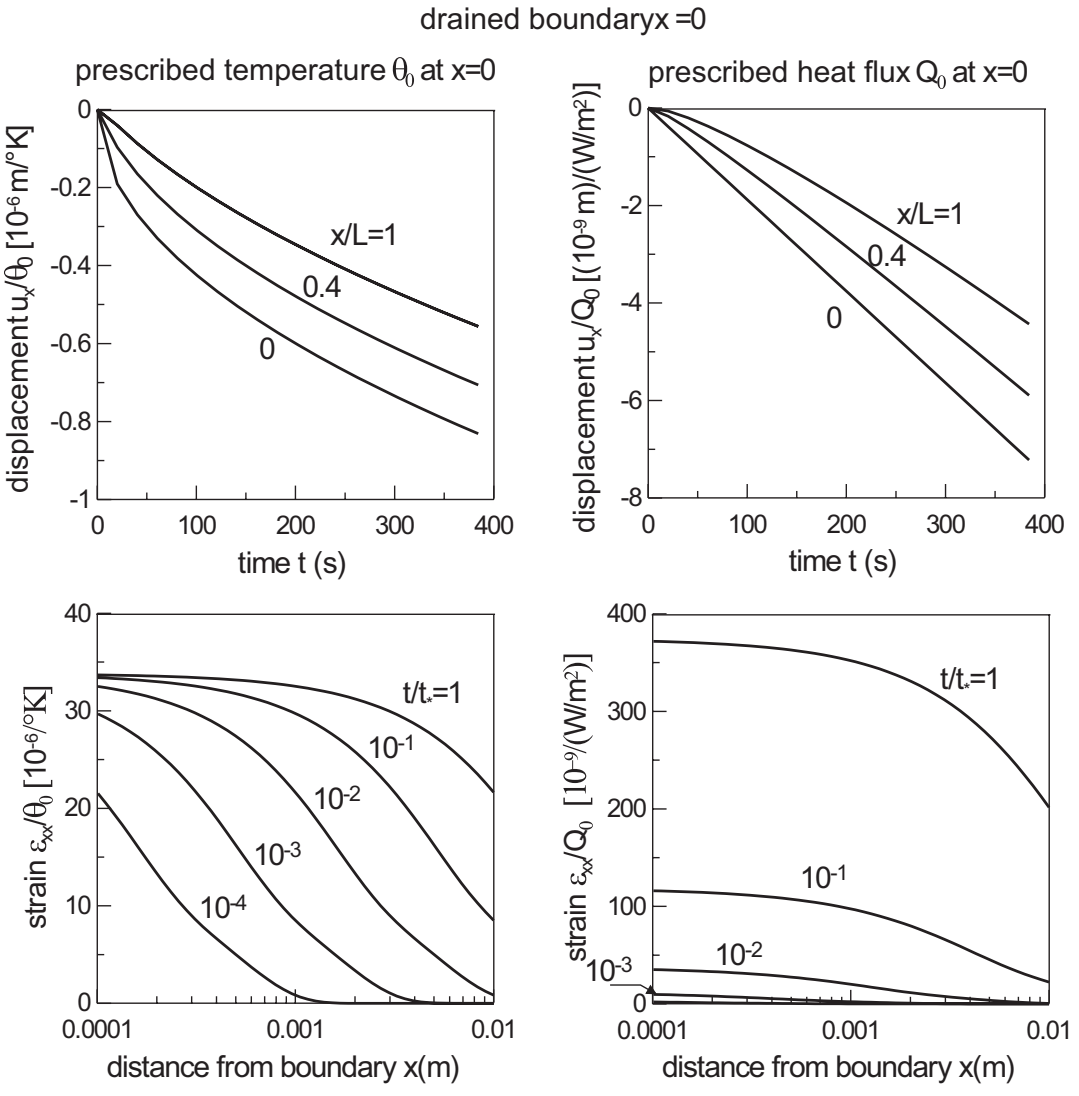

Fig. 9.5.4: Same as Fig. 9.5.2. Time profiles of displacement at selected depths x/L, and spatial profiles of the strain at selected times t/t_* for a drained boundary.

9.5.8 Simulations, drained and undrained limits

9.5.8.1 Simulations with thermal and hydraulic diffusivities of like orders

The parameters used pertain to a clay, McTigue [1986],

- thermal conductivity of porous medium $k_{\mathrm{T}} = 1.02\,\mathrm{W/m/K}$;
- heat capacity of porous medium $C = 3.92 \times 10^6\,\mathrm{J/m^3/K}$;
- cubic thermal expansion of the solid skeleton $\mathrm{tr}\,\mathbf{c}_{\mathrm{T}} = 0.034 \times 10^{-3}\,\mathrm{K}^{-1}$;
- cubic thermal expansion of the fluid $c_{\mathrm{Tw}} = 0.3 \times 10^{-3}\,\mathrm{K}^{-1}$;
- hydraulic permeability $k_{\mathrm{H}} = 2.0 \times 10^{-13}\,\mathrm{m^2/Pa/s}$;
- shear modulus of solid skeleton $\mu = 72 \times 10^3\,\mathrm{Pa}$;
- drained Poisson's ratio $\nu = 0.498$;
- bulk modulus of solid constituent $K_{\mathrm{s}} = 50\,\mathrm{GPa}$;
- bulk modulus of fluid $K_{\mathrm{w}} = 2\,\mathrm{GPa}$;
- volume fraction of fluid $n^{\mathrm{w}} = 0.71$.

Mechanical properties of interest defined in Section 7.3.6.5 follow, e.g., the drained bulk modulus $K = 18\,\mathrm{MPa}$, Skempton coefficient $S = 0.994$, undrained Poisson's ratio $\nu^{\mathrm{U}} = 0.49999$.

The ensuing thermal diffusivity $D_{\rm T} = 0.26 \times 10^{-6}\,{\rm m}^2/{\rm s}$ is an order of magnitude smaller than the hydraulic diffusivity $D_{\rm H} = 3.59 \times 10^{-6}\,{\rm m}^2/{\rm s}$.

Figs. 9.5.2 and 9.5.3 display the spatial profiles of temperature, pressure and heat and fluid fluxes over a depth $L = 10^{-2}\,{\rm m}$, at different times. The thermal diffusion time $t_{\rm T} = L^2/D_{\rm T}$=384.3 s, which is larger than the hydraulic diffusion time $t_{\rm H} = L^2/D_{\rm H}$=27.8 s, controls the time evolution of the processes.

Fig. 9.5.4 displays mechanical output for a drained boundary. The displacement at the boundary increases like the square root of time when the temperature is prescribed, and linearly when the heat flux is prescribed. This effect is a typical one-dimensional feature.

With the above material properties, the hydraulic diffusivity is about 13.8 times larger than the thermal diffusivity, corresponding to $\chi \simeq 3.7$. The thermal information, while diffusing into the body, triggers hydraulic diffusion through thermomechanical coupling. In fact, hydraulic diffusion being faster than thermal diffusion, fluid pressure penetrates the medium ahead of temperature. Both fields contribute to the deformation: at a point inside the medium, the contribution due to pressure takes place first. In the examples considered, the two contributions have the same sign, corresponding to a dilatation if $\theta_0 > 0$ and $Q_0 > 0$. For example, at point $x = L/10$, the pressure reaches its maximum at time about $t_{\rm T}/10^3$ when the boundary is drained, while the temperature has virtually not increased yet, Fig. 9.5.2. At that time, the deformation has reached about 25% of its limit value, Fig. 9.5.4.

9.5.8.2 Thermal and hydraulic diffusivities of different orders

Let us consider first the case where the thermal diffusivity is much smaller than the hydraulic diffusivity, corresponding to $\chi \gg 1$, and $\alpha \ll 1$. Then, the IBVP (9.5.23) indicates that the thermal loading does not trigger significantly the fluid pressure, which is expected to remain small. The problem is therefore close to a drained problem.

Conversely, the problem is approximately undrained when the thermal diffusivity is much larger than the hydraulic diffusivity. Indeed, let $\tilde{t} = t/t_{\rm T}$ and $\tilde{x} = x/L$. Then the field equation (9.5.10) for the dimensionless mass content $\zeta^{\rm w}$ may be rephrased in terms of dimensionless variables associated with the thermal process, namely

$$\Big(\frac{\partial}{\partial \tilde{t}} - \frac{D_{\rm H}}{D_{\rm T}}\,\frac{\partial^2}{\partial \tilde{x}^2}\Big)\zeta^{\rm w} = \frac{D_{\rm H}}{D_{\rm T}} b_2\,\frac{\partial \theta}{\partial \tilde{t}}\,. \tag{9.5.51}$$

Therefore, for $D_{\rm H}/D_{\rm T} \ll 1$, the fluid mass content is constant at the thermal time scale. Similarly, $p_{\rm w} = b_1\theta$ up to a constant according to (9.5.15). The axial strain (9.5.46) can then be cast in terms of the undrained cubic coefficient of thermal expansion $\operatorname{tr}\mathbf{c}_{\rm T}^{\rm U} = \operatorname{tr}\mathbf{c}_{\rm T} + S\,n^{\rm w}\,(c_{\rm Tw} - \operatorname{tr}\mathbf{c}_{\rm T})$ defined by (9.3.16),

$$\epsilon_{xx}(x,t) = \frac{1+\nu^{\rm U}}{1-\nu^{\rm U}}\,\frac{1}{3}\operatorname{tr}\mathbf{c}_{\rm T}^{\rm U}\;\theta(x,t)\,. \tag{9.5.52}$$

9.5.9 Extension of the above model including thermoosmosis

Zhou et al. [1998] consider a one-dimensional saturated porous medium where one boundary is drained, subjected to a thermal shock and to a constant traction, while the other boundary is drained but and has a fixed temperature and zero displacement. They include diffusion couplings, namely the thermoosmotic effect and the symmetric mechanocaloric effect, also referred to as thermal filtration.

They derived an analytical solution through Laplace transform technique. For low hydraulic permeability, the thermal diffusivity is larger than the hydraulic diffusivity. In absence of diffusion couplings, spatial thermal equilibrium is established first. Even for a coupling coefficient $k_{\rm TO}$ lower than one percent of the limit $\sqrt{T\,k_{\rm T}\,k_{\rm H}}$ indicated by (9.3.26), they observe that the magnitudes and time profiles of the pore pressure and mechanical outputs are significantly modified with respect to the uncoupled case $k_{\rm TO} = 0$. On the other hand, this coupling is observed to affect little the thermal field.

In other words, diffusion coupling through $k_{\rm TO}$ affects significantly the hydraulic flow by thermoosmosis, but coupling through $k_{\rm MC}$ affects little the thermal flow. In order to obtain a tractable analytical solution, one might therefore be tempted to abandon Onsager symmetry, so as to be able to decouple the thermal field from the hydraulic flow. This position is adopted by Ghassemi and Diek [2002] in a thermo-poro-chemoelastic analysis of swelling materials. When introduced in the balance of mass, the thermal field contributes due to mechanical coupling and thermoosmosis.

Zhou et al. [1998] and Ghassemi and Diek [2002] address materials that are negatively charged at neutral pH. The former authors use a positive thermoosmotic coefficient and the latter a negative one.

9.5.10 Chemo-poroelasticity versus thermo-poroelasticity

With respect to the chemo-poroelastic problem considered in Section 13.13, the thermal field plays the role of the chemical concentration. The compressibility of the two constituents implies that a specific constitutive equation should be provided for the fluid constituent. In the case of incompressible constituents, this constitutive equation is replaced by a condition of incompressibility, which can be interpreted as a balance of mass within the porous medium.

The mass balance of the chemical and the energy equation play the role of field equation. Both are parabolic diffusion equations. In absence of thermoosmosis, they are decoupled from the flow and deformation and can be solved first. While the method to obtain the concentration profile uses Fourier series, the temperature is calculated via the Laplace transform technique. The methods could be interchanged. As another difference, the chemical diffuses over a finite thickness while the thermal problem considers a semi-infinite body.

Once known, the chemical concentration, or temperature, is used to trigger the flow and deformation.

Viscous coupling through thermoosmosis

In presence of thermoosmosis, as described in Section 9.3.3, the energy equation involves both temperature and fluid pressure. Therefore, an analytical/numerical solution should address both fields simultaneously, Section 9.5.9.

Exercises on Chapter 9

Exercise 9.1 Symmetric versus non symmetric matrices

1. Consider the 2×2 real matrix $\mathbf{A}$,

$$\mathbf{A} = \begin{bmatrix} a & b \\ c & d \end{bmatrix} . \tag{9.E.1}$$

Calculate the eigenvalues and show that positive-definiteness involves the symmetric part of the matrix. Show that the existence of real positive eigenvalues does not imply positive definiteness,

$$\text{all eigenvalues} \quad \lambda(\mathbf{A}) \quad \text{real positive} \quad \not\Rightarrow \quad \mathbf{A} \quad \text{positive definite} \quad \text{if} \quad \mathbf{A} \neq \mathbf{A}^{\mathrm{T}} , \tag{9.E.2}$$

and that the converse proposition does not hold either,

$$\mathbf{A} \quad \text{positive definite} \quad \not\Rightarrow \quad \lambda(\mathbf{A}) \quad \text{real positive} \quad \text{if} \quad \mathbf{A} \neq \mathbf{A}^{\mathrm{T}} . \tag{9.E.3}$$

Answer:

The eigenvalues of $\mathbf{A}$, namely $\lambda_{\pm} = (a+d)/2 \pm \sqrt{(a-d)^2/4 + b\,c}$, are the roots of the polynomial $\lambda^2 - (a+d)\,\lambda + a\,d - b\,c$. They may be real or complex. Moreover,

$$[x\ y]\ \mathbf{A} \begin{bmatrix} x \\ y \end{bmatrix} = a\,x^2 + (b+c)\,x\,y + d\,y^2 = a\Big(x + \frac{b+c}{2\,a}\,y\Big)^2 + \Big(d - \frac{(b+c)^2}{4\,a}\Big)\,y^2 . \tag{9.E.4}$$

The conditions of positive definiteness are therefore

$$a > 0; \quad d - \frac{(b+c)^2}{4\,a} > 0 . \tag{9.E.5}$$

Now consider the special case $a > 0$, $d = 0$, $a^2/4 + b\,c > 0$, $b\,c < 0$: the eigenvalues are real positive but positive definiteness does not hold. Conversely, consider the case $a = d > 0$, $b = -c$. Positive definiteness holds, but the eigenvalues are not real.

2. By contrast, for a symmetric matrix $\mathbf{A}$, namely $b = c$, verify that the conditions for positive definiteness and positive eigenvalues are equivalent.

Answer:

The eigenvalues are real, $\lambda_{\pm} = (a+d)/2 \pm \sqrt{(a-d)^2/4 + b^2}$. They are positive and positive definiteness holds if

$$a > 0; \quad d - \frac{b^2}{a} > 0 . \tag{9.E.6}$$

3. A positive determinant does not imply positive definiteness, even for symmetric matrices.
Hint: consider the matrix $\mathbf{diag}[-1\ \ -1]$.

4. Let $\mathbf{A}$ and $\mathbf{D}$ be two square symmetric matrices, of respective sizes $m \times m$ and $n \times n$, and $\mathbf{B}$ a matrix of size $m \times n$. Show that the block matrix

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^{\mathrm{T}} & \mathbf{D} \end{bmatrix} , \tag{9.E.7}$$

is positive definite (PD) iff

$$\mathbf{A}\ (\text{PD}) \quad \text{and} \quad \mathbf{D} - \mathbf{B}^{\mathrm{T}}\mathbf{A}^{-1}\mathbf{B}\ (\text{PD}) . \tag{9.E.8}$$

Hint: $\mathbf{A}$ should clearly be positive definite. Now

$$\begin{aligned} [\mathbf{x}\ \mathbf{y}] \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^{\mathrm{T}} & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} &= \mathbf{x}^{\mathrm{T}}\mathbf{A}\mathbf{x} + \mathbf{x}^{\mathrm{T}}\mathbf{B}\mathbf{y} + \mathbf{y}^{\mathrm{T}}\mathbf{B}^{\mathrm{T}}\mathbf{x} + \mathbf{y}^{\mathrm{T}}\mathbf{D}\mathbf{y} \\ &= \big(\mathbf{x} + \mathbf{A}^{-1}\mathbf{B}\mathbf{y}\big)^{\mathrm{T}}\mathbf{A}\big(\mathbf{x} + \mathbf{A}^{-1}\mathbf{B}\mathbf{y}\big) + \mathbf{y}^{\mathrm{T}}\big(\mathbf{D} - \mathbf{B}^{\mathrm{T}}\mathbf{A}^{-1}\mathbf{B}\big)\mathbf{y} \quad \square . \end{aligned} \tag{9.E.9}$$

5. Consider now the case where $\mathbf{A}$ and $\mathbf{D}$ may not be symmetric.
Hint: The condition of positive definiteness (9.E.8) still holds but with $\mathbf{A}$ and $\mathbf{D}$ replaced by their symmetric parts.

Chapter 10

Transfers of mass, momentum, and energy

Diffusion is associated with spatial heterogeneity. In a macroscopic analysis, the geometrical points may store information that pertains to lower geometrical scales. Zooming on a point, we may uncover several phases with a definite spatial organization at these lower scales. As a typical example, the lower scale may display unit cells composed of a solid containing pores and capillaries. The role of the pores is to store the liquid while the capillaries are devoted to its circulation. At this scale, the exchange of liquid between the two cavities takes place by diffusion through the solid. At the macroscopic scale, the exchange is realized through *local transfer*: while most of the geometrical details of the lower scales are wiped out, the transfer coefficients attempt to keep some tracks of the physical properties, eg the diffusion coefficients, and of the characteristic diffusion times or lengths.

Both transfer of mass and transfer of heat are targeted in this chapter.

10.1 Summary of balance equations

The supplies contributing to the equations of balance considered in Chapter 4 may be due to exchanges between two or several constituents of the mixture or with the surroundings. It is instrumental to recall these equations and the constraints that the supplies satisfy. With $\mathcal{K}$ the set of all species in the mixture, the four balance equations hold for any species $k \in \mathcal{K}$,

- Balance of mass (4.4.5) : $\dfrac{d^k \rho^k}{dt} + \rho^k \operatorname{div} \mathbf{v}_k = \hat{\rho}^k \,;$
- Balance of momentum (4.5.5) : $\operatorname{div} \boldsymbol{\sigma}^k + \rho^k \left(\mathbf{b}_k - \dfrac{d^k \mathbf{v}_k}{dt}\right) = \begin{cases} \hat{\rho}^k (\mathbf{v}_k - \tilde{\mathbf{v}}_k) - \hat{\boldsymbol{\pi}}^k; \\ \hat{\rho}^k \, \mathbf{v}_k - \hat{\mathbf{p}}^k; \end{cases}$

  Net momentum supply (4.5.3) : $\hat{\mathbf{p}}^k \equiv \hat{\rho}^k \tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k \,;$

- Balance of energy (4.6.11) :

$$\frac{d^k}{dt}(\rho^k u_k) - (\boldsymbol{\sigma}^k - \rho^k u_k \, \mathbf{I}) : \boldsymbol{\nabla} \mathbf{v}_k + \operatorname{div} \mathbf{Q}_k - \Theta_k = \begin{cases} \hat{\rho}^k \left(\tilde{u}_k + \frac{1}{2} (\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\right) + \hat{\mathcal{U}}^k; \\ \hat{U}^k - \hat{\mathbf{p}}^k \cdot \mathbf{v}_k + \frac{1}{2} \hat{\rho}^k \, \mathbf{v}_k^2; \end{cases} \tag{10.1.1}$$

  Net energy supply (4.6.9) : $\hat{U}^k \equiv \hat{\rho}^k \left(\tilde{u}_k + \frac{1}{2} \tilde{\mathbf{v}}_k^2\right) + \hat{\boldsymbol{\pi}}^k \cdot \mathbf{v}_k + \hat{\mathcal{U}}^k \,;$

- Balance of entropy (4.7.4) : $\hat{S}^k_{(\mathrm{i})} = \dfrac{d^k}{dt}(\rho^k s_k) + \rho^k s_k \operatorname{div} \mathbf{v}_k + \operatorname{div} \left(\dfrac{\mathbf{Q}_k}{T_k}\right) - \dfrac{\Theta_k}{T_k} - \hat{S}^k;$

  Net entropy supply (4.7.3) : $\hat{S}^k \equiv \hat{\rho}^k \, \tilde{s}_k + \hat{\mathcal{S}}^k \,.$

If the mixture is closed to mass, momentum, energy and entropy supplies, the net supplies of mass $\hat{\rho}$, of momentum

$\hat{\mathbf{p}}$, of energy $\hat{U}$, and of entropy $\hat{S}$ vanish,

$$\hat{\rho} \equiv \sum_{k\in\mathcal{K}} \hat{\rho}^k = 0, \quad \hat{\mathbf{p}} \equiv \sum_{k\in\mathcal{K}} \hat{\mathbf{p}}^k = \mathbf{0}, \quad \hat{U} \equiv \sum_{k\in\mathcal{K}} \hat{U}^k = 0 \quad \hat{S} \equiv \sum_{k\in\mathcal{K}} \hat{S}^k = 0\,. \tag{10.1.2}$$

The above equations use the current configuration as reference. Their counterparts using a different reference configuration may be found in Chapter 4. These equations apply over a volume. Their specialization across a first order discontinuity may be found in Section 11.1.4 for a solid, and in Section 11.10 for a mixture. The corresponding issues across acceleration waves in elastic and thermoelastic solids and mixtures are dealt with in Sections 11.2 to 11.6. While the above supplies do not contribute across a first or second order discontinuity, there may exist additional surface supplies for a first order discontinuity, Section 11.1.5

The properties of the supplied mass, namely its velocity $\tilde{\mathbf{v}}$, internal energy $\tilde{u}$ and entropy $\tilde{s}$ are denoted through a superimposed tilde. These entities need to be specified. A convenient assumption consists in setting their values equal to their counterparts, namely velocity $\mathbf{v}$, internal energy u and entropy s, at the location where they are supplied. The assumption is challenged in the context of the growth of soft tissues in Section 22.6.

10.2 Intercompartment mass transfers

10.2.1 Linear mass transfer

Let us consider mass transfers between the n species of a mixture which is closed to external mass supplies. Then the rates of all n mass transfers phrased in terms of the mass contents m sum to zero,

$$\sum_{k=1,n} \frac{dm_k}{dt} = 0\,, \tag{10.2.1}$$

and the associated dissipation per unit reference volume $(4.7.31)_2$ may be written as,

$$T\,\underline{\hat{S}}_{(\mathrm{i},2)} = \sum_{k=1,n} -\mu_k \frac{dm_k}{dt}\,. \tag{10.2.2}$$

Let $\boldsymbol{\kappa} = (\kappa_{jk})$ be a symmetric matrix of size $n \times n$, the diagonal components being in fact not involved for the present purpose. The linear rate of mass transfer is adopted in the format,

$$\frac{d}{dt}\begin{bmatrix} m_1 \\ m_2 \\ m_3 \\ \vdots \\ m_n \end{bmatrix} = -\begin{bmatrix} \sum_{j\neq 1}\kappa_{1j} & -\kappa_{12} & -\kappa_{13} & \dots & -\kappa_{1n} \\ -\kappa_{12} & \sum_{j\neq 2}\kappa_{2j} & -\kappa_{23} & \dots & -\kappa_{2n} \\ -\kappa_{13} & -\kappa_{23} & \sum_{j\neq 3}\kappa_{3j} & \dots & -\kappa_{3n} \\ \vdots & \vdots & \vdots & \ddots & \dots \\ -\kappa_{1n} & -\kappa_{2n} & -\kappa_{3n} & \dots & \sum_{j\neq n}\kappa_{nj} \end{bmatrix}\begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \vdots \\ \mu_n \end{bmatrix}. \tag{10.2.3}$$

The dissipation may be recast in a format in which its sign can be easily assessed,

$$\begin{aligned} T\,\underline{\hat{S}}_{(\mathrm{i},2)} &= \sum_{k=1,n} -\mu_k \frac{dm_k}{dt} \\ &= \sum_{k=1,n} \mu_k \sum_{j\neq k} \kappa_{jk}\,(\mu_k - \mu_j) \\ &= \overbrace{\sum_{j\neq k=1,n} \kappa_{jk}\,(\mu_k - \mu_j)\,\mu_k}^{A} \\ &= \sum_{j\neq k=1,n} \kappa_{jk}\,\Big((\mu_k - \mu_j)\,(\mu_k - \mu_j) + (\mu_k - \mu_j)\,\mu_j\Big) \\ &= 2\overbrace{\sum_{j<k=1,n} \kappa_{jk}\,(\mu_k - \mu_j)\,(\mu_k - \mu_j)}^{B} - \overbrace{\sum_{j\neq k=1,n} \kappa_{jk}\,(\mu_k - \mu_j)\,\mu_k}^{A} \\ &= \overbrace{\sum_{j<k=1,n} \kappa_{jk}\,(\mu_k - \mu_j)\,(\mu_k - \mu_j)}^{B}\,. \end{aligned} \tag{10.2.4}$$

A positive contribution to the entropy production results if the $(n-1)\,n/2$ coefficients κ_{kj}, $k \neq j$, are positive.

As a special case, the mixture is now considered to contain the two phases I and E. The two species 1 and 2 are present in the two phases. The mass exchange is driven by the out of balances of individual chemical potentials,

$$\frac{d}{dt}\begin{bmatrix} m_{1\mathrm{I}} \\ m_{1\mathrm{E}} \\ m_{2\mathrm{I}} \\ m_{2\mathrm{E}} \end{bmatrix} = -\begin{bmatrix} \kappa_1 & -\kappa_1 & \kappa' & -\kappa' \\ -\kappa_1 & \kappa_1 & -\kappa' & \kappa' \\ \kappa' & -\kappa' & \kappa'' & -\kappa'' \\ -\kappa' & \kappa' & -\kappa'' & \kappa'' \end{bmatrix}\begin{bmatrix} \mu_{1\mathrm{I}} \\ \mu_{1\mathrm{E}} \\ \mu_{2\mathrm{I}} \\ \mu_{2\mathrm{E}} \end{bmatrix}. \tag{10.2.5}$$

This constitutive equation of transfer has introduced a coupling between an out-of-balance of the chemical potentials of species 2 and a mass transfer of species 1, and conversely. The coupling may be justified if the interface between the phases I and E may be viewed as a semi-permeable membrane that gives rise to the phenomenon of osmosis described in Section 13.7. If $\kappa' \neq 0$, the above rate of transfer can actually be split in two independent parts.

10.2.2 Mass transfer of electrically charged species

If the species are not electrically neutral, the independence of the mass transfers is lost. With ζ_k the valence of species k and $\widehat{m}_k$ its molar mass, electroneutrality constraints the changes of mass contents in each phase K,

$$\zeta_1 \frac{dm_{1\mathrm{K}}}{\widehat{m}_1} + \zeta_2 \frac{dm_{2\mathrm{K}}}{\widehat{m}_2} = 0\,. \tag{10.2.6}$$

Since the mass changes satisfy the additional constraint,

$$dm_{k\mathrm{I}} + dm_{k\mathrm{E}} = 0, \quad k = 1, 2\,, \tag{10.2.7}$$

the dissipation,

$$\begin{aligned} & -(\mu^{\mathrm{ec}}_{1\mathrm{I}} - \mu^{\mathrm{ec}}_{1\mathrm{E}})\frac{dm_{1\mathrm{I}}}{dt} - (\mu^{\mathrm{ec}}_{2\mathrm{I}} - \mu^{\mathrm{ec}}_{2\mathrm{E}})\frac{dm_{2\mathrm{I}}}{dt} \\ = \; & -\Big(\widehat{m}_1\,(\mu^{\mathrm{ec}}_{1\mathrm{I}} - \mu^{\mathrm{ec}}_{1\mathrm{E}}) - \frac{\zeta_1}{\zeta_2}\,\widehat{m}_2\,(\mu^{\mathrm{ec}}_{2\mathrm{I}} - \mu^{\mathrm{ec}}_{2\mathrm{E}})\Big)\,\frac{1}{\widehat{m}_1}\frac{dm_{1\mathrm{I}}}{dt} \\ = \; & -(\mu_{\mathrm{sI}} - \mu_{\mathrm{sE}})\frac{dm_{1\mathrm{I}}}{dt}\,, \end{aligned} \tag{10.2.8}$$

now expresses in terms of a single independent variable and of the jump of the chemical potentials of the neutral salt associated with the ionic species 1 and 2,

$$\widehat{m}_1\,\mu_{\mathrm{sK}} = \widehat{m}_1\,\mu^{\mathrm{ec}}_{1\mathrm{K}} - \frac{\zeta_1}{\zeta_2}\,\widehat{m}_2\,\mu^{\mathrm{ec}}_{2\mathrm{K}}\,. \tag{10.2.9}$$

Note that the fact that this definition of the chemical potential of the salt breaks somehow the symmetry among the two ions is not an issue. Particular cases pertaining to articular cartilages are worked out in more explicit form in Section 16.1.2.4.

These relations may be extended to more general settings, e.g., a neutral species n and three ions 1, 2 and 3. While the exchange (10.2.7) still holds for the four species, the electroneutrality condition changes to,

$$\zeta_1 \frac{dm_{1\mathrm{K}}}{\widehat{m}_1} + \zeta_2 \frac{dm_{2\mathrm{K}}}{\widehat{m}_2} + \zeta_3 \frac{dm_{3\mathrm{K}}}{\widehat{m}_3} = 0\,. \tag{10.2.10}$$

and the dissipation which may be brought in the format,

$$\begin{aligned} & -(\mu_{n\mathrm{I}} - \mu_{n\mathrm{E}})\frac{dm_{n\mathrm{I}}}{dt} - (\mu^{\mathrm{ec}}_{1\mathrm{I}} - \mu^{\mathrm{ec}}_{1\mathrm{E}})\frac{dm_{1\mathrm{I}}}{dt} - (\mu^{\mathrm{ec}}_{2\mathrm{I}} - \mu^{\mathrm{ec}}_{2\mathrm{E}})\frac{dm_{2\mathrm{I}}}{dt} - (\mu^{\mathrm{ec}}_{3\mathrm{I}} - \mu^{\mathrm{ec}}_{3\mathrm{E}})\frac{dm_{3\mathrm{I}}}{dt} \\ = \; & -(\mu_{n\mathrm{I}} - \mu_{n\mathrm{E}})\frac{dm_{n\mathrm{I}}}{dt} - (\mu_{\mathrm{s}_1\mathrm{I}} - \mu_{\mathrm{s}_1\mathrm{E}})\frac{dm_{1\mathrm{I}}}{dt} - (\mu_{\mathrm{s}_2\mathrm{I}} - \mu_{\mathrm{s}_2\mathrm{E}})\frac{dm_{2\mathrm{I}}}{dt}\,, \end{aligned} \tag{10.2.11}$$

now expresses in terms of three independent variables and of the jump of the chemical potential of the neutral species and of the chemical potentials of the two neutral salts associated with the ionic species (1,3) and (2,3),

$$\widehat{m}_k\,\mu_{\mathrm{s}_k\mathrm{K}} = \widehat{m}_k\,\mu^{\mathrm{ec}}_{k\mathrm{K}} - \frac{\zeta_k}{\zeta_3}\,\widehat{m}_3\,\mu^{\mathrm{ec}}_{3\mathrm{K}}, \quad k = 1, 2\,. \tag{10.2.12}$$

The linear constitutive equation of transfer may be provided in the expanded format (10.2.5), or in the equivalent compacted format involving a symmetric positive semi-definite matrix,

$$\frac{d}{dt}\begin{bmatrix} m_{n\mathrm{I}} \\ m_{1\mathrm{I}} \\ m_{2\mathrm{I}} \end{bmatrix} = -\begin{bmatrix} \kappa_{nn} & \kappa_{n1} & \kappa_{n2} \\ \kappa_{n1} & \kappa_{11} & \kappa_{12} \\ \kappa_{n2} & \kappa_{12} & \kappa_{22} \end{bmatrix}\begin{bmatrix} \mu_{n\mathrm{I}} - \mu_{n\mathrm{E}} \\ \mu_{\mathrm{s}_1\mathrm{I}} - \mu_{\mathrm{s}_1\mathrm{E}} \\ \mu_{\mathrm{s}_2\mathrm{I}} - \mu_{\mathrm{s}_2\mathrm{E}} \end{bmatrix} = -\frac{d}{dt}\begin{bmatrix} m_{n\mathrm{E}} \\ m_{1\mathrm{E}} \\ m_{2\mathrm{E}} \end{bmatrix}. \tag{10.2.13}$$

If the mass transfers are uncoupled by setting the out-of-diagonal terms to 0, the remaining diagonal terms may be scaled via a representative mass density ρ_k and a characteristic transfer time $t_{\mathrm{tr},k}$,

$$\kappa_{kk} = \frac{\rho_k}{t_{\mathrm{tr},k}}\,A_k\,,\ k = n, \mathrm{s}_1, \mathrm{s}_2\,, \tag{10.2.14}$$

where $A_k \geq 0$ [unit : $\mathrm{s}^2/\mathrm{m}^2$] is a material parameter.

The approach presented here has used electroneutrality to formulate the transfer equations in terms of neutral species. The electrical potentials have been temporary eliminated from the problem. Still, the difference of electrical potentials between the two compartments can be recovered at equilibrium by requiring the equality of the electro-chemical potentials of any species. Alternatively, if the electrical potentials are of key interest, the explicit use of the electroneutrality might be abandoned, and the rate transfer equations of *all* species are better phrased in terms of the electro-chemical potentials. This method involves one additional unknown (the electrical potential) and one additional equation due to the fact that the rate transfer equations are required for the charged and uncharged species, rather than for the associated neutral species.

10.2.3 Nonlinear constitutive equation of mass transfer

More general constitutive equations of mass transfer that satisfy the dissipation inequality can be postulated if the above uncoupling holds. Indeed, consider the transfer of the species k from phase I to phase E. The dissipation associated with the transfer should be positive, namely

$$-\,[\mu]\,\frac{dm}{dt} \geq 0\,, \tag{10.2.15}$$

where $m = m_{k\mathrm{I}}$ is the mass content of species k in the phase I and $[\mu]$ is understood as the difference $\mu_{k\mathrm{I}} - \mu_{k\mathrm{E}}$.

The analysis below simplifies if the mass content m and time t are thought as dimensionless. The linear rate equation $dm/dt = -A\,[\mu]$ satisfies the inequality if A is a positive scalar. So does the rate equation $dm/dt = (\exp(-\epsilon A[\mu]) - 1)\,\epsilon$, with $\epsilon = \pm 1$. While the latter rate equation reduces to the linear equation at small $[\mu]$, its behavior at large positive and negative $[\mu]$ depends strongly on ϵ, Fig. 10.2.1.

Consider first the transfer of a species with $\epsilon = 1$. If its chemical potential in the phase I is large with respect to the phase E, the above $[\mu]$ is positive, the species tends to leave the phase I but the trend to exhaustion of the species in phase I is limited. On the other hand, if the chemical potential in the phase I is much smaller than in phase E, the rate of replenishment becomes exponential. The value $\epsilon = -1$ has converse effects on the transfer rates.

Now, observe that the rate relation

$$\frac{dm}{dt} = \big(\exp(-A|[\mu]|) - 1\big)\,s_\mu, \tag{10.2.16}$$

with $s_\mu = \mathrm{sign}[\mu]$, is an example of constitutive equation of transfer that

- is motivated by and satisfies the inequality dissipation;
- ensures a finite rate of transfer at any concentration for A a positive scalar, and
- reduces to a linear constitutive equation of transfer close to equilibrium.

With ρ_k the mass density [unit : kg/m^3] of species k and $t_{\mathrm{tr},k}$ a characteristic transfer time [unit : s], the above formula may be written in the more explicit form,

$$\frac{dm_{k\mathrm{I}}}{dt} = \frac{\rho_k}{t_{\mathrm{tr},k}}\big(\exp(-A_k|\mu_{k\mathrm{I}} - \mu_{k\mathrm{E}}|) - 1\big)\,s_\mu, \tag{10.2.17}$$

with $s_\mu = \mathrm{sign}(\mu_{k\mathrm{I}} - \mu_{k\mathrm{E}})$ and A_k [unit : $\mathrm{s}^2/\mathrm{m}^2$] a positive scalar.

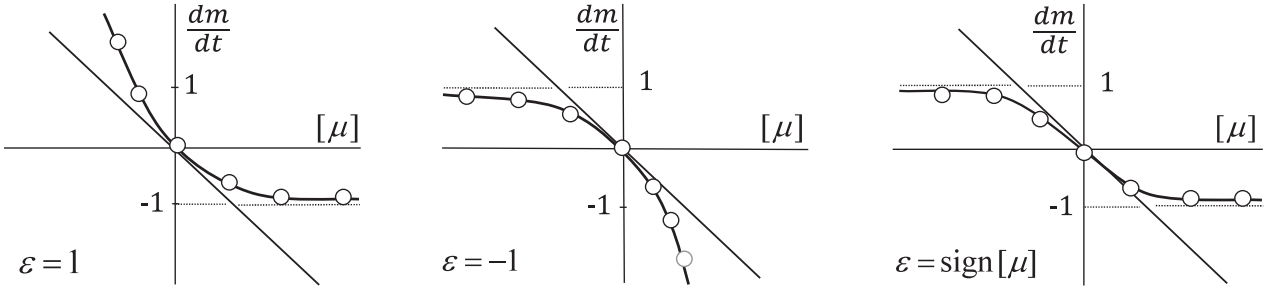

Fig. 10.2.1: Exponential constitutive equation of transfer of the form $dm/dt = (\exp(-\epsilon A[\mu]) - 1)\,\epsilon$, with $A > 0$, behave differently depending on the sign of ϵ but, close to equilibrium, they are tangent to the linear constitutive equation $dm/dt = -A\,[\mu]$. For $\epsilon = \text{sign}\,[\mu]$, the mass rate is bounded whatever the driving jump in chemical potential $[\mu]$.

10.3 Momentum supply in a poroelastic context

In Section 7.3.2, the momentum supply to the fluid phase associated with diffusion through the porous skeleton (seepage) has been identified so as to comply with the standard expression of Darcy's law.

The net momentum supply of water $\hat{\mathbf{p}}^{\rm w}$ as defined by (4.5.3) has been shown to be contributed by three terms, namely a Stokes' drag proportional to the velocity of the solid relative to the fluid $\mathbf{v}_{\rm s} - \mathbf{v}_{\rm w}$, a buoyancy term due to the spatial heterogeneity of the porosity $n^{\rm w}$ and a term associated with the momentum of the supplied mass,

$$\hat{\mathbf{p}}^{\rm w} = \hat{\rho}^{\rm w}\,\tilde{\mathbf{v}}_{\rm w} + \hat{\boldsymbol{\pi}}^{\rm w} = -k_{\rm Sd}\,(\mathbf{v}_{\rm w} - \mathbf{v}_{\rm s}) + p_{\rm w}\boldsymbol{\nabla} n^{\rm w} + \hat{\rho}^{\rm w}\,\mathbf{v}_{\rm w}\,, \tag{10.3.1}$$

where the *coefficient of Stokes' drag* $k_{\rm Sd} \geq 0$ [unit : $\mathrm{kg \times m^{-3} \times s^{-1}}$] is proportional to the inverse of the permeability coefficient.

In absence of external supply, the net momentum supply to the solid $\hat{\mathbf{p}}^{\rm s}$ is equal to $-\hat{\mathbf{p}}^{\rm w}$.

10.4 The bioheat equation

The bioheat equation is intended to account for the heat transferred in the interstitium by the blood flow. The thermoelastic model developed in Section 10.6 offers a larger constitutive framework which embodies the bioheat equation as a particular case but also accounts for thermomechanical couplings. Still even if the tissue is considered rigid, the bioheat equation is worth consideration *per se*.

10.4.1 The bioheat energy equation

The heat convected by the blood is equal to the specific heat capacity of blood c_b [unit : J/kg/K] times the blood perfusion rate w_b [unit : $\mathrm{kg/m^3/s}$] times the blood (arterial) temperature T_b. In the model of Pennes [1948], the transfer of heat is due to the difference of temperature $T_b - T$ between blood and tissue. This heat is instantaneously and totally available to the tissue. The details of the interface between the microvessels and the tissue, like the specific surface area or the interfacial heat transfer coefficient, are elusive here unlike in Section 10.8.

The total heat source Θ [unit : $\mathrm{W/m^3}$] may involve in addition the metabolic heat rate Θ_m as well as other local heat sources Θ_l,

$$\Theta = c_b\,w_b\,(T_b - T) + \Theta_m + \Theta_l\,. \tag{10.4.1}$$

The typical blood perfusion rate w_b is estimated to $0.5\,\mathrm{kg/m^3/s}$ and the metabolic rate Θ_m to $33.8\,\mathrm{kW/m^3}$. The energy equation of the tissue (9.1.23) becomes

$$T\hat{S}_{(\mathrm{i},1)} = T\,\frac{dS}{dt} + \text{div}\;\mathbf{Q} - c_b\,w_b\,(T_b - T) - \Theta_m - \Theta_l = 0\,. \tag{10.4.2}$$

The heat flux $\mathbf{Q}$ [unit : $\mathrm{W/m^2}$] is governed by Fourier's law (15.3.10), namely $\mathbf{Q} = -\mathbf{k}_{\rm T}\cdot\boldsymbol{\nabla} T$, where $\mathbf{k}_{\rm T}$ [unit : W/m/K] is the thermal conductivity. For a rigid tissue, the increment of entropy per unit volume $T\,dS$ is equal to the heat capacity of the tissue $C_{\rm T} > 0$ [unit : $\mathrm{J/m^3/K}$] times the increment of temperature dT. Therefore the bioheat equation,

$$C_{\rm T}\,\frac{\partial T}{\partial t} - \text{div}\,(\mathbf{k}_{\rm T}\cdot\boldsymbol{\nabla} T) - c_b\,w_b\,(T_b - T) - \Theta_m - \Theta_l = 0\,, \tag{10.4.3}$$

appears as a reactive parabolic equation. It is inhomogeneous, that is, it involves source terms and one of these terms includes the unknown temperature.

10.4.2 The bioheat energy equation with a relaxation time

Following the scheme developed in Section 9.1.4, the parabolic equation may be transformed to the hyperbolic equation (9.1.38),

$$C_{\rm T}\left(t_{\rm Cat}\,\frac{\partial^2 T}{\partial t^2}+\frac{\partial T}{\partial t}\right)\;-\;{\rm div}\,(\mathbf{k}_{\rm T}\cdot\boldsymbol{\nabla}T)\;-\;t_{\rm Cat}\,\frac{\partial\Theta}{\partial t}-\Theta=0\,, \tag{10.4.4}$$

with the source Θ given by (10.4.1) including now a reactive term. The relaxation time $t_{\rm Cat}$ is linked to the wave-speed and thermal conductivity, Eqn (11.3.10). For metals, the relaxation time $t_{\rm Cat}\in[10^{-14}\,{\rm s},\,10^{-8}\,{\rm s}]$ is quite small with respect to typical durations of heating processes, Kaminski [1990]. It ranges between 20 to 30 s for biological tissues, Liu [2008].

10.4.3 Thermal boundary conditions

The bioheat equation may be used to simulate boundary value problems aimed at modeling heat treatments of tissues, especially of tumor tissues. Heat may be applied internally, pointwise or distributed, or it may be applied at the surface of the body either through a given normal flux, namely $\mathbf{Q}\cdot\mathbf{n}=q_n$ given with $\mathbf{n}$ outward unit normal to the body, or through a convective boundary condition,

$$\mathbf{Q}\cdot\mathbf{n}=h_{{\rm s}\beta}\,(T-T_{\rm ext})\,, \tag{10.4.5}$$

with $T_{\rm ext}$ the given external temperature and $h_{{\rm s}\beta}$ [unit : $\rm W/m^2/K$] the interfacial heat transfer coefficient between the solid and the fluid β. The heat may be supplied as well by radiation,

$$\mathbf{Q}\cdot\mathbf{n}=\epsilon\,\sigma\,(T^4-T_{\rm rad}^4)\,, \tag{10.4.6}$$

with $T_{\rm rad}$ the radiant temperature, $\sigma=5.6704\times10^{-8}\,\rm W/m^2/K^4$ the Stefan-Boltzmann constant and ϵ a coefficient lumping the (dimensionless) emissivity and a view (shape) factor. The wave-lengths of thermal radiation range from 10^{-1} to 10^2 µm, Bejan [1993], p. 505[10.1]. For modeling purposes, the radiative boundary condition (10.4.6) may be recast in the convective format (10.4.5) via a radiative coefficient $h_{\rm rad}$ [unit : $\rm W/m^2/K$],

$$\mathbf{Q}\cdot\mathbf{n}=h_{\rm rad}\,(T-T_{\rm rad})\,. \tag{10.4.7}$$

Whole-body measurements in dry air conditions indicate a natural convection coefficient $h_{\rm sa}$ of about $3.3\,\rm W/m^2/K$ and a radiative coefficient $h_{\rm rad}$ of about $4.5\,\rm W/m^2/K$, de Dear et al. [1997].

Unsolved key issues in hyperthermia include the intensity and duration of the thermal loading.

10.4.4 Significance of the Biot number

Let us consider a porous medium with a single porosity, namely a solid s bathed in a fluid β which can be water ($\beta=$ w) or air ($\beta=$ a). The thermal gradients are assumed to be negligible and only heat conduction and heat transfer are accounted for. With help of (10.8.1), the energy equation of the solid constituent (10.8.2) can be cast in the form,

$$C^{\rm s}\,\frac{dT_{\rm s}}{dt}+h_{{\rm s}\beta}\,a_{{\rm s}\beta}\,(T_{\rm s}-T_\beta)=0\,, \tag{10.4.8}$$

where $C^{\rm s}$ [unit : $\rm J/m^3/K$] is the apparent heat capacity of the solid, $h_{{\rm s}\beta}$ [unit : $\rm W/m^2/K$] is the interfacial heat transfer coefficient and $a_{{\rm s}\beta}$ [unit : $\rm m^2/m^3$] is the specific interfacial area. If the above material properties are constant in time as well as the fluid temperature T_β, the solid temperature,

$$\frac{T_{\rm s}-T_\beta}{T_{\rm s}(t_*)-T_\beta}=\exp\Big(-\frac{t-t_*}{t_{\rm T}}\Big)\,, \tag{10.4.9}$$

is found to decrease exponentially with a characteristic time $t_{\rm T}$ equal to $C^{\rm s}/h_{{\rm s}\beta}\,a_{{\rm s}\beta}$. Here t_* is a reference time beyond which the assumption of negligible gradient holds.

[10.1] The complete electromagnetic spectrum is displayed in Fig. 24.3.7.

The validity of the assumption of a negligible thermal gradient inside the body can be checked as suggested by Bejan [1993], p. 146. At a regular boundary point, the normal heat flux is given in two ways, by Fourier's law applied over a characteristic length L and by the boundary condition (10.4.5),

$$\mathbf{Q}\cdot\mathbf{n} \simeq -k_{\rm Ts}\,\frac{T_b - T_{\rm s}}{L} = h_{{\rm s}\beta}\,(T_b - T_\beta)\,, \tag{10.4.10}$$

with $T_{\rm s}$ and T_b respectively temperatures inside the solid at distance L from the boundary and at the boundary. Therefore, the gradient of temperature in a skin of width L inside the solid,

$$\frac{T_{\rm s} - T_b}{L} = \frac{\rm Bi}{1+{\rm Bi}}\,\frac{T_{\rm s} - T_\beta}{L}\,, \tag{10.4.11}$$

will be negligible only if the Biot number ${\rm Bi} = L\,h_{{\rm s}\beta}/k_{\rm Ts}$ defined by (10.8.8) is sufficiently small.

10.5 Mass and energy transfers between a liquid and a solid

In Section 10.2, it has been shown how mass exchange between liquid phases can be dealt with in terms of their out-of-balance chemical potentials. Solids are endowed with a chemical potential which is a symmetric second order tensor defined by (4.7.22). However the split of the dissipation into a transfer contribution and a diffusion contribution is easily tractable only for liquid phases, as stressed in Note 4.7. The Massieu function,

$$\Xi_k = -\frac{\rho^k e_k}{T_k} = \rho^k\,\big(s_k - \frac{u_k}{T_k}\big)\,, \tag{10.5.1}$$

provides an alternative to the chemical potential. The analysis below considers a mixture of a viscous liquid $k = {\rm w}$ and of an elastic solid s which can exchange mass, momentum and energy, the latter exchange being a consequence of the fact that they are in local thermal non equilibrium (LTNE), Fig. 10.5.1.

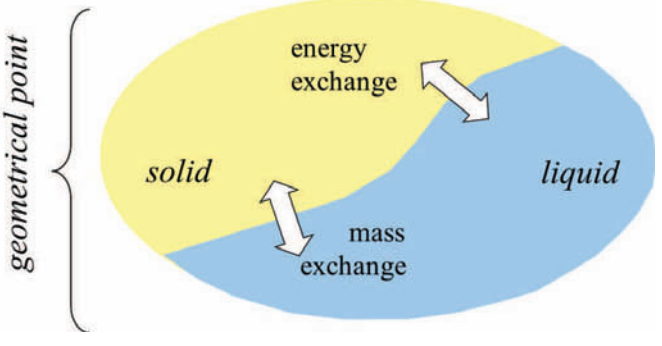

Fig. 10.5.1: Exchange of mass and of energy between the solid and the liquid of a porous medium.

10.5.1 Constitutive equations for the solid and liquid

The entropy production (10.1.1) for the species $k \in \mathcal{K} \equiv \{{\rm s}, {\rm w}\}$ may be expressed in terms of the Massieu function and of the net supplies defined in Section 10.1. Manipulating the balance of energy and the entropy production (10.1.1) to eliminate the term $\operatorname{div}\mathbf{Q}_k - \Theta_k$ yields a relation involving the strain rate $\mathbf{D}_k$,

$$\hat{S}^k_{\rm (i)} = \frac{d^k\Xi_k}{dt} + \Big(\frac{\boldsymbol{\sigma}^k}{T_k} + \Xi_k\,\mathbf{I}\Big) : \mathbf{D}_k + \rho^k\,u_k\,\frac{d^k}{dt}\Big(\frac{1}{T_k}\Big) + \mathbf{Q}_k\cdot\boldsymbol{\nabla}\Big(\frac{1}{T_k}\Big) + \frac{\hat{U}^k}{T_k} - \hat{S}^k - \frac{\hat{\mathbf{p}}^k}{T_k}\cdot\mathbf{v}_k + \frac{\hat{\rho}^k}{T_k}\,\frac{\mathbf{v}_k^2}{2}\,. \tag{10.5.2}$$

Constitutive assumptions are needed to exploit the dissipation inequality. The Massieu function of the elastic solid will be assumed to depend on the right Cauchy-Green tensor $\mathbf{C}_{\rm s}$, of its coldness $T_{\rm s}^{-1}$ and of its apparent mass density $\rho^{\rm s}$,

$$\Xi_{\rm s} = \Xi_{\rm s}(\mathbf{C}_{\rm s},\, T_{\rm s}^{-1},\, \rho^{\rm s})\,. \tag{10.5.3}$$

With help of the differential relation (2.5.14), the entropy production becomes,

$$\begin{aligned}\hat{S}^{\rm s}_{\rm (i)} &= \Big(\frac{\boldsymbol{\sigma}^{\rm s}}{T_{\rm s}} + (\Xi_{\rm s} - \rho^{\rm s}\,\frac{\partial \Xi_{\rm s}}{\partial \rho^{\rm s}})\,\mathbf{I} + 2\,\mathbf{F}_{\rm s}^{\rm T}\cdot\frac{\partial \Xi_{\rm s}}{\partial \mathbf{C}_{\rm s}}\cdot\mathbf{F}_{\rm s}\Big) : \mathbf{D}_{\rm s} + \Big(\rho^{\rm s}\,u_{\rm s} + \frac{\partial \Xi_{\rm s}}{\partial T_{\rm s}^{-1}}\Big)\,\frac{d^{\rm s}}{dt}\Big(\frac{1}{T_{\rm s}}\Big) + \mathbf{Q}_{\rm s}\cdot\boldsymbol{\nabla}\Big(\frac{1}{T_{\rm s}}\Big)\\ &+ \hat{\rho}^{\rm s}\,\Big(\frac{\partial \Xi_{\rm s}}{\partial \rho^{\rm s}} + \frac{\mathbf{v}_{\rm s}^2}{2T_{\rm s}}\Big) + \frac{\hat{U}^{\rm s}}{T_{\rm s}} - \hat{S}^{\rm s} - \frac{\hat{\mathbf{p}}^{\rm s}}{T_{\rm s}}\cdot\mathbf{v}_{\rm s}\,.\end{aligned} \tag{10.5.4}$$

The Massieu function of the viscous liquid will be assumed to depend on its coldness $T_{\rm w}^{-1}$ and of its apparent mass density $\rho^{\rm w}$,

$$\Xi_{\rm w} = \Xi_{\rm w}(T_{\rm w}^{-1},\,\rho^{\rm w})\,, \tag{10.5.5}$$

in such a way that the entropy production becomes,

$$\begin{aligned}\hat{S}^{\rm w}_{\rm (i)} &= \Big(\frac{\boldsymbol{\sigma}^{\rm w}}{T_{\rm w}} + (\Xi_{\rm w} - \rho^{\rm w}\,\frac{\partial \Xi_{\rm w}}{\partial \rho^{\rm w}})\,\mathbf{I}\Big) : \mathbf{D}_{\rm w} + \Big(\rho^{\rm w}\,u_{\rm w} + \frac{\partial \Xi_{\rm w}}{\partial T_{\rm w}^{-1}}\Big)\,\frac{d^{\rm w}}{dt}\Big(\frac{1}{T_{\rm w}}\Big) + \mathbf{Q}_{\rm w}\cdot\boldsymbol{\nabla}\Big(\frac{1}{T_{\rm w}}\Big)\\ &+ \hat{\rho}^{\rm w}\,\Big(\frac{\partial \Xi_{\rm w}}{\partial \rho^{\rm w}} + \frac{\mathbf{v}_{\rm w}^2}{2T_{\rm w}}\Big) + \frac{\hat{U}^{\rm w}}{T_{\rm w}} - \hat{S}^{\rm w} - \frac{\hat{\mathbf{p}}^{\rm w}}{T_{\rm w}}\cdot\mathbf{v}_{\rm w}\,.\end{aligned} \tag{10.5.6}$$

In line with Note 4.5, the entropy production of the mixture as a whole is requested to be positive. This procedure does not preclude interesting constraints for the individual species. Indeed, arguing of the independence of velocity gradient of the solid and of the time rate and spatial gradient of its temperature, the following constitutive equations result,

$$\begin{aligned}\frac{\boldsymbol{\sigma}^{\rm s}}{T_{\rm s}} &= -(\Xi_{\rm s} - \rho^{\rm s}\,\frac{\partial \Xi_{\rm s}}{\partial \rho^{\rm s}})\,\mathbf{I} - 2\,\mathbf{F}_{\rm s}^{\rm T}\cdot\frac{\partial \Xi_{\rm s}}{\partial \mathbf{C}_{\rm s}}\cdot\mathbf{F}_{\rm s},\\ \rho^{\rm s}\,s_{\rm s} &= \Xi_{\rm s} - T_{\rm s}^{-1}\,\frac{\partial \Xi_{\rm s}}{\partial T_{\rm s}^{-1}} = \Xi_{\rm s} + \frac{\rho^{\rm s}\,u_{\rm s}}{T_{\rm s}}\\ \frac{\mathbf{Q}_{\rm s}}{T_{\rm s}^2} &= \mathbf{k}_{T_{\rm s}}\cdot\boldsymbol{\nabla}\Big(\frac{1}{T_{\rm s}}\Big)\,,\end{aligned} \tag{10.5.7}$$

where $\mathbf{k}_{T_{\rm s}}$ is the positive definite second order tensor of thermal conductivity in the solid [unit : W/m/K]. The liquid being viscous, its stress depends on the strain rate $\mathbf{D}_{\rm w}$, in such a way that the independence of $\mathbf{D}_{\rm w}$ can not be exploited directly as pointed out in Section 4.9. The way out of this difficulty consists in postulating the dissipation associated with this strain rate in a specific format. For a Newtonian liquid, the dissipation would be of the form $\mathbf{D}_{\rm w} : \mathbb{E}_v : \mathbf{D}_{\rm w}$ where $\mathbb{E}_v$ [unit : Pa×s] is a (semi-)positive definite fourth order tensor. For a Newtonian isotropic liquid, this tensor is defined in terms of the Lamé viscosities λ_v and μ_v obeying the inequalities $\lambda_v + (2/3)\,\mu_v \geq 0$ and $\mu_v \geq 0$. The constitutive equations are then compatible with a positive entropy production,

$$\begin{aligned}\frac{\boldsymbol{\sigma}^{\rm w}}{T_{\rm w}} &= -(\Xi_{\rm w} - \rho^{\rm w}\,\frac{\partial \Xi_{\rm w}}{\partial \rho^{\rm w}})\,\mathbf{I} + \mathbb{E}_v : \mathbf{D}_{\rm w},\\ \rho^{\rm w}\,s_{\rm w} &= \Xi_{\rm w} - T_{\rm w}^{-1}\,\frac{\partial \Xi_{\rm w}}{\partial T_{\rm w}^{-1}} = \Xi_{\rm w} + \frac{\rho^{\rm w}\,u_{\rm w}}{T_{\rm w}}\\ \frac{\mathbf{Q}_{\rm w}}{T_{\rm w}^2} &= \mathbf{k}_{T_{\rm w}}\boldsymbol{\nabla}\Big(\frac{1}{T_{\rm w}}\Big)\,,\end{aligned} \tag{10.5.8}$$

where $\mathbf{k}_{T_{\rm w}}$ is the positive definite second order tensor of thermal conductivity in the liquid.

10.5.2 Constitutive equations for mass and heat transfers

Given the closure relations (10.1.2) in absence of external supplies, the sum of the reduced dissipations results in the format,

$$\hat{S}_{\rm (i)} = \hat{\rho}^{\rm s}\,\Big(\frac{\partial \Xi_{\rm s}}{\partial \rho^{\rm s}} - \frac{\partial \Xi_{\rm w}}{\partial \rho^{\rm w}} + \tfrac{1}{2}\,(\frac{\mathbf{v}_{\rm s}^2}{T_{\rm s}} - \frac{\mathbf{v}_{\rm w}^2}{T_{\rm w}})\Big) + \hat{U}^{\rm s}\,\Big(\frac{1}{T_{\rm s}} - \frac{1}{T_{\rm w}}\Big) - \hat{\mathbf{p}}^{\rm s}\cdot\Big(\frac{\mathbf{v}_{\rm s}}{T_{\rm s}} - \frac{\mathbf{v}_{\rm w}}{T_{\rm w}}\Big)\,. \tag{10.5.9}$$

Neglecting the buoyancy term, the identification of the net momentum supply of the liquid (10.3.1) may be used to modify this expression,

$$\begin{aligned}\hat{S}_{\rm (i)} &= \hat{\rho}^{\rm s}\,\Big(\frac{\partial \Xi_{\rm s}}{\partial \rho^{\rm s}} - \frac{\partial \Xi_{\rm w}}{\partial \rho^{\rm w}} + \tfrac{1}{2}\,\frac{(\mathbf{v}_{\rm w} - \mathbf{v}_{\rm s})^2}{T_{\rm w}}\Big) + \Big(\hat{U}^{\rm s} - \hat{\mathbf{p}}^{\rm s}\cdot\mathbf{v}_{\rm s} + \hat{\rho}^{\rm s}\,\frac{\mathbf{v}_{\rm s}^2}{2}\Big)\,\Big(\frac{1}{T_{\rm s}} - \frac{1}{T_{\rm w}}\Big)\\ &+ k_{\rm Sd}\,\frac{(\mathbf{v}_{\rm w} - \mathbf{v}_{\rm s})^2}{T_{\rm w}}\,.\end{aligned} \tag{10.5.10}$$

The coefficient of Stokes' drag $k_{\rm Sd}$ being positive, the entropy production is ensured to be positive for the following linear constitutive equations of mass transfer and energy transfer,

$$\begin{aligned} \hat{\rho}^{\rm s} &= \kappa_\rho \Big(\frac{\partial \Xi_{\rm s}}{\partial \rho^{\rm s}} - \frac{\partial \Xi_{\rm w}}{\partial \rho^{\rm w}} + \tfrac{1}{2} \frac{(\mathbf{v}_{\rm w} - \mathbf{v}_{\rm s})^2}{T_{\rm w}} \Big), \\ \hat{U}^{\rm s} - \hat{\mathbf{p}}^{\rm s} \cdot \mathbf{v}_{\rm s} + \hat{\rho}^{\rm s} \frac{\mathbf{v}_{\rm s}^2}{2} &= \kappa_T \Big(\frac{1}{T_{\rm s}} - \frac{1}{T_{\rm w}} \Big), \end{aligned} \tag{10.5.11}$$

if the transfer coefficients satisfy the inequalities,

$$\kappa_\rho \geq 0, \quad \kappa_T \geq 0\,. \tag{10.5.12}$$

The energy transfer equation features the rhs of the energy equation of the solid (10.1.1) and indicates that the energy of the solid increases if its temperature is lower than that of the liquid.

In absence of external mass supply, the rate of mass transfer to the fluid is the negative of its solid counterpart, $\hat{\rho}^{\rm w} = -\hat{\rho}^{\rm s}$. However, attention should be paid to the fact that the solid and liquid do not play symmetric roles in the energy equation due to the identification of the momentum transfer of the liquid. The energy exchange for the liquid writes,

$$\hat{U}^{\rm w} - \hat{\mathbf{p}}^{\rm w} \cdot \mathbf{v}_{\rm s} + \hat{\rho}^{\rm w} \frac{\mathbf{v}_{\rm s}^2}{2} = \kappa_T \Big(\frac{1}{T_{\rm w}} - \frac{1}{T_{\rm s}} \Big), \tag{10.5.13}$$

and the entity involved in this equation is *not* the rhs of the energy equation (10.1.1) of the liquid.

An energy exchange between a solid and two liquids is derived in Section 10.6.3: the constitutive relation features the same lhs as in (10.5.11) and (10.5.13) to within the fact that the term $\hat{\rho}^{\rm s}$ does not appear as the solid does not exchange mass in that section. An estimation of the heat transfer coefficient in terms of physical and geometrical properties of the solid and liquid is proposed in Section 10.8.

The interpretation of the constitutive equation of mass transfer is less immediate. In the analysis of isothermal solidification/fluidification, Henson [2013] works out the Massieu function for a neo-Hookean elastic solid with the ratio of $\rho^{\rm s} (\det \mathbf{C}_{\rm s})^{1/2}$ over the reference mass density $\underline{\rho}^{\rm s}$ (at $\mathbf{C}_{\rm s} = \mathbf{I}$) as an additional argument, as allowed by the formulation (10.5.3). Note that this ratio would vanish in absence of mass exchange. Similarly, the Massieu function of the liquid contains the ratio of the current and reference mass densities, the current mass density being obtained from the mass balance. The sense of the mass exchange is driven both by the difference of mass densities between the solid and the liquid and by the strain. Note that the elastic constitutive equations should be such that increase of mass leads to a compressive stress in agreement with (7.2.14) and (7.2.15). The above derivations closely follows Henson [2013], except in the identification of the momentum supply of the liquid, which leads to somehow different transfer equations.

10.6 A porous medium with two porosities and three temperatures

Specialized cavities:

Porous media with double porosity contain two types of cavities with distinct roles, Fig. 10.6.1. Pores provide most of the space to store fluid while vessels provide most of the permeability. Barenblatt et al. [1960] appear to be the first to have introduced the double porosity concept in the study of non-deformable fissured rock aquifers. For many applications, the restriction to rigid skeletons is not admissible: it has been alleviated by Duguid and Lee [1977] who however considered an incompressible solid constituent, and by Aifantis [1977] in a more general approach. Wilson and Aifantis [1984] presented analytical solutions for the borehole problem with various boundary conditions. A mixed finite element formulation with the solid displacement and the fluid pressures as unknowns is presented by Khaled et al. [1984] and applied to display the quantitative effects of double porosity in one- and two-dimensional consolidation analyses.

The deformation coupling used by Aifantis and coworkers was not complete and more general coupling equations are presented in Khalili and Valliappan [1996] and Tuncay and Corapcioglu [1996]a [1996]b.

The influence of a single porosity on the number, amplitude and attenuation of harmonic waves has received much more attention than the effect of double porosity. Biot [1956]I-II has evidenced the existence of two, one fast and the other slow, longitudinal waves due to the coupling between the solid skeleton and a fluid phase. The slow wave is attenuated so that its experimental measurement has been made by Plona [1980] more than twenty years after

Biot's papers. For double porosity mixtures, Wilson and Aifantis [1984] report the existence of three longitudinal waves, with much attenuation for the second and third waves, and of one rotational wave. The analysis of Tuncay and Corapcioglu [1996]a [1996]b is more general as it concerns actually a mixture with four species: the pores are saturated by air and water, capillary effects are included and the pore pressure is approximated through volume averaging. They report the effects of frequency, saturation and volume fractions on the speed and attenuation of the four longitudinal and single rotational waves.

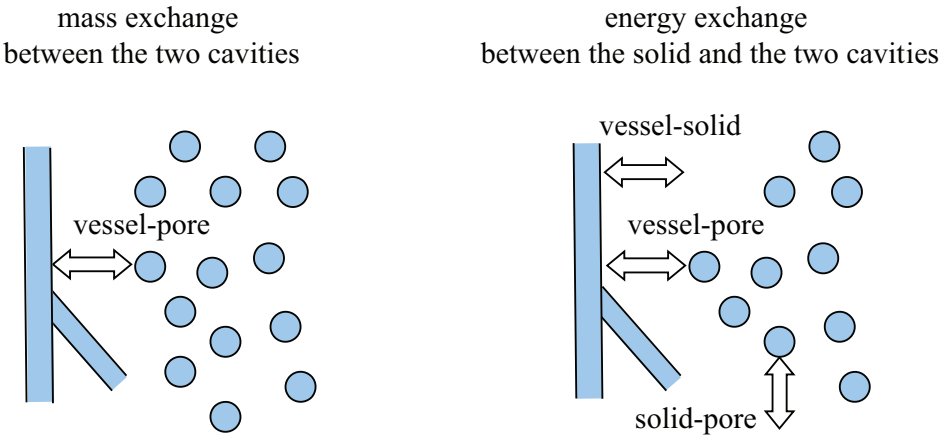

Fig. 10.6.1: The double porosity concept highlights two cavities with distinct roles.

Spatial scale separation and time scale separation:

Pore spacing is assumed to be much smaller than vessel spacing and therefore the representative elementary volume should be at least an order of magnitude larger than the vessel spacing. The method suggested to identify the mechanical constants uses this spatial scale separation.

Another method to identify material constants has been suggested by Wilson and Aifantis [1984]: it exploits the time scale separation implied by the contrast in hydraulic conductivities of the pores and vessels. Berryman and Wang [1995] propose a mixed method using the existence of two scales in both time and space. Both works concern isotropic solid skeletons under isothermal conditions.

Thermomechanical analysis, mass transfer and energy transfer:

The fluids of the two cavities flow through the solid skeleton essentially according to Darcy's law for the pore fluid. Moreover, pores and vessels exchange fluid (phenomenon referred to as *mass transfer*). The mass of each fluid may vary due to mass transfer with the sister cavity and due to diffusion from/to the surroundings. On the other hand, the solid constituent does not undergo a mass change, which could be due to a mass transfer or a growth/resorption. The porous medium itself is closed in the thermodynamic sense defined in Chapter 4.

Here, the thermomechanical analysis considers local thermal non equilibrium (LTNE) and the three species are endowed with their own temperatures. Convection of heat by the fluid of the vessels is an important aspect that generates/makes possible LTNE. Therefore, the solid and fluid constituents exchange energy (phenomenon referred to as *energy transfer*).

The approach capitalizes upon attempts in the framework of unsaturated porous media, Loret and Khalili [2000], Khalili and Loret [2001], and in clays, Khalili [2003], Khalili and Selvadurai [2003]. The model has been used to solve initial and boundary value problems through a finite element approach, Gelet [2011].

Anisotropy in mechanical, diffusion and thermal properties:

All the above works concern isothermal elastic isotropic solid skeletons. The formulation of Loret and Rizzi [1999] includes mechanical anisotropy in the solid constituent and in the solid skeleton. Here, diffusion properties and the thermal expansion properties may a priori be anisotropic as well.

10.6.1 Thermomechanical equations

10.6.1.1 Thermodynamic derivation

The expression $(7.2.28)_1$ of the mechanical entropy production and the definitions of the thermodynamic functions in Table 7.2.2 stand as our starting point. Repeated use is also made of the rate relation (2.7.2).

For the solid, upon multiplication by $T_\mathrm{s} \det \mathbf{F}$, Eqn $(7.2.28)_1$ is modified so as to display entropy and free energy,

$$T_\mathrm{s}\, \underline{\hat{S}}^\mathrm{s}_{(\mathrm{i},1)} = -\frac{d}{dt}(m^\mathrm{s} e_\mathrm{s}) + \boldsymbol{\tau}^\mathrm{s} : \boldsymbol{\nabla} \mathbf{v}_\mathrm{s} - m^\mathrm{s} s_\mathrm{s} \frac{dT_\mathrm{s}}{dt}\,. \tag{10.6.1}$$

Recall that terms in the mechanical entropy production involving a chemical potential do not pertain to solid constituent.

For a fluid constituent $k \in \mathcal{K}^{**}$, upon multiplication by $T_\mathrm{s} \det \mathbf{F}$, use of the identity $\mu_k\, dm^k = d(\mu_k\, m^k) - d\mu_k\, m^k$, and of (7.2.31), Eqn $(7.2.28)_1$ takes the form,

$$T_\mathrm{s}\, \underline{\hat{S}}^k_{(\mathrm{i},1)} = \frac{d}{dt}\Big(v^k\, \tilde{p}_k\Big) + \tilde{\boldsymbol{\tau}}^k : \boldsymbol{\nabla} \mathbf{v}_\mathrm{s} - v^k \frac{d\tilde{p}_k}{dt}\,, \tag{10.6.2}$$

where $\tilde{p}_k$ is a modified intrinsic pressure and $\tilde{\boldsymbol{\tau}}^k$ a modified partial Kirchhoff stress,

$$\tilde{\boldsymbol{\tau}}^k = -v^k\, \tilde{p}_k\, \mathbf{I}, \quad \tilde{p}_k = p_k \frac{T_\mathrm{s}}{T_k}, \quad k \in \mathcal{K}^{**}\,. \tag{10.6.3}$$

Upon summation over the solid constituent and all fluid constituents, the mechanical part of entropy production for the mixture multiplied by T_s,

$$T_\mathrm{s}\, \underline{\hat{S}}_{(\mathrm{i},1)} = -\frac{d\underline{\mathcal{W}}}{dt} + \tilde{\boldsymbol{\tau}} : \boldsymbol{\nabla} \mathbf{v}_\mathrm{s} - m^\mathrm{s} s_\mathrm{s} \frac{dT_\mathrm{s}}{dt} - \sum_{k \in \mathcal{K}^{**}} v^k \frac{d\tilde{p}_k}{dt}\,, \tag{10.6.4}$$

expresses in terms of the thermo-poroelastic energy of the mixture $\underline{\mathcal{W}}$,

$$\underline{\mathcal{W}} = \underline{\mathcal{W}}(\boldsymbol{\epsilon},\ \cup_{k\,\in\,\mathcal{K}^{**}}\ \tilde{p}_k,\ T_\mathrm{s}) = m^\mathrm{s}\, e_\mathrm{s} - \sum_{k\,\in\,\mathcal{K}^{**}} v^k\, \tilde{p}_k\,. \tag{10.6.5}$$

The second order tensor $\tilde{\boldsymbol{\tau}}$ is a modified total Kirchhoff stress,

$$\tilde{\boldsymbol{\tau}} = \boldsymbol{\tau}^\mathrm{s} + \sum_{k \in \mathcal{K}^{**}} \tilde{\boldsymbol{\tau}}^k\,. \tag{10.6.6}$$

The total Kirchhoff stress deduces as,

$$\boldsymbol{\tau} = \boldsymbol{\tau}^\mathrm{s} + \sum_{k \in \mathcal{K}^{**}} \boldsymbol{\tau}^k = \tilde{\boldsymbol{\tau}} - \sum_{k \in \mathcal{K}^{**}} v^k\, (p_k - \tilde{p}_k)\, \mathbf{I}\,. \tag{10.6.7}$$

Setting the entropy production to zero, constitutive equations result for the dependent variables,

$$\tilde{\boldsymbol{\tau}} = \frac{\partial \underline{\mathcal{W}}}{\partial \boldsymbol{\epsilon}}\,; \quad -v^k = \frac{\partial \underline{\mathcal{W}}}{\partial \tilde{p}_k}, \quad k \in \mathcal{K}^{**}; \quad -\underline{S}^\mathrm{s} = -m^\mathrm{s} s_\mathrm{s} = \frac{\partial \underline{\mathcal{W}}}{\partial T_\mathrm{s}}\,. \tag{10.6.8}$$

The above derivation is quite distinct from that of Bowen and Garcia [1970] who, for each species, introduced a Massieu function Ξ_k as defined by (10.5.1). They obtain constitutive equations for the internal energies and partial stresses. Each Massieu function is developed up to second order in terms of the main variables, which are the strains of the species and their temperatures. An application to a porous medium including a solid matrix and a fluid is presented in Bowen and Chen [1975].

By contrast, the present derivation aims at highlighting some specific symmetries and decouplings of thermomechanical properties as can be observed already in (10.6.8).

The analysis is now restricted:

1. the porous medium is constituted by a solid skeleton saturated by two non miscible fluids, referred to by the indices 1 and 2;
2. the temperatures of the species are distinct, but their ratios are close enough to 1 that the differences between the pressures p_k and $\tilde{p}_k$ defined by (10.6.3) are neglected;
3. the thermomechanical equations to be developed are linear and the current configuration is taken as reference.

The thermomechanical constitutive relations simplify to,

$$\boldsymbol{\sigma} = \frac{\partial \mathcal{W}}{\partial \boldsymbol{\epsilon}}\,; \quad -v^k = \frac{\partial \mathcal{W}}{\partial p_k}; \quad k \in \mathcal{K}^{**} = \{1, 2\}, \quad -S^\mathrm{s} = -\rho^\mathrm{s} s_\mathrm{s} = \frac{\partial \mathcal{W}}{\partial T_\mathrm{s}}\,. \tag{10.6.9}$$

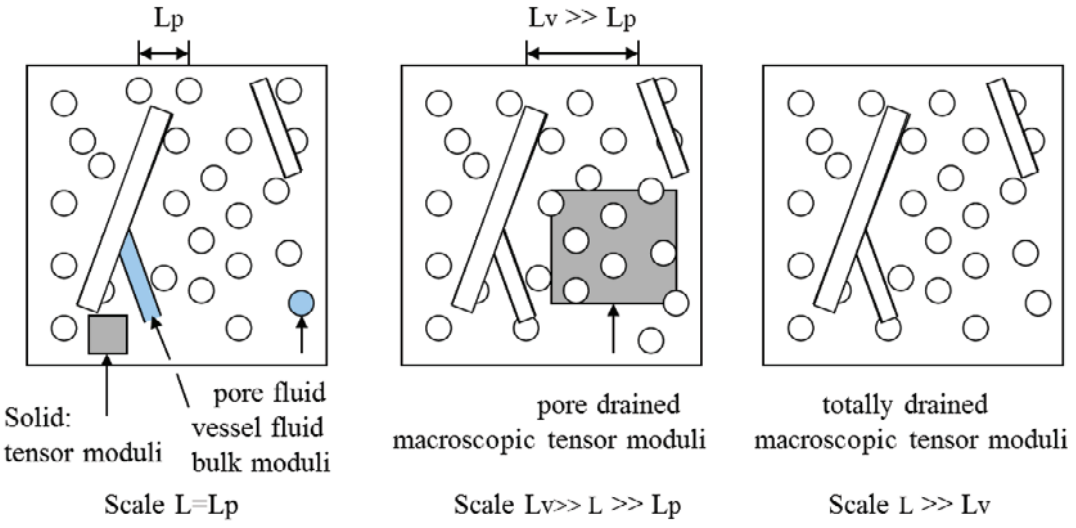

Fig. 10.6.2: The measurement of the elastic constants uses the spatial scale separation and considers three scales: the smallest scales devoid of pores, an intermediate scale devoid of vessels and the largest scale with both pores and vessels.

10.6.1.2 The generalized effective stress

The effective stress introduced in (9.3.10) is extended so as to include two pressures, the strain coming into picture being the elastic strain, that is, the total strain minus the thermal expansion,

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma} + \boldsymbol{\alpha}_1\, p_1 + \boldsymbol{\alpha}_2\, p_2 = \mathbb{E} : \big(\boldsymbol{\epsilon} - \mathbf{c}_{\rm T}\,(T_{\rm s} - T_{\rm s}^0)\big)\,. \tag{10.6.10}$$

This effective stress involves three types of constitutive tensors:

- when full drainage is allowed, $p_1 = p_2 = 0$ and, under isothermal conditions, the effective stress is then equal to the partial stress of the solid skeleton, $\boldsymbol{\sigma}' = \boldsymbol{\sigma} = \boldsymbol{\sigma}^{\rm s} = \mathbb{E} : \boldsymbol{\epsilon}$, which shows that the tensor moduli $\mathbb{E}$ are the elastic moduli of the *underlying drained solid*;
- the symmetric second order tensor $\mathbf{c}_{\rm T}$ [unit : K^{-1}] is clearly the tensor of thermal expansion of the drained solid skeleton, equal to the tensor of thermal expansion of the solid constituent, as indicated by Proposition 9.4;
- the two symmetric second order tensors $\boldsymbol{\alpha}_1$ and $\boldsymbol{\alpha}_2$ will be identified below.

The existence of a thermo-poroelastic energy,

$$\begin{aligned} \mathcal{W}(\boldsymbol{\epsilon},\, \cup_{k=1,2}\, p_k,\, T_{\rm s}) \;&=\; \frac{1}{2}\,\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} - (T_{\rm s} - T_{\rm s}^0)\,\mathbf{c}_{\rm T} : \mathbb{E} : \boldsymbol{\epsilon} - (p_1\,\boldsymbol{\alpha}_1 + p_2\,\boldsymbol{\alpha}_2) : \boldsymbol{\epsilon} \\ &-\; \frac{1}{2}\,(a_{11}\,p_1^2 + 2\,a_{12}\,p_1\,p_2 + a_{22}\,p_2^2) - v_0^1\,p_1 - v_0^2\,p_2 \\ &-\; (a_{1T}\,p_1 + a_{2T}\,p_2 + S_0^{\rm s})\,(T_{\rm s} - T_{\rm s}^0) - \frac{1}{2}\,\frac{C_{\epsilon p}^{\rm s}}{T_{\rm s}^0}\,(T_{\rm s} - T_{\rm s}^0)^2\,, \end{aligned} \tag{10.6.11}$$

implies the matrix form of the thermomechanical equations to be endowed with the major symmetry,

$$\begin{bmatrix} -\boldsymbol{\sigma} \\ v^1 - v_0^1 \\ v^2 - v_0^2 \\ S^{\rm s} - S_0^{\rm s} \end{bmatrix} = \begin{bmatrix} -\mathbb{E} & \boldsymbol{\alpha}_1 & \boldsymbol{\alpha}_2 & \mathbb{E} : \mathbf{c}_{\rm T} \\ \boldsymbol{\alpha}_1 & a_{11} & a_{12} & a_{1{\rm T}} \\ \boldsymbol{\alpha}_2 & a_{12} & a_{22} & a_{2{\rm T}} \\ \mathbf{c}_{\rm T} : \mathbb{E} & a_{1{\rm T}} & a_{2{\rm T}} & C_{\epsilon p}^{\rm s}/T_{\rm s}^0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ p_1 \\ p_2 \\ T_{\rm s} - T_{\rm s}^0 \end{bmatrix}. \tag{10.6.12}$$

Here $C_{\epsilon p}^{\rm s}$ [unit : $\mathrm{J/m^3/K}$] is the *apparent heat capacity* of the solid, at constant strain and fluid pressures, per unit volume of porous medium, i.e. heat capacity times volume fraction.

The coefficients defining the thermal response, and the entropy of the solid, result from Proposition 9.3 (where $T = T_{\rm s}$) namely

$$a_{k{\rm T}} = (n^k\,\mathbf{I} - \boldsymbol{\alpha}_k) : \mathbf{c}_{\rm T}, \quad k = 1, 2\,. \tag{10.6.13}$$

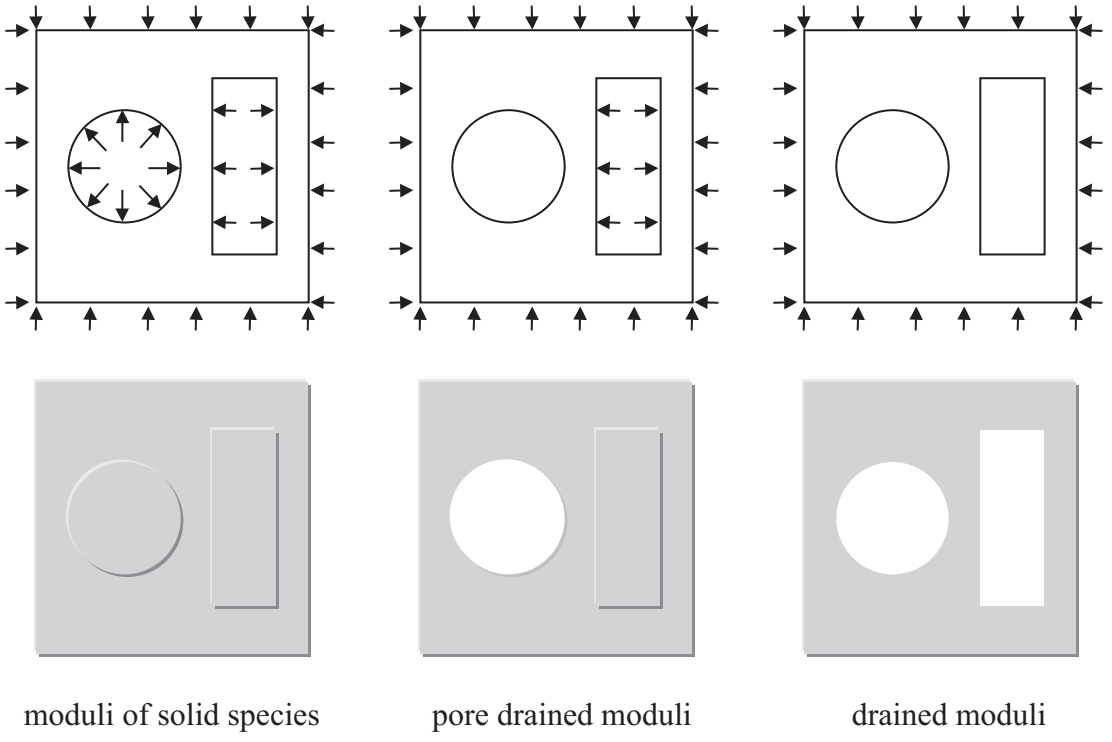

Fig. 10.6.3: The elastic constants are accessible to measurements by well chosen loadings of the pores, of the vessels and of the solid.

The remaining mechanical coefficients may be calculated in terms of three types of constitutive moduli that are measurable through experiments performed at different scales, as sketched in Fig. 10.6.2, namely:

- the tensor moduli $\mathbb{E}_s$ of the solid constituent, that link its intrinsic strain $\boldsymbol{\epsilon}_s$ and its intrinsic stress $\boldsymbol{\sigma}_s$, Eqn (7.2.14). The involved scale corresponds to that provided by the solid constituent devoid of the two porosities;
- the tensor moduli $\mathbb{E}^{PD}$ corresponding to a zero pressure in the pores of type 1 (p_1=0), the acronym 'PD' standing for *Pore Drained mixture*. The experiments should be performed on specimens an order of magnitude larger than the spacing of the smaller pores but devoid of the larger pores;
- the tensor moduli $\mathbb{E}$ of the underlying Drained Solid, or solid skeleton, corresponding to zero pressures in the two types of pores, (p_1=p_2=0). The experiments should be performed at the largest scale, say an order of magnitude larger than the spacing of the vessels.

The identification makes use of

Proposition 10.1 on homogeneous deformation under homogeneous isothermal mechanical loading.

For an isothermal loading, i.e. $\Delta T_s = 0$, and a homogeneous mechanical loading, $\boldsymbol{\sigma} = -p\,\mathbf{I}$, $p_k = p$, $k \in \mathcal{K}^{**}$, the material responds as if it was devoid of porosity, and the volume change of each species is proportional to its volume fraction, $\Delta v^k = n^k \operatorname{tr} \boldsymbol{\epsilon}$, $k \in \mathcal{K}$.

The proposition is illustrated by Fig. 10.6.3. Then the strain is governed by both the effective stress law Eqn (10.6.10) and the mechanical response of the solid constituent, Eqn (7.2.14) with $\boldsymbol{\sigma}_s = -p\,\mathbf{I}$, namely,

$$\boldsymbol{\epsilon} = \mathbb{E}^{-1} : (-p\,\mathbf{I} + \boldsymbol{\alpha}_1\, p + \boldsymbol{\alpha}_2\, p) = \mathbb{E}_s^{-1} : (-p\,\mathbf{I}) \ , \tag{10.6.14}$$

while the volume changes of the pores are in proportion with their volume fractions,

$$\Delta v = \mathbf{I} : \boldsymbol{\epsilon} \ , \quad \Delta v^1 = n^1 \Delta v \ , \quad \Delta v^2 = n^2 \Delta v \ . \tag{10.6.15}$$

On the other hand, for the loading defined by ($\boldsymbol{\sigma}$, p_1, p_2)=($-p\,\mathbf{I}$, 0, p), the strain is governed by both the effective stress law Eqn (10.6.10) and the moduli $\mathbb{E}^{PD}$,

$$\boldsymbol{\epsilon} = \mathbb{E}^{-1} : (-p\,\mathbf{I} + \boldsymbol{\alpha}_2\, p) = (\mathbb{E}^{PD})^{-1} : (-p\,\mathbf{I}) \tag{10.6.16}$$

and

$$\Delta v = \mathbf{I} : \boldsymbol{\epsilon} \,, \quad \Delta v^2 = n^2 \Delta v \,. \tag{10.6.17}$$

The tensors $\boldsymbol{\alpha}_1$ and $\boldsymbol{\alpha}_2$ result from Eqns (10.6.15) and (10.6.17), namely

$$\boldsymbol{\alpha}_1 = \mathbb{E} : (\mathbb{E}^{\text{PD}})^{-1} : \mathbf{I} - \mathbb{E} : \mathbb{E}_{\text{s}}^{-1} : \mathbf{I}, \quad \boldsymbol{\alpha}_2 = \mathbf{I} - \mathbb{E} : (\mathbb{E}^{\text{PD}})^{-1} : \mathbf{I} \,. \tag{10.6.18}$$

It is convenient to define the bulk moduli associated with the tensor moduli $\mathbb{E}_{\text{s}}$, $\mathbb{E}^{\text{PD}}$ and $\mathbb{E}$ as

$$\frac{1}{K_{\text{s}}} = \mathbf{I} : \mathbb{E}_{\text{s}}^{-1} : \mathbf{I}, \quad \frac{1}{K^{\text{PD}}} = \mathbf{I} : (\mathbb{E}^{\text{PD}})^{-1} : \mathbf{I}, \quad \frac{1}{K} = \mathbf{I} : \mathbb{E}^{-1} : \mathbf{I} \,. \tag{10.6.19}$$

Then, the coefficients a_{11}, a_{12} and a_{11} result by comparing the fluid volume contents given by the constitutive equations (10.6.12) and by equations (10.6.15) and (10.6.17), for the two above particular loadings, namely

$$\begin{aligned} a_{11} &= \frac{1-n^2}{K^{\text{PD}}} - \frac{1+n^1-n^2}{K_{\text{s}}} - \boldsymbol{\alpha}_1 : \mathbb{E}^{-1} : \boldsymbol{\alpha}_1 \,; \\ a_{12} &= \frac{n^2}{K^{\text{PD}}} - \frac{n^2}{K_{\text{s}}} - \boldsymbol{\alpha}_1 : \mathbb{E}^{-1} : \boldsymbol{\alpha}_2 \,; \\ a_{22} &= \frac{1}{K} - \frac{1+n^2}{K^{\text{PD}}} - \boldsymbol{\alpha}_2 : \mathbb{E}^{-1} : \boldsymbol{\alpha}_2 \,. \end{aligned} \tag{10.6.20}$$

In Wilson and Aifantis [1984], see their Eqn (10), the coupling coefficient a_{12}, which links the volume changes of the fluids, vanishes. For an isotropic solid skeleton, a_{12} can be cast in the format $\big((1/K^{\text{PD}} - 1/K_{\text{s}}\big)\big(n^2 - (1 - K/K^{\text{PD}})\big)$. Its vanishing yields the bulk modulus $K^{\text{PD}}{=}K/(1-n^2)$. This uncoupling is somehow incompatible with the incompressibility of the fluids: together they give rise to discontinuous pressure response under specific loadings, Khalili [2003].

The mixed matrix form (10.6.12) can be partially inverted to obtain a generalized strain vector in terms of a generalized stress vector,

$$\begin{bmatrix} \boldsymbol{\epsilon} \\ v^1 - v_0^1 \\ v^2 - v_0^2 \\ S^{\text{s}} - S_0^{\text{s}} \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{-1} & \mathbb{E}^{-1} : \boldsymbol{\alpha}_1 & \mathbb{E}^{-1} : \boldsymbol{\alpha}_2 & \mathbf{c}_{\text{T}} \\ \boldsymbol{\alpha}_1 : \mathbb{E}^{-1} & b_{11} & b_{12} & n^1 \mathbf{I} : \mathbf{c}_{\text{T}} \\ \boldsymbol{\alpha}_2 : \mathbb{E}^{-1} & b_{12} & b_{22} & n^2 \mathbf{I} : \mathbf{c}_{\text{T}} \\ \mathbf{c}_{\text{T}} & n^1 \mathbf{I} : \mathbf{c}_{\text{T}} & n^2 \mathbf{I} : \mathbf{c}_{\text{T}} & C_{\sigma p}^{\text{s}}/T_{\text{s}}^0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\sigma} \\ p_1 \\ p_2 \\ T_{\text{s}} - T_{\text{s}}^0 \end{bmatrix} , \tag{10.6.21}$$

where

$$b_{11} = a_{11} + \boldsymbol{\alpha}_1 : \mathbb{E}^{-1} : \boldsymbol{\alpha}_1 \,, \quad b_{12} = a_{12} + \boldsymbol{\alpha}_1 : \mathbb{E}^{-1} : \boldsymbol{\alpha}_2 \,, \quad b_{22} = a_{22} + \boldsymbol{\alpha}_2 : \mathbb{E}^{-1} : \boldsymbol{\alpha}_2 \,, \tag{10.6.22}$$

and $C_{\sigma p}^{\text{s}}$ is the heat capacity of the solid at constant stress and pressures, per unit volume of porous medium,

$$C_{\sigma p}^{\text{s}} - C_{\epsilon p}^{\text{s}} = T_{\text{s}}^0 \; \mathbf{c}_{\text{T}} : \mathbb{E} : \mathbf{c}_{\text{T}} \,. \tag{10.6.23}$$

Similar differences between the heat capacities at constant stress and constant strain have been obtained for a fluid in Eqn (3.3.18), for a solid in Eqn (9.1.9), and for a porous medium in local thermal equilibrium in Eqn (9.3.15).

Again, the choice of primary and dependent variables is a key decision, both for the major symmetry of the constitutive matrix and parameter identification. For example, the use of the volume contents, as opposed to the mass contents, does not involve the bulk moduli of the fluids.

10.6.1.3 The complete thermomechanical constitutive equations

The changes of fluid mass contents in a dimensionless form $\zeta^k = \Delta m^k/\rho_k^0$, $k = 1, 2$, derive from (7.2.9). They involve additional material parameters, namely the bulk moduli K_1 and K_2, the coefficients of thermal expansion $c_{\text{T}1}$ and $c_{\text{T}2}$, which characterize the relative changes of the intrinsic mass densities of the fluids, as defined by Eqn (7.2.5). The apparent entropies of the fluids S^1 and S^2 given by (7.2.11) involve in addition the apparent heat capacities at

constant pressure of each fluid C_p^1 and C_p^2. The comprehensive thermomechanical constitutive equations in mixed form can be cast in the form,

$$\begin{bmatrix} -\boldsymbol{\sigma} \\ \zeta^1 \\ \zeta^2 \\ \Delta S^{\rm s} \\ \Delta S^1 \\ \Delta S^2 \end{bmatrix} = \begin{bmatrix} -\mathbb{E} & \boldsymbol{\alpha}_1 & \boldsymbol{\alpha}_2 & \mathbb{E} : \mathbf{c}_{\rm T} & 0 & 0 \\ \boldsymbol{\alpha}_1 & a_{11} + n^1/K_1 & a_{12} & a_{1{\rm T}} & -n^1\, c_{\rm T1} & 0 \\ \boldsymbol{\alpha}_2 & a_{12} & a_{22} + n^2/K_2 & a_{2{\rm T}} & 0 & -n^2\, c_{\rm T2} \\ \mathbf{c}_{\rm T} : \mathbb{E} & a_{1{\rm T}} & a_{2{\rm T}} & C^{\rm s}_{\epsilon p}/T^0_{\rm s} & 0 & 0 \\ 0 & -n^1\, c_{\rm T1} & 0 & 0 & C^1_p/T^0_1 & 0 \\ 0 & 0 & -n^2\, c_{\rm T2} & 0 & 0 & C^2_p/T^0_2 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ p_1 \\ p_2 \\ \Delta T_{\rm s} \\ \Delta T_1 \\ \Delta T_2 \end{bmatrix}. \tag{10.6.24}$$

This format is aimed at finite element simulations where the primary unknowns are the solid displacement, the fluid pressures and the temperatures. The three first lines are already in appropriate form. The field equations to be used are

- the balance of momentum of the mixture, Eqn (4.5.9);
- the balances of mass of the fluids, Eqn (4.4.9);
- the energy equations for the three species, Eqn (4.6.11), expressed either in terms of the entropies, or in terms of the internal energies. If the latter option is chosen, the internal energies should be recovered first.

The mixed representation is endowed with two nice features: first, the matrix form is symmetric and, second, it displays decouplings which are not easily realized when the equations are phrased in terms of other primary variables.

Indeed, as another equivalent form of the thermomechanical equations, consider the primary variables to be the apparent strains defined by (7.2.1), and the temperatures, while the dependent variables are the apparent stresses and entropies. Then

$$\begin{bmatrix} \boldsymbol{\sigma}^{\rm s} \\ -p^1 \\ -p^2 \\ -\Delta S^{\rm s} \\ -\Delta S^1 \\ -\Delta S^2 \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\rm s} & \boldsymbol{\lambda}_1 & \boldsymbol{\lambda}_2 & -\mathbb{E}^{\rm s}\colon \mathbf{c}_{\rm T} & -\boldsymbol{\lambda}_1\, c_{\rm T1} & -\boldsymbol{\lambda}_2\, c_{\rm T2} \\ \boldsymbol{\lambda}_1 & \lambda_{11} & \lambda_{12} & -\boldsymbol{\lambda}_1 : \mathbf{c}_{\rm T} & -\lambda_{11}\, c_{\rm T1} & -\lambda_{12}\, c_{\rm T2} \\ \boldsymbol{\lambda}_2 & \lambda_{12} & \lambda_{22} & -\boldsymbol{\lambda}_2 : \mathbf{c}_{\rm T} & -\lambda_{12}\, c_{\rm T1} & -\lambda_{22}\, c_{\rm T2} \\ -\mathbf{c}_{\rm T} : \mathbb{E}^{\rm s} & -\boldsymbol{\lambda}_1\colon \mathbf{c}_{\rm T} & -\boldsymbol{\lambda}_2\colon \mathbf{c}_{\rm T} & -C^{\rm s}_m/T^0_{\rm s} & (\boldsymbol{\lambda}_1\colon \mathbf{c}_{\rm T})\, c_{\rm T1} & (\boldsymbol{\lambda}_2\colon \mathbf{c}_{\rm T})\, c_{\rm T2} \\ -c_{\rm T1}\, \boldsymbol{\lambda}_1 & -\lambda_{11}\, c_{\rm T1} & -\lambda_{12}\, c_{\rm T1} & (\boldsymbol{\lambda}_1\colon \mathbf{c}_{\rm T})\, c_{\rm T1} & -C^1_v/T^0_1 & \lambda_{12}\, c_{\rm T1}\, c_{\rm T2} \\ -c_{\rm T2}\, \boldsymbol{\lambda}_2 & -\lambda_{12}\, c_{\rm T2} & -\lambda_{22}\, c_{\rm T2} & (\boldsymbol{\lambda}_2\colon \mathbf{c}_{\rm T})\, c_{\rm T2} & \lambda_{12}\, c_{\rm T2} c_{\rm T1} & -C^2_v/T^0_2 \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ {\rm tr}\, \tilde{\boldsymbol{\epsilon}}^1 \\ {\rm tr}\, \tilde{\boldsymbol{\epsilon}}^2 \\ \Delta T_{\rm s} \\ \Delta T_1 \\ \Delta T_2 \end{bmatrix}, \tag{10.6.25}$$

with associated moduli,

$$\begin{aligned} &\frac{1}{\Gamma} = \big(a_{11} + \frac{n^1}{K_1}\big)\,\big(a_{22} + \frac{n^2}{K_2}\big) - (a_{12})^2, \quad \Lambda = (n^1 n^2)^2\, \Gamma; \\ &\lambda_{11} = (n^1)^2\,\big(a_{22} + \frac{n^2}{K_2}\big)\,\Gamma, \quad \lambda_{12} = -n^1 n^2\, a_{12}\,\Gamma, \quad \lambda_{22} = (n^2)^2\,\big(a_{11} + \frac{n^1}{K_1}\big)\,\Gamma; \\ &\boldsymbol{\lambda}_1 = -\lambda_{11}\,\big(\mathbf{I} - \frac{\boldsymbol{\alpha}_1}{n^1}\big) - \lambda_{12}\,\big(\mathbf{I} - \frac{\boldsymbol{\alpha}_2}{n^2}\big), \quad \boldsymbol{\lambda}_2 = -\lambda_{12}\,\big(\mathbf{I} - \frac{\boldsymbol{\alpha}_1}{n^1}\big) - \lambda_{22}\,\big(\mathbf{I} - \frac{\boldsymbol{\alpha}_2}{n^2}\big); \\ &\mathbb{E}^{\rm s} = \mathbb{E} + \frac{1}{\Lambda}\,\big(\lambda_{22}\, \boldsymbol{\lambda}_1 \otimes \boldsymbol{\lambda}_1 + \lambda_{11}\, \boldsymbol{\lambda}_2 \otimes \boldsymbol{\lambda}_2 - \lambda_{12}\,(\boldsymbol{\lambda}_1 \otimes \boldsymbol{\lambda}_2 + \boldsymbol{\lambda}_2 \otimes \boldsymbol{\lambda}_1)\big)\,, \end{aligned} \tag{10.6.26}$$

and heat capacities,

$$\begin{aligned} &C^{\rm s}_m = C^{\rm s}_{\epsilon p} + \mathbf{c}_{\rm T} : (\mathbb{E} - \mathbb{E}^{\rm s}) : \mathbf{c}_{\rm T}\, T^0_{\rm s} = C^{\rm s}_{\sigma p} - \mathbf{c}_{\rm T} : \mathbb{E}^{\rm s} : \mathbf{c}_{\rm T}\, T^0_{\rm s}; \\ &C^1_v = C^1_p - \lambda_{11}\,(c_{\rm T1})^2\, T^0_1, \quad C^2_v = C^2_p - \lambda_{22}\,(c_{\rm T2})^2\, T^0_2\,. \end{aligned} \tag{10.6.27}$$

The explicit expressions of the above coefficients are provided by Loret and Rizzi [1999] for an isotropic solid skeleton. In fact, in their isotropic form, the above constitutive equations are identical to those given in Tuncay and Corapcioglu [1996]a [1996]b.

The couplings, uncouplings and symmetry properties of the constitutive matrices involved in this analysis are encapsulated in the two propositions below:

Proposition 10.2 on thermomechanical constitutive couplings and uncouplings.

- the thermomechanical constitutive equations (10.6.12) or (10.6.21) yielding the changes of volume contents do not involve the temperatures of the fluids. Indeed, the volume changes of the fluids are here entirely controlled by the solid skeleton, as already alluded for in Section 9.3.2;
- these uncouplings may be concealed by arbitrary choices of dependent and independent variables, e.g., Eqn (10.6.25);
- in contrast to the volume contents, the changes of mass contents of the fluids depend on their own temperatures, Eqn (10.6.24).

Proposition 10.3 on thermomechanical constitutive symmetries.

- the thermomechanical constitutive equations (10.6.12) or (10.6.21) yielding the changes of volume contents express in terms of a 4×4 symmetric matrix;
- the comprehensive thermomechanical constitutive equations (10.6.24) yielding the changes of mass contents and of entropies of the fluids express in terms of a 6×6 symmetric matrix;
- the comprehensive thermomechanical constitutive equations (10.6.25) yielding the apparent stresses and entropies express also in terms of a 6×6 symmetric matrix;
- the comprehensive thermomechanical constitutive equations of the form (10.6.24) but involving the changes of volume contents, instead of mass contents, would express in terms of a 6×6 *non* symmetric matrix.

The conditions of positive definiteness (PD) of the purely mechanical part of the equations, associated with the 3×3 principal minor, namely

$$\begin{bmatrix} \boldsymbol{\sigma}^{\mathrm{s}} \\ -p^1 \\ -p^2 \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\mathrm{s}} & \boldsymbol{\lambda}_1 & \boldsymbol{\lambda}_2 \\ \boldsymbol{\lambda}_1 & \lambda_{11} & \lambda_{12} \\ \boldsymbol{\lambda}_2 & \lambda_{12} & \lambda_{22} \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ \operatorname{tr} \tilde{\boldsymbol{\epsilon}}^1 \\ \operatorname{tr} \tilde{\boldsymbol{\epsilon}}^2 \end{bmatrix} . \tag{10.6.28}$$

may be expressed in the form, Loret and Rizzi [1999],

$$\mathbb{E} \ \text{ PD}; \quad \big(a_{11} + \frac{n^1}{K_1}\big)\big(a_{22} + \frac{n^2}{K_2}\big) - (a_{12})^2 > 0; \quad a_{11} + \frac{n^1}{K_1} > 0\,. \tag{10.6.29}$$

Indeed, the mechanical strain energy can be cast in the following format,

$$\begin{aligned} &\frac{1}{2}\,\boldsymbol{\sigma}^{\mathrm{s}} : \boldsymbol{\epsilon} - \frac{1}{2}\,p^1 \operatorname{tr} \tilde{\boldsymbol{\epsilon}}^1 - \frac{1}{2}\,p^2 \operatorname{tr} \tilde{\boldsymbol{\epsilon}}^2 \\ &= \frac{1}{2}\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon} \\ &+ \frac{1}{2\Lambda}\big(\boldsymbol{\lambda}_1 : \boldsymbol{\epsilon}\,\sqrt{\lambda_{22}}\,\cos\omega + \boldsymbol{\lambda}_2 : \boldsymbol{\epsilon}\,\sqrt{\lambda_{11}}\,\cos\theta + \operatorname{tr}\tilde{\boldsymbol{\epsilon}}^1\,\sqrt{\lambda_{11}\,\Lambda}\,\sin\theta - \operatorname{tr}\tilde{\boldsymbol{\epsilon}}^2\,\sqrt{\lambda_{22}\,\Lambda}\,\sin\omega\big)^2 \\ &+ \frac{1}{2\Lambda}\big(\boldsymbol{\lambda}_1 : \boldsymbol{\epsilon}\,\sqrt{\lambda_{22}}\,\sin\omega + \boldsymbol{\lambda}_2 : \boldsymbol{\epsilon}\,\sqrt{\lambda_{11}}\,\sin\theta - \operatorname{tr}\tilde{\boldsymbol{\epsilon}}^1\,\sqrt{\lambda_{11}\,\Lambda}\,\cos\theta + \operatorname{tr}\tilde{\boldsymbol{\epsilon}}^2\,\sqrt{\lambda_{22}\,\Lambda}\,\cos\omega\big)^2 , \end{aligned} \tag{10.6.30}$$

where the two real angles θ and ω are defined by the relations,

$$\cos(\omega-\theta) = -\frac{\lambda_{12}}{\sqrt{\lambda_{11}\lambda_{22}}}, \quad \sin(\omega-\theta) = -\frac{\sqrt{\Lambda}}{\sqrt{\lambda_{11}\lambda_{22}}}\,. \tag{10.6.31}$$

10.6.1.4 The volume fractions

The relations $(7.2.4)_4$ and (7.2.5) provide the rate of volume fraction dn^k/dt of the fluid k,

$$\frac{dn^k}{dt} = -n^k\,\mathbf{I} : \frac{d\boldsymbol{\epsilon}}{dt} - n^k\,(\frac{1}{K_k}\frac{dp_k}{dt} - c_{\mathrm{T}k}\,\frac{dT_k}{dt}) + \frac{n^k}{m^k}\,\frac{dm^k}{dt}\,, \quad k = 1,2\,. \tag{10.6.32}$$

Upon insertion of the rate of mass content (10.6.24) in (10.6.32) and elimination of the thermoelastic strain via (10.6.10), the fluid volume fractions express in terms of the total stress and fluid pressures only,

$$\begin{aligned} \frac{dn^1}{dt} &= (\boldsymbol{\alpha}_1 - n^1\,\mathbf{I}) : \mathbb{E}^{-1} : \frac{d}{dt}\big(\boldsymbol{\sigma} + p_1\,\mathbf{I}\big) + \big(n^1\,(\boldsymbol{\alpha}_2 - n^2\,\mathbf{I}) - n^2\,(\boldsymbol{\alpha}_1 - n^1\,\mathbf{I})\big) : \mathbb{E}^{-1} : \mathbf{I}\,\frac{d}{dt}(p_1 - p_2), \\ \frac{dn^2}{dt} &= (\boldsymbol{\alpha}_2 - n^2\,\mathbf{I}) : \mathbb{E}^{-1} : \frac{d}{dt}\big(\boldsymbol{\sigma} + p_2\,\mathbf{I}\big)\,. \end{aligned} \tag{10.6.33}$$

The single porosity limit (9.3.23) is retrieved along the schemes indicated in Section 10.6.8.1.

The rate of change of the volume fraction $n^{\rm s} = v^{\rm s}/\det \mathbf{F}$ of the solid constituent follows from (7.2.16),

$$\frac{dn^{\rm s}}{dt} = (-n^{\rm s}\,\mathbf{I} : \mathbb{E}^{-1} + \mathbf{I} : \mathbb{E}_{\rm s}^{-1}) : \frac{d\boldsymbol{\sigma}}{dt} + \big(\frac{n^1}{K_{\rm s}} - n^{\rm s}\,\mathbf{I} : \mathbb{E}^{-1} : \boldsymbol{\alpha}_1\big)\,\frac{dp_1}{dt} + \big(\frac{n^2}{K_{\rm s}} - n^{\rm s}\,\mathbf{I} : \mathbb{E}^{-1} : \boldsymbol{\alpha}_2\big)\,\frac{dp_2}{dt}\,, \tag{10.6.34}$$

or alternatively from the compatibility condition $n^{\rm s} + n^1 + n^2 = 1$.

10.6.2 Generalized diffusion

The internal entropy production due to diffusion through the whole porous medium is obtained by summation of the contributions (7.2.32) associated with individual species,

$$\hat{S}_{(\rm i,3)} = -\sum_{k=1,2,{\rm s}} \mathbf{Q}_k \cdot \frac{\boldsymbol{\nabla} T_k}{T_k^2} - \sum_{k=1,2} \mathbf{J}_k \cdot \frac{\boldsymbol{\nabla} P_k}{T_k} \geq 0, \quad \boldsymbol{\nabla} P_k \equiv \boldsymbol{\nabla} p_k + \rho_k\,(\frac{d^k \mathbf{v}_k}{dt} - \mathbf{b}_k)\,. \tag{10.6.35}$$

The pores occupy distinct positions in the matrix. Therefore, diffusion coupling between the two fluids is neglected. On the other hand, thermoosmosis may take place within each pore fluid, as described in Section 9.3.3. The fluid fluxes and heat fluxes $\mathcal{J} = -\mathcal{K}\,\mathcal{F}$ are related linearly to the gradients of pressure and temperature $\mathcal{F}$ through the matrix $\mathcal{K}$,

$$\begin{bmatrix} \mathbf{J}_1 \\ \mathbf{J}_2 \\ \mathbf{Q}_{\rm s} \\ \mathbf{Q}_1 \\ \mathbf{Q}_2 \end{bmatrix} = - \begin{bmatrix} T_1\,\mathbf{k}_{\rm H1} & 0 & 0 & T_1\,n^1\,\mathbf{k}_{\rm TO1} & 0 \\ 0 & T_2\,\mathbf{k}_{\rm H2} & 0 & 0 & T_2\,n^2\,\mathbf{k}_{\rm TO2} \\ 0 & 0 & (T_{\rm s})^2\,n^{\rm s}\,\mathbf{k}_{\rm Ts} & 0 & 0 \\ T_1\,n^1\,\mathbf{k}_{\rm MC1} & 0 & 0 & (T_1)^2\,n^1\,\mathbf{k}_{\rm T1} & 0 \\ 0 & T_2\,n^2\,\mathbf{k}_{\rm MC2} & 0 & 0 & (T_2)^2\,n^2\,\mathbf{k}_{\rm T2} \end{bmatrix} \begin{bmatrix} \boldsymbol{\nabla} P_1/T_1 \\ \boldsymbol{\nabla} P_2/T_2 \\ \boldsymbol{\nabla} T_{\rm s}/(T_{\rm s})^2 \\ \boldsymbol{\nabla} T_1/(T_1)^2 \\ \boldsymbol{\nabla} T_2/(T_2)^2 \end{bmatrix}. \tag{10.6.36}$$

As stressed in Section 4.9, there is a certain arbitrariness in defining the 'fluxes' and 'forces'. The diffusion properties are assumed to inherit the anisotropic properties of the solid skeleton. The $\mathbf{k}$'s are symmetric second order tensors, with units as indicated in Section 9.3.3. They satisfy the conditions (9.E.8),

$$\mathbf{k}_{\rm Ts}\ ({\rm PD}); \quad \mathbf{k}_{{\rm H}k}\ ({\rm PD}); \quad \text{and} \quad T_k\,n^k\,\mathbf{k}_{{\rm T}k} - \frac{n^k}{2}\,(\mathbf{k}_{{\rm TO}k} + \mathbf{k}_{{\rm MC}k}) \cdot \mathbf{k}_{{\rm H}k}^{-1} \cdot \frac{n^k}{2}\,(\mathbf{k}_{{\rm TO}k} + \mathbf{k}_{{\rm MC}k})\ ({\rm PD}), \quad k = 1,2\,, \tag{10.6.37}$$

so as to comply with the entropy inequality $\hat{S}_{(\rm i,3)} \geq 0$.

If the temperatures are spatially uniform, and the fluid pressures are equal, say $P_1 = P_2 = P$, the fluid flux $\mathbf{J}_1 + \mathbf{J}_2$ is equal to $-\mathbf{k}_{\rm H}\,\boldsymbol{\nabla} P$, with an equivalent hydraulic permeability $\mathbf{k}_{\rm H}$ equal to $\mathbf{k}_{\rm H1} + \mathbf{k}_{\rm H2}$,

$$(\mathbf{k}_{\rm H1},\, \mathbf{k}_{\rm H2}) \quad \overset{P_1 = P_2 = P}{\Longrightarrow} \quad \mathbf{k}_{\rm H} = \mathbf{k}_{\rm H1} + \mathbf{k}_{\rm H2}\,. \tag{10.6.38}$$

If the pressures are spatially uniform, and the temperatures are equal, say $T_{\rm s} = T_1 = T_2 = T$, the heat flux through the porous medium $\mathbf{Q}_{\rm s} + \mathbf{Q}_1 + \mathbf{Q}_2$ is equal to $-\mathbf{k}_{\rm T} \cdot \boldsymbol{\nabla} T$, with an equivalent thermal conductivity $\mathbf{k}_{\rm T}$ equal to the volume (surface) average over the species of the mixture, namely $\mathbf{k}_{\rm T} = n^{\rm s}\,\mathbf{k}_{\rm Ts} + n^1\,\mathbf{k}_{\rm T1} + n^2\,\mathbf{k}_{\rm T2}$,

$$(\mathbf{k}_{\rm Ts},\, \mathbf{k}_{\rm T1},\, \mathbf{k}_{\rm T2}) \quad \overset{T_{\rm s} = T_1 = T_2 = T}{\Longrightarrow} \quad \mathbf{k}_{\rm T} = n^{\rm s}\,\mathbf{k}_{\rm Ts} + n^1\,\mathbf{k}_{\rm T1} + n^2\,\mathbf{k}_{\rm T2}\,. \tag{10.6.39}$$

10.6.3 Mass and energy transfers

The particular status of mass and energy exchanges in the model of interest here is sketched in Fig. 10.6.1. Summing the individual contributions $(7.2.28)_2$ over species, and accounting for the definitions (7.2.29) and conditions (7.2.30), the entropy production associated with transfers reduces to,

$$\hat{S}_{(\rm i,2)} = \sum_{k=1,2,{\rm s}} -x_k^{({\rm M})}\,y_k^{({\rm M})} - x_k^{({\rm E})}\,y_k^{({\rm E})} \geq 0\,, \tag{10.6.40}$$

where some temporary notation has been introduced, namely for mass transfer,

$$x_k^{({\rm M})} \equiv \hat{\rho}^k; \quad y_k^{({\rm M})} \equiv \big(\mu_k + \tfrac{1}{2}\,(\mathbf{v}_k - \mathbf{v}_{\rm s})^2\big)\frac{1}{T_k}\,, \tag{10.6.41}$$

and for energy transfer,

$$x_k^{({\rm E})} \equiv \hat{U}^k - \hat{\mathbf{p}}^k \cdot \mathbf{v}_{\rm s} + \tfrac{1}{2}\,\hat{\rho}^k\,\mathbf{v}_{\rm s}^2; \quad y_k^{({\rm E})} \equiv -\frac{1}{T_k}\,. \tag{10.6.42}$$

10.6.4 Linear constitutive equations of mass transfer

No mass exchange between the solid and the fluids is considered to take place. Consequently, the rates of mass exchanges between the two fluids sum up to zero, since the system is closed. The resulting entropy production can be cast in the form,

$$-\sum_{k=1,2,\mathrm{s}} x_k^{(\mathrm{M})}\, y_k^{(\mathrm{M})} = -x_1^{(\mathrm{M})}\,(y_1^{(\mathrm{M})} - y_2^{(\mathrm{M})})\,. \tag{10.6.43}$$

The linear rate of mass transfer,

$$\begin{bmatrix} x_1^{(\mathrm{M})} \\ x_2^{(\mathrm{M})} \end{bmatrix} = -\kappa \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} y_1^{(\mathrm{M})} \\ y_2^{(\mathrm{M})} \end{bmatrix}, \quad \kappa \geq 0\,, \tag{10.6.44}$$

yields a positive contribution to the entropy production,

$$-\sum_{k=1,2,\mathrm{s}} x_k^{(\mathrm{M})}\, y_k^{(\mathrm{M})} = \kappa\,(y_1^{(\mathrm{M})} - y_2^{(\mathrm{M})})^2 \geq 0\,, \tag{10.6.45}$$

provided the coefficient of mass transfer κ [unit : kg × m^{-5} × s × K] is positive.

To get an insight into the sense the mass will transfer (from the tissue pores to vessels or conversely), it is useful to analyze the limit case of an incompressible and not dilatable fluid. Then the chemical potential of the generic fluid reduces to, Eqn (3.3.34),

$$\mu = \mu_0 + v_0\,(p - p_0) + (c - s_0)\,(T - T_0) - c\,T\,\mathrm{Ln}\,\frac{T}{T_0}\,, \tag{10.6.46}$$

where v [unit : m^3/kg] is the specific volume and c [unit : kJ/kg/K] the heat capacity. While the reference value of the chemical potential μ_0 [unit : J/kg] does not affect its variations in a (p, T) plane, the reference value of entropy s_0 [unit : J/kg/K] does.

Now, the rate of mass transfer is governed by (10.6.44) which, neglecting the kinetic energy terms, simplifies to [10.2],

$$\hat{\rho}^1 = -\kappa\left(\frac{\mu_1}{T_1} - \frac{\mu_2}{T_2}\right) = -\hat{\rho}^2\,, \quad \kappa \geq 0\,. \tag{10.6.48}$$

The chemical potentials increase linearly with pressure. For isothermal analyses, or when the two fluids are in thermal equilibrium, *mass will thus transfer from the high pressure cavities to the low pressure cavities.*

The situation is more complex for thermal non equilibrium. However, the partial derivatives,

$$\frac{\partial \mu}{\partial T} = -s_0 - c\,\mathrm{Ln}\,\frac{T}{T_0}, \quad \frac{\partial}{\partial T}\left(\frac{\mu}{T}\right) = -\frac{1}{T^2}\left(\mu_0 + s_0\,T_0 + v_0\,(p - p_0) + c\,(T - T_0)\right). \tag{10.6.49}$$

are both expected to be negative for pressure and temperature higher than the reference values. So is indeed the case as observed in Fig. 10.6.4 at least in the ranges of pressure and temperature displayed on the figure and for the chosen reference value of entropy. Therefore, if the pressures in the two cavities are identical, *the mass will transfer from the cold cavities to the hot cavities.* Conversely, if both pressure and temperature are smaller than the reference values, the direction of mass transfer is opposite[10.3].

[10.2] Phrased in terms of the Massieu chemical potential $\psi = -\mu/T$, the constitutive equation of mass transfer,

$$\hat{\rho}^1 = -\kappa\,(\psi_2 - \psi_1) = -\hat{\rho}^2\,, \quad \kappa \geq 0\,, \tag{10.6.47}$$

indicates that mass transfer takes place at increasing Massieu chemical potential.

[10.3] This outcome may be compared with the flows that are induced by thermoosmosis, a phenomenon of coupled transport through a membrane. At identical pressures, fluid flow may be directed either to the hot side or to the cold side, depending on the properties of the fluid and of the membrane, Sections 9.3.3 and 9.5.9.

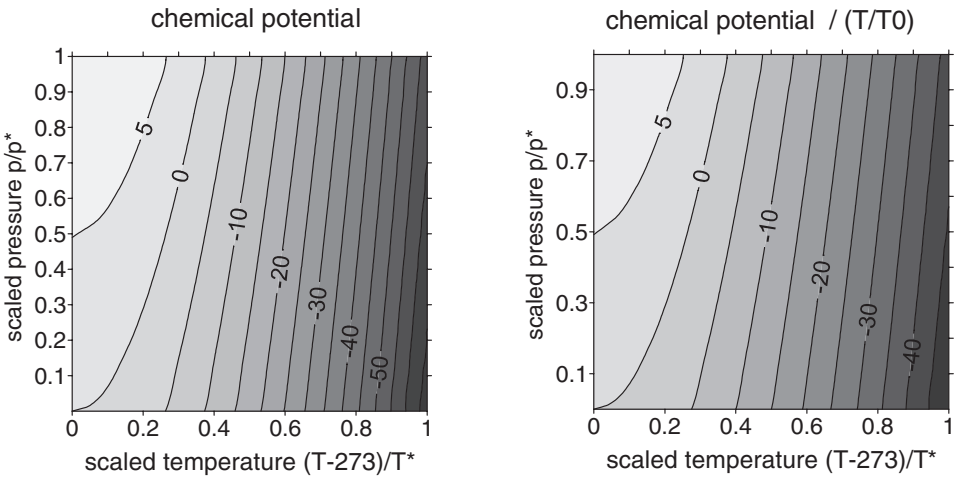

Fig. 10.6.4: Contours of the chemical potential μ and of the chemical potential $\mu/(T/T_0)$ of water [unit : MJ/kg] for a heat capacity $c = 4.18\,\mathrm{kJ/kg/K}$, and the reference values of entropy $s_0 = 0\,\mathrm{J/kg/K}$, and chemical potential $\mu_0 = p_0\, v_0\,\mathrm{J/kg}$ at triple point of water, namely pressure $p_0 = 611\,\mathrm{Pa}$, temperature $T_0 = 273.16\,\mathrm{K}$, specific volume $v_0 \sim 10^{-3}\,\mathrm{m^3/kg}$. The scaling temperature and pressure are respectively $T*$=100 K, and $p*$=10 MPa.

10.6.5 Linear constitutive equations of energy transfer

The rates of energy transfer sum to zero,

$$\sum_{k=1,2,\mathrm{s}} x_k^{(\mathrm{E})} = 0\,, \tag{10.6.50}$$

so that the associated dissipation rate may be brought to the form,

$$-\,x_1^{(\mathrm{E})}\,(y_1^{(\mathrm{E})} - y_\mathrm{s}^{(\mathrm{E})}) - x_2^{(\mathrm{E})}\,(y_2^{(\mathrm{E})} - y_\mathrm{s}^{(\mathrm{E})})\,. \tag{10.6.51}$$

The linear rate of energy transfer,

$$\begin{bmatrix} x_\mathrm{s}^{(\mathrm{E})} \\ x_1^{(\mathrm{E})} \\ x_2^{(\mathrm{E})} \end{bmatrix} = -\begin{bmatrix} \kappa_{\mathrm{s}1} + \kappa_{\mathrm{s}2} & -\kappa_{\mathrm{s}1} & -\kappa_{\mathrm{s}2} \\ -\kappa_{\mathrm{s}1} & \kappa_{\mathrm{s}1} + \kappa_{12} & -\kappa_{12} \\ -\kappa_{\mathrm{s}2} & -\kappa_{12} & \kappa_{\mathrm{s}2} + \kappa_{12} \end{bmatrix} \begin{bmatrix} y_\mathrm{s}^{(\mathrm{E})} \\ y_1^{(\mathrm{E})} \\ y_2^{(\mathrm{E})} \end{bmatrix}, \tag{10.6.52}$$

with positive coefficients of energy transfer [unit : $\mathrm{W \times m^{-3} \times K = kg \times m^{-1} \times s^{-3} \times K}$],

$$\kappa_{\mathrm{s}1} \geq 0, \quad \kappa_{\mathrm{s}2} \geq 0, \quad \kappa_{12} \geq 0\,, \tag{10.6.53}$$

yields a positive contribution to the entropy production,

$$\sum_{k=1,2,\mathrm{s}} -x_k^{(\mathrm{E})}\, y_k^{(\mathrm{E})} = \kappa_{\mathrm{s}1}\,(y_1^{(\mathrm{E})} - y_\mathrm{s}^{(\mathrm{E})})^2 + \kappa_{\mathrm{s}2}\,(y_2^{(\mathrm{E})} - y_\mathrm{s}^{(\mathrm{E})})^2 + \kappa_{12}\,(y_1^{(\mathrm{E})} - y_2^{(\mathrm{E})})^2 \geq 0\,. \tag{10.6.54}$$

In essence, the rate equation indicates, as expected, that *energy transfers from the hot species to the cold species.*

10.6.6 The energy equations

The balance of energy (4.6.11) of any species $k = \mathrm{s}, 1, 2$, phrased in terms of specific internal energies is first transformed and phrased in terms of the internal energies per unit volume,

$$\begin{aligned} &\rho^k\,\frac{d^k u_k}{dt} + \hat{\rho}^k\,u_k - \boldsymbol{\sigma}^k : \boldsymbol{\nabla}\mathbf{v}_k - \hat{\rho}^k\left(\tilde{u}_k + \tfrac{1}{2}\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\right) - \hat{\mathcal{U}}^k + \mathrm{div}\ \mathbf{Q}_k - \Theta_k = 0\,, \\ &\frac{dU^k}{dt} + \mathrm{div}\,(u_k\,\mathbf{M}_k) + U^k\,\mathrm{div}\,\mathbf{v}_\mathrm{s} - \boldsymbol{\sigma}^k : \boldsymbol{\nabla}\mathbf{v}_k - \hat{\rho}^k\left(\tilde{u}_k + \tfrac{1}{2}\,(\tilde{\mathbf{v}}_k - \mathbf{v}_k)^2\right) - \hat{\mathcal{U}}^k + \mathrm{div}\ \mathbf{Q}_k - \Theta_k = 0\,. \end{aligned} \tag{10.6.55}$$

Given the thermo-poroelastic energy $\underline{\mathcal{W}}$, the internal energy of the solid results from (10.6.5),

$$\underline{U}^{\mathrm{s}} = \underline{\mathcal{W}} + T_{\mathrm{s}}\,\underline{S}^{\mathrm{s}} + \sum_{k=1,2} v^k\,p_k\,, \tag{10.6.56}$$

and, with help of (10.6.8), its rate form simplifies to,

$$\begin{aligned} \frac{d\underline{U}^{\mathrm{s}}}{dt} &= \boldsymbol{\tau} : \frac{d\boldsymbol{\epsilon}}{dt} + \sum_{k=1,2} p_k\,\frac{dv^k}{dt} + T_{\mathrm{s}}\,\frac{d\underline{S}^{\mathrm{s}}}{dt} \\ \frac{dU^{\mathrm{s}}}{dt} &= (\boldsymbol{\sigma}^{\mathrm{s}} - E^{\mathrm{s}}\,\mathbf{I}) : \frac{d\boldsymbol{\epsilon}}{dt} + \sum_{k=1,2} p_k\,\frac{dn^k}{dt} + T_{\mathrm{s}}\,\frac{dS^{\mathrm{s}}}{dt}\,. \end{aligned} \tag{10.6.57}$$

Therefore, the balance of energy of the solid is obtained by inserting (10.6.57) into (10.6.55), namely,

$$\frac{dS^{\mathrm{s}}}{dt} + S^{\mathrm{s}}\,\mathrm{div}\,\mathbf{v}_{\mathrm{s}} + \frac{1}{T_{\mathrm{s}}}\sum_{k=1,2} p_k\,\frac{dn^k}{dt} + \frac{1}{T_{\mathrm{s}}}\,\mathrm{div}\;\mathbf{Q}_{\mathrm{s}} - \frac{\Theta_{\mathrm{s}}}{T_{\mathrm{s}}} + \underbrace{x_{\mathrm{s}}^{(\mathrm{E})}\,y_{\mathrm{s}}^{(\mathrm{E})}}_{\text{energy transfer}} = 0\,. \tag{10.6.58}$$

As for the fluids, insertion of (7.2.13) into (10.6.55) with help of the balance momentum (4.5.5) yields an expression that displays the total heat flux,

$$\begin{aligned} \frac{dS^k}{dt} + S^k\,\mathrm{div}\,\mathbf{v}_{\mathrm{s}} + \frac{\mu_k}{T_k}\,\frac{1}{\det\mathbf{F}}\,\frac{dm^k}{dt} - \frac{p_k}{T_k}\,\frac{dn^k}{dt} + \frac{1}{T_k}\,\mathrm{div}\,\Big(\overbrace{\mathbf{Q}_k + h_k\,\mathbf{M}_k}^{\substack{\text{conductive + convective}\\ \text{heat fluxes}}}\Big) - \frac{\Theta_k}{T_k} \\ + \frac{1}{2}\,(\mathbf{v}_k - \mathbf{v}_{\mathrm{s}})^2\,\frac{\hat{\rho}^k}{T_k} + \underbrace{x_k^{(\mathrm{E})}\,y_k^{(\mathrm{E})}}_{\text{energy transfer}} + \frac{\mathbf{M}_k}{T_k}\cdot\Big(\frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big) = 0\,. \end{aligned} \tag{10.6.59}$$

Using the balance of mass (4.4.9) and the differential expression (7.2.31), the alternative expression, more akin to the expression (10.6.58) for the solid, highlights mass and energy transfers,

$$\begin{aligned} \frac{dS^k}{dt} + S^k\,\mathrm{div}\,\mathbf{v}_{\mathrm{s}} + s_k\,\mathrm{div}\,\mathbf{M}_k - \frac{p_k}{T_k}\,\frac{dn^k}{dt} + \frac{1}{T_k}\,\mathrm{div}\;\mathbf{Q}_k - \frac{\Theta_k}{T_k} \\ + \underbrace{x_k^{(\mathrm{M})}\,y_k^{(\mathrm{M})}}_{\text{mass transfer}} + \underbrace{x_k^{(\mathrm{E})}\,y_k^{(\mathrm{E})}}_{\text{energy transfer}} + \frac{\mathbf{M}_k}{T_k}\cdot(\nabla h_k + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k) = 0\,. \end{aligned} \tag{10.6.60}$$

The expression below in terms of intrinsic entropy per unit mass,

$$\begin{aligned} \rho^k\,\frac{ds_k}{dt} - \frac{p_k}{T_k}\,\frac{dn^k}{dt} + \frac{1}{T_k}\,\mathrm{div}\;\mathbf{Q}_k - \frac{\Theta_k}{T_k} \\ + \underbrace{\Big(h_k + \frac{1}{2}\,(\mathbf{v}_k - \mathbf{v}_{\mathrm{s}})^2\Big)\,\frac{\hat{\rho}^k}{T_k}}_{\text{mass transfer}} + \underbrace{x_k^{(\mathrm{E})}\,y_k^{(\mathrm{E})}}_{\text{energy transfer}} + \frac{\mathbf{M}_k}{T_k}\cdot(\nabla h_k + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k) = 0\,, \end{aligned} \tag{10.6.61}$$

is more appropriate to phase change as it highlights the role of the enthalpy. Summing the contributions of the two phases, e.g., liquid water l and vapor v, displays the latent heat of evaporation $h_v - h_l$.

The next equivalent expression highlights mass transfer, energy transfer and seepage in the very format in which the constitutive equations of these phenomena are formulated,

$$\begin{aligned} \frac{dS^k}{dt} + S^k\,\mathrm{div}\,\mathbf{v}_{\mathrm{s}} + \mathrm{div}\,(s_k\,\mathbf{M}_k) - \frac{p_k}{T_k}\,\frac{dn^k}{dt} + \frac{1}{T_k}\,\mathrm{div}\;\mathbf{Q}_k - \frac{\Theta_k}{T_k} \\ + \underbrace{x_k^{(\mathrm{M})}\,y_k^{(\mathrm{M})}}_{\text{mass transfer}} + \underbrace{x_k^{(\mathrm{E})}\,y_k^{(\mathrm{E})}}_{\text{energy transfer}} + \underbrace{\frac{\mathbf{M}_k}{T_k}\cdot\Big(\frac{\nabla p_k}{\rho_k} + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big)}_{\text{seepage}} = 0\,. \end{aligned} \tag{10.6.62}$$

The energy equations may also be expressed in a format that involves the entropy productions associated with generalized diffusion and transfers, e.g., for the fluid k,

$$\frac{dS^k}{dt} + S^k \,\mathrm{div}\,\mathbf{v}_\mathrm{s} - \frac{p_k}{T_k}\frac{dn^k}{dt} + \mathrm{div}\,\Big(\frac{\mathbf{Q}_k}{T_k} + s_k\,\mathbf{M}_k\Big) - \frac{\Theta_k}{T_k} - \big(\hat{S}^k_{(\mathrm{i},2)} + \hat{S}^k_{(\mathrm{i},3)} + \hat{S}^k\big) = 0\,. \tag{10.6.63}$$

If the species are in local thermal equilibrium, summing up the energy equations over species, accounting for the closure relations (7.2.30), the energy equation for the mixture boils down to,

$$\begin{aligned}\frac{dS}{dt} + S\,\mathrm{div}\,\mathbf{v}_\mathrm{s} + \frac{1}{\det\mathbf{F}}\sum_{k=1,2}\frac{\mu_k}{T}\frac{dm^k}{dt} + \frac{1}{T}\sum_{k=\mathrm{s},1,2}\mathrm{div}\,(\mathbf{Q}_k + h_k\,\mathbf{M}_k) - \frac{\Theta_k}{T}\\ + \sum_{k=\mathrm{s},1,2}\frac{1}{2}\,(\mathbf{v}_k - \mathbf{v}_\mathrm{s})^2\,\frac{\hat{\rho}^k}{T} \;+\; \frac{\mathbf{M}_k}{T}\cdot\Big(\frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big) \;=\; 0\,,\end{aligned} \tag{10.6.64}$$

which further simplifies to (9.3.33) under the conditions stated in Section 9.3.4. An equivalent form deduced from (10.6.62) writes,

$$\begin{aligned}\frac{dS}{dt} + S\,\mathrm{div}\,\mathbf{v}_\mathrm{s} + \sum_{k=1,2}\mathrm{div}\,(s_k\,\mathbf{M}_k) + \frac{1}{T}\sum_{k=\mathrm{s},1,2}\mathrm{div}\,\mathbf{Q}_k - \frac{\Theta_k}{T}\\ + \sum_{k=1,2}x_k^{(\mathrm{M})}\,y_k^{(\mathrm{M})} \;+\; \sum_{k=1,2}\frac{\mathbf{M}_k}{T}\cdot\Big(\frac{\nabla p_k}{\rho_k} + \frac{d^k\mathbf{v}_k}{dt} - \mathbf{b}_k\Big) = 0\,.\end{aligned} \tag{10.6.65}$$

For the record, let us note that the dimension of the energy equations above are actually that of the dissipation rate, namely $\mathrm{W/m^3/K}$.

10.6.7 The complete set of field equations

The six field equations associated with the six primary unknowns, namely ($\boldsymbol{\epsilon}$, p_1, p_2, T_s, T_1, T_2), include

- the balance of momentum of the mixture as a whole, Eqn (4.5.6),

$$\mathrm{div}\,\boldsymbol{\sigma} + \sum_{k=\mathrm{s},1,2}\rho^k\,\Big(\mathbf{b}_k - \frac{d\mathbf{v}_k}{dt} - \boldsymbol{\nabla}\mathbf{v}_k\cdot(\mathbf{v}_k - \mathbf{v}_\mathrm{s})\Big) + \hat{\rho}^k\,\mathbf{v}_k = \mathbf{0}\,; \tag{10.6.66}$$

- the two balances of mass of the fluids, Eqn (4.4.9),

$$\frac{1}{\det\mathbf{F}}\frac{dm^k}{dt} = -\mathrm{div}\;\mathbf{M}_k + \hat{\rho}^k, \quad k = 1,2\,; \tag{10.6.67}$$

- the three energy equations, namely Eqn (10.6.58) for the solid and Eqns (10.6.59) for the two fluids.

The dependent entities are expressed in terms of the six primary variables $(\boldsymbol{\epsilon}, p_1, p_2, T_\mathrm{s}, T_1, T_2)$ through

- the thermomechanical constitutive equations (10.6.24) for the dependent variables $(\boldsymbol{\sigma}, \zeta^1, \zeta^2, S^\mathrm{s}, S^1, S^2)$;
- the constitutive generalized diffusion equations (10.6.36) for the fluid fluxes $\mathbf{J}_1$, $\mathbf{J}_2$ and heat fluxes $\mathbf{Q}_\mathrm{s}$, $\mathbf{Q}_1$, $\mathbf{Q}_2$;
- the constitutive equations of mass transfer and energy transfer, (10.6.44) and (10.6.52), respectively;
- the relations (10.6.32) that provide the rates of volume fraction dn^k/dt of the fluids;
- the nonlinear definitions (3.3.28), or linearized approximations (3.3.30), of the specific thermodynamic functions s_k, u_k, h_k, and nonlinear definitions of the specific free energy e_k and chemical potential μ_k of the fluid k. Recall that, by construction, the entropies of the fluids (7.2.11) given by the constitutive equations (10.6.24) are equivalent to the linearized relations (3.3.30). The accuracy of the linearized approximations of the specific thermodynamic functions is commented at the end of Section 3.3.3. The fluids of the cavities have been assumed to be identical. If the fluids are not miscible, they are separated by a meniscus, whose temperature and thermal properties have to be defined. Accordingly, the thermodynamic functions of the fluids are altered.

10.6.8 Increasing and decreasing the degree of sophistication

The two pressure, three temperature model embodies simpler models analyzed in this chapter, namely by decreasing order of complexity,

- the porous medium with a single type of cavity but still in local thermal non equilibrium is retrieved in Section 10.7;
- the latter is specialized to the porous medium with a single porosity and in local thermal equilibrium (LTE) exposed in Section 9.3;
- the thermo-poroelastic model reduces to the purely poroelastic model of Section 7.3 for isothermal processes.

10.6.8.1 From double to single porosity

The single porosity, single temperature model developed in Section 9.3 can be recovered in two ways:

- by letting the volume fraction n^2 of the porosity 2 tend to zero. Then the pore drained stiffness $\mathbb{E}^{\text{PD}}$ tends to the drained stiffness $\mathbb{E}$, the matrix form (10.6.21) can be checked to collapse to the form (9.3.9), and the mass balance of the fluid of porosity 2 becomes elusive;
- alternatively, the contributions of the two cavities may be summed, under the assumption that their pressures are identical. The summation procedure applies to the lines and columns of the constitutive matrices and to the two balances of fluid mass.

Conversely, the two cavities may be isolated from one another by zeroing their mass exchange, which amounts to set the coefficient κ to 0 in the constitutive equation of mass transfer exposed in Section 10.6.4. Then, setting to zero the hydraulic conductivity of one of the cavities retrieves an occluded porosity.

10.6.8.2 From local thermal non equilibrium to local thermal equilibrium

A model of local thermal equilibrium is retrieved from the model of local thermal non equilibrium in two ways:

- by a penalty method, where the coefficients of energy transfer in the constitutive equation exposed in Section 10.6.5 are set to a large value, the complete structure of the local thermal non equilibrium model being preserved;
- by setting the temperatures to a common value, summing the corresponding lines and columns in the constitutive matrices as well as the energy equations.

10.7 A porous medium with a single porosity and two temperatures

It is worth recording the linearized thermomechanical relations in the simpler case of a porous medium with a single porosity but where the solid and fluid constituents are endowed with their own temperatures. Starting from (10.6.21) where $T_1 = T_2 = T_{\text{w}}$, the thermomechanical relations may be cast in the format,

$$\begin{bmatrix} \boldsymbol{\sigma}^{\text{s}} \\ -p^{\text{w}} \\ -\Delta S^{\text{s}} \\ -\Delta S^{\text{w}} \end{bmatrix} = \begin{bmatrix} \mathbb{E}^{\text{s}} & \boldsymbol{\lambda}_{\text{w}} & -\mathbb{E}^{\text{s}} : \mathbf{c}_{\text{T}} & -\boldsymbol{\lambda}_{\text{w}}\, c_{\text{Tw}} \\ \boldsymbol{\lambda}_{\text{w}} & M\,(n^{\text{w}})^2 & -\boldsymbol{\lambda}_{\text{w}} : \mathbf{c}_{\text{T}} & -M\,(n^{\text{w}})^2\, c_{\text{Tw}} \\ -\mathbf{c}_{\text{T}} : \mathbb{E}^{\text{s}} & -\boldsymbol{\lambda}_{\text{w}} : \mathbf{c}_{\text{T}} & -C^{\text{s}}_m/T^0_{\text{s}} & (\boldsymbol{\lambda}_{\text{w}} : \mathbf{c}_{\text{T}})\, c_{\text{Tw}} \\ -c_{\text{Tw}}\, \boldsymbol{\lambda}_{\text{w}} & -M\,(n^{\text{w}})^2\, c_{\text{Tw}} & (\boldsymbol{\lambda}_{\text{w}} : \mathbf{c}_{\text{T}})\, c_{\text{Tw}} & -C^{\text{w}}_v/T^0_{\text{w}} \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ \operatorname{tr} \boldsymbol{\epsilon}^{\text{w}} \\ \Delta T_{\text{s}} \\ \Delta T_{\text{w}} \end{bmatrix}, \tag{10.7.1}$$

where use as been made of (7.2.3), (7.2.9), $\boldsymbol{\alpha}_{\text{w}}$ is defined by (7.4.14), M by (7.4.17) and (7.4.19), and [10.4]

$$\begin{aligned} &\frac{1}{M} = \frac{1}{S}\mathbf{I} : \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\text{w}} - \boldsymbol{\alpha}_{\text{w}} : \mathbb{E}^{-1} : \boldsymbol{\alpha}_{\text{w}}, \quad \boldsymbol{\lambda}_{\text{w}} = -M\,(n^{\text{w}})^2 \left(\mathbf{I} - \frac{\boldsymbol{\alpha}_{\text{w}}}{n^{\text{w}}}\right); \\ &\mathbb{E}^{\text{s}} = \mathbb{E} + M\,(n^{\text{w}})^2 \left(\mathbf{I} - \frac{\boldsymbol{\alpha}_{\text{w}}}{n^{\text{w}}}\right) \otimes \left(\mathbf{I} - \frac{\boldsymbol{\alpha}_{\text{w}}}{n^{\text{w}}}\right), \end{aligned} \tag{10.7.2}$$

and

$$\begin{aligned} &C^{\text{s}}_m = C^{\text{s}}_{\epsilon p} + \mathbf{c}_{\text{T}} : (\mathbb{E} - \mathbb{E}^{\text{s}}) : \mathbf{c}_{\text{T}}\, T^0_{\text{s}} = C^{\text{s}}_{\sigma p} - \mathbf{c}_{\text{T}} : \mathbb{E}^{\text{s}} : \mathbf{c}_{\text{T}}\, T^0_{\text{s}}, \\ &C^{\text{w}}_v = C^{\text{w}}_p - M\,(n^{\text{w}})^2\,(c_{\text{Tw}})^2\, T^0_{\text{w}}\,. \end{aligned} \tag{10.7.3}$$

[10.4] $\boldsymbol{\lambda}_{\text{w}}$ was denoted by $\lambda^{\text{sw}}\,\boldsymbol{\lambda}_{\text{w}}$ in Section 7.3.6.

For an isotropic solid skeleton,

$$\frac{1}{M} = \frac{1-n^{\rm w}}{K_{\rm s}} + \frac{n^{\rm w}}{K_{\rm w}} - \frac{K}{K_{\rm s}^2}, \quad \boldsymbol{\lambda}_{\rm w} = -M\, n^{\rm w} \Big(-n^{\rm s} + \frac{K}{K_{\rm s}} \Big) \mathbf{I}\,. \tag{10.7.4}$$

The thermomechanical equations (10.6.24) reduce to

$$\begin{bmatrix} -\boldsymbol{\sigma} \\ \zeta^{\rm w} \\ \Delta S^{\rm s} \\ \Delta S^{\rm w} \end{bmatrix} = \begin{bmatrix} -\mathbb{E} & \boldsymbol{\alpha}_{\rm w} & \mathbb{E} : \mathbf{c}_{\rm T} & 0 \\ \boldsymbol{\alpha}_{\rm w} & 1/M & a_{\rm wT} & -n^{\rm w}\, c_{\rm Tw} \\ \mathbf{c}_{\rm T} : \mathbb{E} & a_{\rm wT} & C^{\rm s}_{\epsilon p}/T^0_{\rm s} & 0 \\ 0 & -n^{\rm w}\, c_{\rm Tw} & 0 & C^{\rm w}_{p}/T^0_{\rm w} \end{bmatrix} \begin{bmatrix} \boldsymbol{\epsilon} \\ p_{\rm w} \\ \Delta T_{\rm s} \\ \Delta T_{\rm w} \end{bmatrix}, \tag{10.7.5}$$

where $a_{\rm wT} = (n^{\rm w}\,\mathbf{I} - \boldsymbol{\alpha}_{\rm w}) : \mathbf{c}_{\rm T}$ in agreement with (10.6.13).

These constitutive relations further boil down to (9.3.14) when the solid and fluid are in local thermal equilibrium.

10.8 Interfacial transfer coefficients and specific surface areas

In a porous medium with two porosities, heat exchange takes place across the interface between the solid and the fluids, and across the menisci that separates the two fluids. Therefore the coefficients of heat exchange $\kappa_{\alpha\beta}$ between species α and β introduced in (10.6.52) are assumed to take the multiplicative form

$$\frac{\kappa_{\alpha\beta}}{T_0^2} = h_{\alpha\beta}\, a_{\alpha\beta}\,, \tag{10.8.1}$$

where T_0 is a reference temperature and

- $h_{\alpha\beta}$ [unit : W/m^2/K] is the interfacial heat transfer coefficient, a property of the interface, i.e. of the two species;
- $a_{\alpha\beta}$ [unit : m^2/m^3] is the specific surface area, i.e. the area $A_{\alpha\beta}$ of the interface between the two species in the volume V of porous medium.

A boundary condition of the convective type, say between a solid and air, involves the interfacial heat transfer coefficient $h_{\rm sa}$, Section 10.4.

10.8.1 Interfacial heat transfer coefficients

Experimental determination of the solid-fluid interfacial heat transfer coefficient $h_{\rm sw}$

Consider a porous medium with a single porosity, and assume that the thermal gradients can be neglected. If only heat conduction and heat transfer are accounted for, the energy equation of the solid constituent boils down to,

$$\frac{C^{\rm s}}{T_{\rm s}}\frac{dT_{\rm s}}{dt} + \frac{\kappa_{\rm sw}}{T_{\rm s}}\Big(\frac{1}{T_{\rm w}} - \frac{1}{T_{\rm s}}\Big) = 0\,, \tag{10.8.2}$$

and therefore, for $T_{\rm s} \sim T_{\rm w} \sim T_0$,

$$\frac{\kappa_{\rm sw}}{T_0^2} = -C^{\rm s}\,\frac{dT_{\rm s}/dt}{T_{\rm s} - T_{\rm w}}\,. \tag{10.8.3}$$

A basic experimental setup to measure the solid-fluid heat transfer coefficient consists in circulating a fluid through a relatively thin porous wall, so that the inlet and outlet temperatures are quite close. The heat transfer coefficient is then defined by (10.8.3) where the temperatures are approximated by their averages over the wall boundaries.

In the context of porous media with double porosity, the above experiment would correspond to the tissue-vessel (porosity 2) heat transfer coefficient $\kappa_{\rm s2}$. The interfacial tissue-water heat transfer coefficient $h_{\rm sw} = \kappa_{\rm s2}/T_0^2/a_{\rm s2}$ may be deduced, assuming the specific surface area of the vessel network $a_{\rm s2}$ to be known. The tissue-pore heat transfer coefficient $\kappa_{\rm s1} = T_0^2\, h_{\rm sw}\, a_{\rm s1}$ deduces in turn, assuming the specific surface area $a_{\rm s1}$ of the pore network (porosity 1) to be known as well. Alternatively, if at all possible, one may repeat the experiment by isolating a piece of the matrix with a single type of porosity.

Theoretical determination of the solid-fluid interfacial heat transfer coefficient $h_{\rm sw}$

The interfacial solid-fluid heat transfer coefficient has been calculated for certain geometries, in particular for a cylindrical capillary, in terms of the thermal conductivities of the solid and fluid and of geometrical characteristics, Kaviany [1995], p. 398, or for in-line periodic arrays of three-dimensional cubes, Hsu [1999]. Typically, if L is a characteristic length of the porous network, the heat transfer coefficient may be estimated to be of the order of the thermal conductivity of the fluid divided by this length,

$$h_{\rm sw} \sim \frac{k_{\rm Tw}}{L}\,. \tag{10.8.4}$$

The medium we consider is a fluid-infiltrated solid. For the somehow dual configuration, namely for spherical particles bathed in a Newtonian fluid, a general expression of $h_{\rm sw}$ is obtained via the Nusselt number, which has been related to the Reynolds and Prandtl numbers, Kaviany [1995], p. 403, namely

$$\mathrm{N_u} = 2 + 1.1\,\mathrm{R_e^{0.6}}\,\mathrm{P_r^{0.33}}\,. \tag{10.8.5}$$

The Nusselt $\mathrm{N_u}$ number is a measure of the relative weight of convective and conductive heats, the Reynolds number $\mathrm{R_e}$ a measure of the relative weight of the inertial and viscous contributions to the momentum balance, and the Prandtl number $\mathrm{P_r}$ quantifies the ratio of momentum diffusivity (kinematic viscosity) over thermal diffusivity,

$$\mathrm{R_e} = \frac{v_{\rm w}\,L}{\nu_{\rm w}},\quad \mathrm{P_r} = \frac{C^{\rm w}\nu_{\rm w}}{k_{\rm Tw}} = \frac{\nu_{\rm w}}{D_{\rm Tw}},\quad \mathrm{N_u} = \frac{h_{\rm sw}\,L}{k_{\rm Tw}}\,, \tag{10.8.6}$$

with

- L [unit : m] typical dimension of the problem, e.g., that of the pores;
- $v_{\rm w}$ [unit : m/s] fluid velocity (Darcy's velocity in a porous medium);
- $\nu_{\rm w}$ [unit : $\mathrm{m^2/s}$] kinematic viscosity defined by (7.3.14);
- $k_{\rm Tw}$ [unit : W/m/K] thermal conductivity of the fluid;
- $C^{\rm w}$ [unit : $\mathrm{J/m^3/K}$] thermal capacity of the fluid;
- $D_{\rm Tw} = k_{\rm Tw}/C^{\rm w}$ [unit : $\mathrm{m^2/s}$] thermal diffusivity of the fluid;
- $h_{\rm sw}$ [unit : $\mathrm{W/m^2/K{=}kg/s^3/K}$] interfacial solid-fluid heat transfer coefficient.

In hydrodynamics, the transition from laminar to turbulent flows is considered to take place typically at a Reynolds number of 2000. For fluid-saturated porous media, using a microstructure based definition, Kaviany [1995], p. 48, suggests to reduce this transition value to 300. Actually, a definition of a Reynolds number for porous media is suggested in Section 15.7.9.2. The Prandtl number is low for mercury, about 7.07 for water at 20 °C, and much higher for engine oil, Bejan [1993]. The Péclet number defined by (15.5.3) is a relative measure of the convective and diffusive characters of the equation that controls the diffusion of temperature or of particles in a fluid. It is in fact the product of the Reynolds and Prandtl numbers,

$$\mathrm{P_e} = \mathrm{R_e} \times \mathrm{P_r}\,. \tag{10.8.7}$$

Perhaps, it is worth to delineate the Nusselt and Biot numbers. These two numbers are formally identical but they have quite distinct meanings. For a solid in contact with a fluid β,

$$\mathrm{N_u} = \frac{h_{\mathrm{s}\beta}\,L}{k_{\mathrm{T}\beta}},\quad \mathrm{Bi} = \frac{h_{\mathrm{s}\beta}\,L}{k_{\rm Ts}}\,. \tag{10.8.8}$$

The Nusselt number involves the thermal conductivity of the fluid. The Biot number, which involves the thermal conductivity of the solid, gives an indication of the relative influence of the thermal resistance at the surface and inside a body. See Section 10.4.4 for more details.

As Reynolds number tends to 0, Nusselt number tends to 2 according to (10.8.5), and therefore the interfacial heat transfer coefficient tends to $2\,k_{\rm Tw}/L$.

Fluid-fluid heat transfer coefficient κ_{12}

Heat transfer through the meniscus separating two immiscible fluids may be modeled via heat conduction. Indeed, if the two fluids have not too dissimilar properties, the heat conduction of the meniscus $k_{\rm T}$ may be approximated as $\frac{1}{2}\,(k_{\rm T1} + k_{\rm T2})$. Then the transfer of power through the meniscus of width L is, via Fourier's law, equal to,

$$-\,k_{\rm T}\,\frac{T_2 - T_1}{L} \times \frac{1}{L}\,. \tag{10.8.9}$$

This transfer may also be expressed via the constitutive relations for heat transfer (10.6.42) and (10.6.52). Indeed, the power transferred to fluid 2 from fluid 1 expresses as,

$$\hat{U}^2 = -\hat{U}^1 = -\kappa_{12}\,(\frac{1}{T_1} - \frac{1}{T_2}) \simeq -\frac{\kappa_{12}}{T_0^2}\,(T_2 - T_1)\,, \tag{10.8.10}$$

assuming the two temperatures T_1 and T_2 to be close to the reference value T_0. Moreover in this thought experiment, the specific surface area is equal to $1/L$. Then

$$\frac{\kappa_{12}}{T_0^2} = \frac{k_{T1} + k_{T2}}{2\,L^2}, \quad h_{12} = \frac{k_{T1} + k_{T2}}{2\,L}\,. \tag{10.8.11}$$

The width over which the heat transfer between the two fluids takes place may be estimated as a percentage of the diameters of the pores and vessels, whether the fluids are miscible or immiscible.

The above considerations address heat transfer as a limit case of heat conduction without phase change. Heat transfer due for example to film condensation over vertical tubes or walls involves the latent heat of vaporization, see, e.g., Bird et al. [1960].

10.8.2 Specific surface area

Since the heat exchanges are directly proportional to the specific surface area on the interfaces, it is of interest to explore the influence of basic geometrical characteristics[10.5].

1. Decreasing the pore size:

As a particular setting, consider a porous medium containing spherical pores of uniform diameter d, the entire surface of which is available for solid-pore heat transfer. Therefore, each pore is completely embedded in the matrix. The maximum volume fraction is equal to the ratio of the volume of a sphere over the volume of the cube it is contained in, namely $n \leq \pi/6 \sim 0.52$. The volume fraction n of the pores is equal to the number N of pores over the volume V of porous medium times the volume $\pi\,d^3/6$ of a pore. Hence $N/V = 6\,n/(\pi\,d^3)$. The specific surface area a_{s1}, namely the area of contact between the matrix and the pores in a volume V, is equal to N/V times $\pi\,d^2$, that is $a_{s1} = 6\,n/d$[10.6]. The specific surface area of a cube of size d is larger, namely $6/d$, but smaller than the specific surface area of a parallelepiped of sides $d_1 \times d_2 \times d_3$, namely $2\,(d_1\,d_2 + d_2\,d_3 + d_3\,d_1)/(d_1\,d_2\,d_3)$, which, for small d_3, behaves like $2/d_3$. Thus particulate materials which are foliated are expected to have a larger specific surface area than granular materials: in fact, typical values for sand, fine sandstone and montmorillonite increase from $1.5 \times 10^4\,\mathrm{m}^2/\mathrm{m}^3$ to $1.5 \times 10^5\,\mathrm{m}^2/\mathrm{m}^3$ and $1.5 \times 10^9\,\mathrm{m}^2/\mathrm{m}^3$, de Marsily [1986], p. 22.

For cylindrical tubes of uniform diameter, the solid-vessel specific surface area becomes $a_{s2} = 4\,n/d$, and the maximum volume fraction is equal to $\pi/4 \sim 0.78$.

The specific surface area a_{12} of the two fluids may be assumed, as a first approximation, to be equal to n^1 times the tissue-vessel specific surface area a_{s2}.

2. Optimization under a physical constraint:

One may reconsider the above construction in a two-dimensional context, by concentrating on cross-sections. Consider a circular cylinder of radius R and unit height. Its cross-section S and circumference L are respectively equal to $\pi\,R^2$ and $2\,\pi\,R$. Now, consider N identical cylinders of radius r. When increasing the number of cylinders, one may require the volume fraction n to remain constant. Thus the radius r is equal to $R/N^{1/2}$, and the sum of all circumferences $2\,\pi\,R\,N^{1/2}$. The specific surface area is then equal to $2\,n/r$, that is $2\,n/R$ times $N^{1/2}$.

Alternatively, the axial flow may be required to remain constant. The flow rate of a newtonian fluid in a cylinder is known to be proportional to the fourth power of the radius, Eqn (15.6.13). Thus the radius r is equal to $R/N^{1/4}$, the sum of all sections is $\pi\,R^2\,N^{1/2}$, and the sum of all circumferences to $2\,\pi\,R\,N^{3/4}$. Thus the volume fraction varies like $N^{1/2}$ and the specific surface area like $N^{3/4}$. Therefore, increasing the number of cylinders appears favorable to exchanges that depend (linearly) on the length (or area) of the interface. Now, there are physiological limitations to a too large N. In particular, the volume fraction has certainly to be bounded for structural reasons. Moreover, a minimum size of the cylinders is required so that small particles can be convected by the flow: red blood cells are disk-like with a diameter about 7.5 μm, while the smallest micro-vessels have a diameter about 9 μm.

[10.5] Typical values of the specific surface areas associated with vessels in normal tissues and tumor tissues are shown in Table 24.8.1. In some geological materials, namely montmorillonites, the specific surface area reaches very high values, up to $700\,\mathrm{m}^2$ per gram, which correlate with their propensity to attract water.

[10.6] The formula holds by reversing the roles of solid and fluid, i.e., the specific surface area of a porous medium containing solid spheres of diameter d bathed in a fluid is equal to $6\,n/d$ where n is now the volume fraction of the solid.

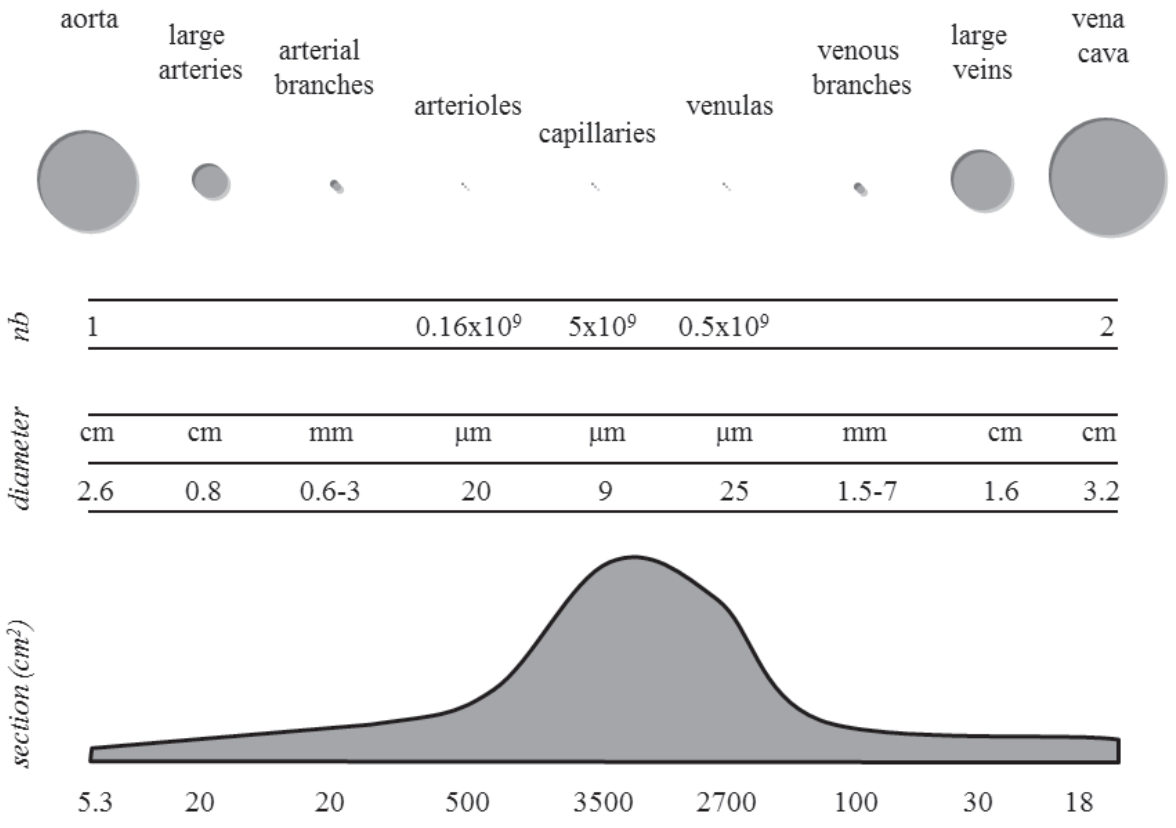

Fig. 10.8.1: Indicative distribution of blood vessel number, diameter and section in human adults, adapted from APP [2000], p. 157.

The actual distribution of the size of the vessels in humans does not follow exactly these relations, although the trends are correct, with a total cross-section that increases considerably as the diameter of the vessels decreases, Fig. 10.8.1. In fact, the above considerations have assumed that the driving gradient was constant along the cylinders and independent of their size. Such is not the case along the blood circuit: the resistance to flow due to the Hagen-Poiseuille relation varies like $1/r^4$, and therefore becomes quite large in the capillaries, so that the gradient of pressure drops, both axially and transmurally. Moreover, the average blood velocity varies like the square of the vessel diameter, Eqn (15.6.13): the low velocity in the capillaries, about 0.3 mm/s against 0.2 m/s in the aorta, allows sufficient contact time for exchanges of mass and heat across the capillary wall to actually take place. The surface offered by the capillaries for these exchanges is about 300 m^2, APP [2000], p. 156.

3. Optimization via a fractal construction:

The above process has consisted in creating a number of objects, similar in shape to the initiator (the cylinder of radius R), but of smaller size. Alternatively, one may keep considering the initiator, but insist in working its boundary. Indeed, it is worth recalling that there are two-dimensional mathematical objects with finite area but infinite circumference. The fractal called island of von Koch constitutes a famous instance. The construction goes as follows:

- start from an equilateral triangle of side ℓ;
- remove the central third of each of the three sides, and replace it by an inverted V, each side having length $L/3$;
- repeat the above generating process.

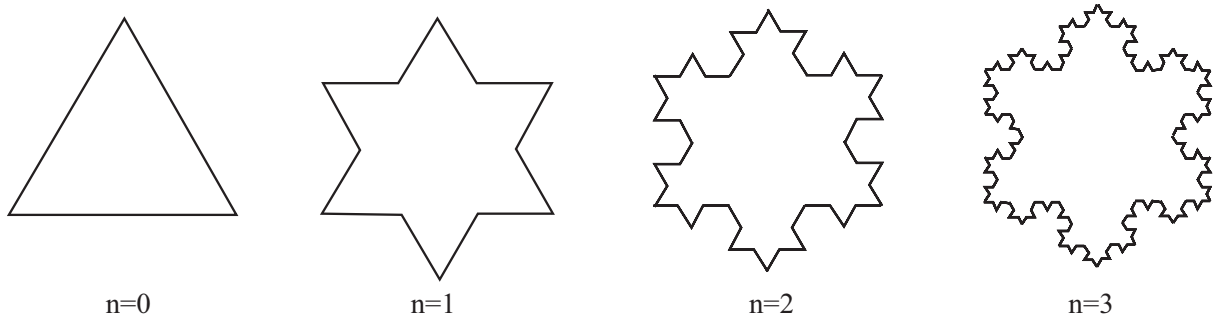

Fig. 10.8.2: The fractal construction of so-called von Koch island ends up with an object with a finite surface but the boundary has infinite length. The sketch shows four pre-fractal objects associated with the first steps of the construction.

Fig. 10.8.2 displays the generator and three pre-fractals $n = 1, 2$ and 3. At step n, the length L_n of the boundary and the area S_n of the pre-fractal domain have simple explicit expressions,

$$L_n = 3\,\ell\left(\frac{4}{3}\right)^n, \quad S_n = \ell^2\,\frac{\sqrt{3}}{4}\left(\,1 + \frac{1}{3}\,\frac{1-\left(\frac{4}{9}\right)^n}{1-\frac{4}{9}}\,\right), \tag{10.8.12}$$

and therefore the length L_∞ of the boundary of the fractal domain is infinite while the area S_∞ remains finite[10.7],

$$L_\infty = \infty, \quad S_\infty = \ell^2\,\frac{\sqrt{3}}{4}\left(1 + \frac{3}{5}\right). \tag{10.8.13}$$

Perhaps, one may wish to alter the fractal generator of von Koch island by introducing some additional constraint, like maintaining a constant area, etc.

Actually, maintaining a single main channel has pros and cons. The large interfacial area offered by pre-fractals participates to increased transmural exchanges. On the other hand, the advantages associated with small circular cylinders mentioned above (reduced velocity, etc.) should be re-examined for the pre-fractal boundary. Moreover, even if exchanges take actually place, heat or mass which has crossed the vessel wall should diffuse through the tissue. The dense micro-vessel network was an ideal tool for that purpose.

10.9 The coefficients of transfer: two scale derivation

In Section 10.8, the coefficients of transfer have been factorized based on qualitative arguments. As an alternative, a two scale derivation is sketched here. The underlying motivation is to account for the diffusion properties at a scale lower than the macroscopic scale, Fig. 10.9.1.

10.9.1 Small scale boundary value problems

10.9.1.1 Sphere bathed in a fluid at fixed given temperature

A solid sphere Ω of radius R is suddenly bathed in a fluid. The fluid temperature is constant in time and uniform in space, it is not influenced by the presence of the solid sphere. Let $\theta_{\rm s}(r,t)$ and $\theta_{\rm w}$ be the temperatures of the solid and fluid relative to some common reference.

The heat diffusion equation in the sphere,

$$C_{\rm s}\,\frac{\partial\theta_{\rm s}}{\partial t} - \mathrm{div}(k_{T{\rm s}}\boldsymbol{\nabla}\theta_{\rm s}) = 0\,, \tag{10.9.1}$$

[10.7] On a similar mood, consider a staircase of stringer length L inclined at 45°, with steps of equal run and rise. A path that follows the steps has length $L\sqrt{2}$ independently of the size of the steps.

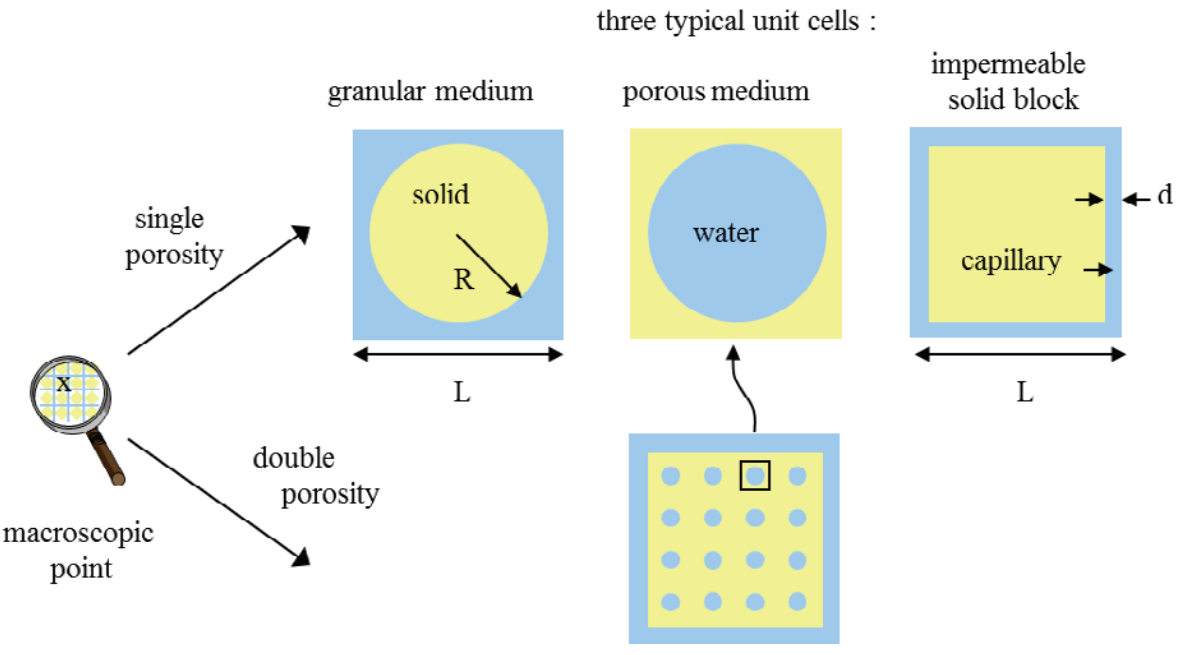

Fig. 10.9.1: Zooming on a geometrical point unveils the unit cells that deliver information on the geometrical arrangements of the phases at a lower scale either in a single porosity model or in a double porosity model.

simplifies to $\partial\theta_{\rm s}/\partial t - D_{T\rm s}\,{\rm div}\boldsymbol{\nabla}\theta_{\rm s} = 0$ if the thermal conductivity $k_{T\rm s}$ [unit : W/m/K] is spatially uniform. Here $C_{\rm s}$ [unit : J/m^3/K] is the heat capacity of the solid (at constant pressure), and $D_{T\rm s} = k_{T\rm s}/C_{\rm s}$ [unit : m^2/s] the thermal diffusivity. Integration of (10.9.1) and use of the Green's theorem implies,

$$\int_\Omega C_{\rm s}\,\frac{\partial\theta_{\rm s}}{\partial t}\;d\Omega = \int_\Omega {\rm div}(k_{T\rm s}\boldsymbol{\nabla}\theta_{\rm s})\;d\Omega = -q_{\rm s}(t)\,, \tag{10.9.2}$$

where $q_{\rm s}(t)$ [unit : W] is the heat flux that exits the sphere Ω,

$$q_{\rm s}(t) = -\int_{\partial\Omega} k_{T\rm s}\boldsymbol{\nabla}\theta_{\rm s}\cdot\mathbf{e}_r\;dS\;\Big(= -\int_{\partial\Omega} k_{T\rm s}\frac{\partial\theta_{\rm s}}{\partial r}\;dS = -4\,\pi\,R^2\,k_{T\rm s}\frac{\partial\theta_{\rm s}}{\partial r}(R,t)\Big)\,. \tag{10.9.3}$$

Since the thermal capacity is spatially uniform, (10.9.2) writes also

$$\Omega\;C_{\rm s}\;\frac{d\theta_{\rm s}^{\rm av}}{dt}(t) = -q_{\rm s}(t)\,, \tag{10.9.4}$$

where $\Omega = (4/3)\,\pi\,R^3$ is the volume of the sphere and $\theta_{\rm s}^{\rm av}(t) = \Omega^{-1}\int_\Omega \theta_{\rm s}(r,t)\;d\Omega$ is the spatial average of the temperature in the sphere.

The heat transfer coefficient is defined as

$$\beta(t) = \frac{-q_{\rm s}(t)}{\theta_{\rm w} - \theta_{\rm s}^{\rm av}(t)} = \frac{\Omega\;C_{\rm s}}{\theta_{\rm w} - \theta_{\rm s}^{\rm av}(t)}\;\frac{d\theta_{\rm s}^{\rm av}}{dt}(t)\,. \tag{10.9.5}$$

The solution to the boundary value problem (10.9.1) with $\theta_{\rm s}(R,t) = \theta_{\rm w}$ is given by Carslaw and Jaeger [1959], p. 233. They also provide the spatial average, which is the only information that is needed here,

$$\frac{\theta_{\rm s}^{\rm av}(t)}{\theta_{\rm w}} = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\,e^{-n^2\,\tilde{t}}\,, \tag{10.9.6}$$

where $\tilde{t} \equiv t/t_{\rm D}$ is the dimensionless time and $t_{\rm D}$ the characteristic time,

$$t_{\rm D} = \frac{1}{\pi^2}\,\frac{R^2}{D_{T\rm s}}\,. \tag{10.9.7}$$

10.9.1.2 Sphere bathed in a fluid at prescribed temperature evolving in time

Now, let us consider a small change of the fluid temperature at time τ in the form

$$\delta\theta_{\rm w}(t) = \mathcal{H}(t-\tau)\,\delta\theta_{\rm w}(\tau)\,, \tag{10.9.8}$$

with $\mathcal{H}$ the Heaviside step function. The resulting thermal change in the solid sphere is given in the form,

$$\delta\theta_{\rm s}^{\rm av}(t) = \mathcal{T}(t-\tau)\,\mathcal{H}(t-\tau)\,\delta\theta_{\rm w}(\tau)\,, \tag{10.9.9}$$

where the function $\mathcal{T}$ is given by (10.9.6), namely,

$$\mathcal{T}(u) = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\,e^{-n^2\,\tilde{u}}\,. \tag{10.9.10}$$

Then upon integration, the average temperature in the sphere,

$$\begin{aligned}
\theta_{\rm s}^{\rm av}(t) - \theta_{\rm s}^{\rm av}(0) &= \mathcal{T}(t-0)\,\mathcal{H}(t-0)\,\theta_{\rm w}(0) + \int_0^t \mathcal{T}(t-\tau)\,\mathcal{H}(t-\tau)\,\frac{\delta\theta_{\rm w}(\tau)}{\delta\tau}\;\delta\tau \\
&= \mathcal{T}(t-0)\,\theta_{\rm w}(0) + \int_0^t \mathcal{T}(t-\tau)\,\frac{\delta\theta_{\rm w}(\tau)}{\delta\tau}\;\delta\tau \\
&= \mathcal{T}(t-t)\,\theta_{\rm w}(t) - \int_0^t \frac{\partial\mathcal{T}(t-\tau)}{\partial\tau}\;\theta_{\rm w}(\tau)\;\delta\tau \\
&= \frac{d}{dt}\int_0^t \mathcal{T}(t-\tau)\;\theta_{\rm w}(\tau)\;\delta\tau\,,
\end{aligned} \tag{10.9.11}$$

adopts the format of a Stieltjes convolution integral. Clearly, if $\theta_{\rm w}$ is constant, the result (10.9.6) is recovered.

Therefore by (10.9.4),

$$-\,q_{\rm s}(t) = \Omega\;C_{\rm s}\,\frac{d\theta_{\rm s}^{\rm av}}{dt}(t) = \Omega\;C_{\rm s}\,\frac{d^2}{dt^2}\int_0^t \mathcal{T}(t-\tau)\;\theta_{\rm w}(\tau)\;\delta\tau\,. \tag{10.9.12}$$

10.9.2 Heat transfer with a characteristic time

A modification of the constitutive equation of heat transfer may be formulated in a macroscopic context, i.e., referring to a single spatial scale, using the idea presented in Section 9.1.4 that led from Fourier's heat conduction law to Cattaneo's heat conduction law in a thermodynamic framework.

For both the solid ($k = {\rm s}$) and the liquid ($k = {\rm w}$), the starting point is to enlarge the set of state variables $\mathcal{V}_k$ by including the rate of energy transfer $\hat{U}^k$ [unit : W/m^3]. The Massieu function Ξ_k is then postulated in the format,

$$\Xi_k(\mathcal{V}_k, \hat{U}^k) = \Xi_{k1}(\mathcal{V}_k) - \frac{1}{2}\,A_{Tk}(\hat{U}^k)^2\,, \tag{10.9.13}$$

where A_{Tk} is a constant. Manipulating the balance of energy and the entropy production (10.1.1) to eliminate the term div $\mathbf{Q}_k - \Theta_k$, the energy exchange process is seen to contribute to the entropy production of the porous medium by the terms,

$$\begin{aligned}
\hat{S}_{\rm (i)} &= \frac{\partial\Xi_{\rm s}}{\partial\hat{U}^{\rm s}}\,\frac{d\hat{U}^{\rm s}}{dt} + \frac{\hat{U}^{\rm s}}{T_{\rm s}} \quad + \quad \frac{\partial\Xi_{\rm w}}{\partial\hat{U}^{\rm w}}\,\frac{d\hat{U}^{\rm w}}{dt} + \frac{\hat{U}^{\rm w}}{T_{\rm w}} \\
&= -A_{T{\rm s}}\,\hat{U}^{\rm s}\,\frac{d\hat{U}^{\rm s}}{dt} + \frac{\hat{U}^{\rm s}}{T_{\rm s}} \quad - \quad A_{T{\rm w}}\,\hat{U}^{\rm w}\,\frac{d\hat{U}^{\rm w}}{dt} + \frac{\hat{U}^{\rm w}}{T_{\rm w}} \\
&= -(A_{T{\rm s}} + A_{T{\rm w}})\,\hat{U}^{\rm s}\,\frac{d\hat{U}^{\rm s}}{dt} \quad + \quad \hat{U}^{\rm s}\left(\frac{1}{T_{\rm s}} - \frac{1}{T_{\rm w}}\right),
\end{aligned} \tag{10.9.14}$$

the last line accounting for the fact that the energy exchange is assumed to be closed, namely $\hat{U}^{\rm s} + \hat{U}^{\rm w} = 0$.

Moreover, in this approach the rate $d\hat{U}^{\rm s}/dt = -d\hat{U}^{\rm w}/dt$ is viewed as a dependent variable that satisfies the relation,

$$t_{\hat{U}}\,\frac{d\hat{U}^{\rm s}}{dt} + \hat{U}^{\rm s} = \kappa_{\rm sw}\left(\frac{1}{T_{\rm s}} - \frac{1}{T_{\rm w}}\right). \tag{10.9.15}$$

Here $\kappa_{\rm sw} \geq 0$ [unit : W/m$^3\times$ K] is the coefficient of energy transfer while $t_{\hat{U}}$ [unit : s] is a characteristic time of energy transfer. For $t_{\hat{U}} = 0$, the process is instantaneous.

Insertion of the rate $d\hat{U}^k/dt$ obtained from (10.9.15) in the entropy production (10.9.14) yields,

$$\hat{S}_{\rm (i)} \;=\; \left(A_{T{\rm s}} + A_{T{\rm w}}\right)\frac{(\hat{U}^{\rm s})^2}{t_{\hat{U}}} + \hat{U}^{\rm s}\left(\frac{1}{T_{\rm s}} - \frac{1}{T_{\rm w}}\right)\left(1 - \kappa_{\rm sw}\,\frac{A_{T{\rm s}} + A_{T{\rm w}}}{t_{\hat{U}}}\right). \tag{10.9.16}$$

Setting

$$\frac{A_{T{\rm s}} + A_{T{\rm w}}}{t_{\hat{U}}} = \frac{1}{\kappa_{\rm sw}} \geq 0\,, \tag{10.9.17}$$

ensures the entropy production to be positive or zero,

$$\hat{S}_{\rm (i)} \;=\; \frac{(\hat{U}^{\rm s})^2}{\kappa_{\rm sw}} \geq 0\,. \tag{10.9.18}$$

The rate of energy transfer emanating from (10.9.15) is a convolution integral with an exponential kernel,

$$\hat{U}^{\rm s}(t) = \exp\Big(-\frac{t}{t_{\hat{U}}}\Big)\,\hat{U}^{\rm s}(0) + \int_0^t \kappa\,\exp\Big(-\frac{t-\tau}{t_{\hat{U}}}\Big)\,\big(T_{\rm w}(\tau) - T_{\rm s}(\tau)\big)\,\frac{d\tau}{t_{\hat{U}}}\,, \tag{10.9.19}$$

where the following notation was introduced,

$$\kappa = \frac{\kappa_{\rm sw}}{T_{\rm s}\,T_{\rm w}}\,. \tag{10.9.20}$$

The correspondence between the two scale analysis of Section 10.9.1.1 which involves a sphere of volume Ω and this macroscopic analysis is realized by the relations

- $\hat{U}^{\rm s} = -q_{\rm s}/\Omega$ rate of energy transfer per unit volume of solid [unit : W/m^3];
- $\kappa = \kappa_{\rm sw}/(T_{\rm s}\,T_{\rm w}) = \beta/\Omega$ energy transfer coefficient [unit : W/m^3/K] .

The constitutive equation of transfer endowed with a characteristic time sketched above can certainly match more accurately time course data than an instantaneous formulation. Still it is also more heavy on a computational point of view. While the constitutive equations of transfer adopted in this chapter are easily amenable to computational implementation and consistent with a thermodynamic analysis, leading to positive dissipation, they are also known to be inaccurate at early times. The nonlinear Vermeulen scheme has been adopted by Zimmerman et al. [1993] in the analysis of fractured geothermal reservoirs where, at each point of the fracture continuum, a porous block of spherical shape is attached: the fluid diffuses in the block and the net flow through its boundary is viewed as a source/sink term for the fracture continuum. Lu and Connell [2007] have devised a one-dimensional semi-analytical scheme that provides the time course of the transferred mass in a gas reservoir. At early times, the rate of mass transfer tends to vanish for the latter model, it approaches a constant for the linear transfer scheme and infinity for the Vermeulen scheme. Correspondingly, the mass transferred depends linearly on time in the linear transfer scheme, but on the square root of time in the schemes of Vermeulen and Lu and Connell, albeit with distinct scaling factors. A simple, accurate while computationally efficient, model of transfer that avoids delving with a convolution integral, is yet to come.

10.9.3 Identification of the transfer coefficients

Warren and Root [1963] identify the coefficient of transfer using a two scale analysis in the mood of Section 10.9.1.1. They address a fractured network where the solid blocks are parallelepipeds. In the case where the latter have identical dimension L in all directions, they define the heat transfer coefficient κ [unit : W/m^3/K] in the form,

$$\kappa = \overline{\alpha}\,k_{T{\rm s}}, \quad \overline{\alpha} = 4\,\frac{n\,(n+2)}{L^2}\,, \tag{10.9.21}$$

where $n = 1, 2$ or 3 is the number of orthogonal fracture planes, which can be associated with the dimension of the space. Actually, several interpretations have been proposed for the coefficient $\overline{\alpha}$.

For a *cubic solid block*,

- Warren and Root [1963] take $\overline{\alpha} = 60/L^2$;
- Zimmerman et al. [1993] suggest to take $\overline{\alpha} = \pi^2/\tilde{L}^2$, with $\tilde{L} = 3/a$, where a is the specific surface area. For a cube, $a = 6/L$ so that $\tilde{L} = L/2$ and $\overline{\alpha} = 4\,\pi^2/L^2$;
- the first term in the analytical solution of the diffusion problem is equal to $\overline{\alpha} = 3\,\pi^2/L^2$, Carslaw and Jaeger [1959], p. 184.

For a *spherical solid block* of radius R, the specific surface area is equal to $3/R$, so that the Zimmerman suggestion yields $\overline{\alpha} = \pi^2/R^2$. Now, if we retain only the first term in the solution (10.9.6),

$$\frac{T_{\rm s} - T_0}{T_{\rm w} - T_0} = 1 - \frac{6}{\pi^2}\, e^{-\tilde{t}}\,, \tag{10.9.22}$$

we obtain from (10.9.5) and (10.9.7),

$$\overline{\alpha} = \frac{\pi^2}{R^2}\,, \tag{10.9.23}$$

which agrees with the suggestion by Zimmerman et al. [1993] related with the specific surface area.

A characteristic time of energy transfer $t_{\hat{U}}$ might be obtained by considering thermal diffusion in the solid as in Section 10.9.2, and by setting $t_{\hat{U}}$ equal to the diffusion time $t_{\rm D}$ defined by (10.9.7). The radius R is to be viewed as half of the characteristic length of the transfer process.

This section has considered energy transfer. Still, the results concerning the transfer coefficients apply in essence to mass transfer. For example, consider the transfer of mass between the compartments 1 and 2 driven by the pressure differential $p^1 - p^2$ and ruled by the constitutive relation $\hat{\rho}^1/\rho^1 = -\kappa\,(p^1 - p^2)$. The mass transfer coefficient κ [unit : 1/Pa/s] adopts the Warren and Root format (10.9.21),

$$\kappa = \overline{\alpha}\, k_{\rm H}, \quad \overline{\alpha} = 4\,\frac{n\,(n+2)}{L^2}\,, \tag{10.9.24}$$

with $k_{\rm H}$ [unit : $\rm m^2 \times Pa^{-1} \times s^{-1}$] the *hydraulic permeability* of the porous medium.

Chapter 11

Waves in thermoelastic solids and saturated porous media

Dynamic methods are used to probe engineering materials, and biological tissues in particular. Efforts are deployed to efficiently tune ultrasonic techniques and magnetic-resonance elastography to living tissues. Their deformability and spatial heterogeneity and the presence of water pose considerable challenges. Nevertheless, dynamic methods are expected to help the diagnosis as they are seen as quick tools able to contrast the mechanical properties of normal and pathological tissues.

On another side, extracorporeal shock wave lithotripsy and intracorporeal ultrasound lithotripsy using lower frequencies but higher intensities than for medical diagnosis are routinely used to trigger the comminution of kidney stones. Further potential applications of shock waves, such as *in vitro* and *in vivo* damaging of tumor cells and healing of muskulo-skeletal disorders, have been suggested. The high amplitude waves generate positive and negative pressures that are thought to induce cavitation. The mechanisms through which cavitation acts to succeed in the healing process are not yet understood. Neo-vascularization induced by micro-injuries and enhancement of cellular reactions are potential candidates.

As yet another venue, damage induced by shock waves in specific organs, e.g., the inner ear, the optical nerve, brain vessels, is being investigated with a view to improve the protection against blasts.

11.1 Basic definitions

11.1.1 Phase wave and discontinuity wave

A wave is a mode of propagation in which some property is maintained on a surface that moves through the medium. If this property is a phase, the phenomenon is referred to as a *phase wave*. As an example, consider the motion along the axis x defined by the displacement $\phi(x,t) = a\,\sin(2\pi\,(x - c\,t)/L)$, where a characterizes the amplitude of the motion, L is the wave-length and c the wave-speed. When we analyze the motion, we pay attention to the motion of the maxima $2\pi\,(x - c\,t)/L = \pi/2$, Fig. 11.1.1. As a generalization to three dimensions, a *plane wave* is defined by a motion in a direction $\mathbf{n}$, all points of the planes orthogonal to $\mathbf{n}$ being disturbed equally, say $\phi(\mathbf{x},t) = a\,\sin(2\pi\,(\mathbf{n}\cdot\mathbf{x} - c\,t)/L)$.

When the property that moves through the medium is a discontinuity, we speak of a *discontinuity wave*. Let $\mathcal{S}(t)$ be a smooth surface separating two domains $V_-(t)$ and $V_+(t)$ across which some function ϕ is discontinuous. $\mathcal{S}$ is referred to as a *singular surface*. The discontinuity, or jump, of the function $\phi(\mathbf{x},t)$ at $\mathbf{x}\in\mathcal{S}$ is denoted via the symbol,

$$[\![\phi]\!]\,(\mathbf{x},t) = \lim_{\mathbf{x}_+\in V_+\to\mathbf{x}} \phi(\mathbf{x}_+,t) - \lim_{\mathbf{x}_-\in V_-\to\mathbf{x}} \phi(\mathbf{x}_-,t)\,. \tag{11.1.1}$$

By convention, V_- and V_+ are respectively the domains behind and ahead of the wave. Please notice that, as defined by (11.1.1), the jump of ϕ is the opposite of its time change. The jump of a sum is equal to the sum of the jumps and the jump of a product is given by the expression,

$$[\![\phi\,\psi]\!](\mathbf{x},t) = [\![\phi]\!](\mathbf{x},t)\times\tfrac{1}{2}\,(\psi_- + \psi_+) + \tfrac{1}{2}\,(\phi_- + \phi_+)\times[\![\psi]\!](\mathbf{x},t)\,, \tag{11.1.2}$$

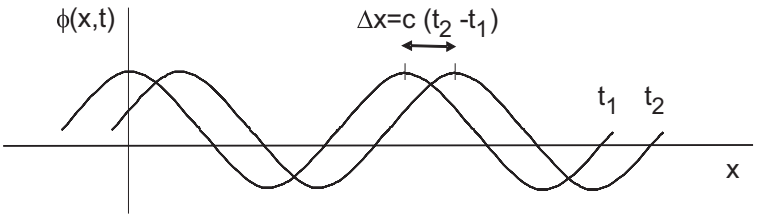

Fig. 11.1.1: A phase wave propagating at speed c captured at two instants t_1 and $t_2 > t_1$: the top of the wave has moved the distance $c\,(t_2 - t_1)$.

where $\phi_\pm(\mathbf{x},t) = \lim_{\mathbf{x}_\pm \in V_\pm \to \mathbf{x}} \ \phi(\mathbf{x}_\pm,t)$, and similarly for $\psi_\pm$. The formula applies to scalars and tensors in the indicated order.

If the singular surface is composed of the same material points at any time, the phenomenon is referred to as a *stationary discontinuity*, and the domains V_- and V_+ might be assigned arbitrarily.

If across the singular surface, all derivatives of the function $\phi(x,t)$ are continuous up to order $m-1$, while some derivatives are discontinuous at order m, we refer

- to a *strong discontinuity* or *first order wave* if $m = 1$;
- to an *ordinary wave* if $m \geq 2$, and in particular to a second order wave or *acceleration wave* if $m = 2$.

There does not exist a wave of order $m = 0$ which would correspond to a discontinuous displacement, and therefore to an infinite discontinuity of velocity. The term *shock wave* is usually restricted to an accumulation of acceleration waves giving rise to a higher order discontinuity.

11.1.2 Lagrangian and Eulerian analyses

Let the singular surfaces at times t and $t+dt$ be denoted respectively by $\mathcal{S}(t)$ and $\mathcal{S}(t+dt)$. The sets of material points, which form the surfaces $\mathcal{S}(t)$ and $\mathcal{S}(t+dt)$, are located on the surfaces $\underline{\mathcal{S}}(t)$ and $\underline{\mathcal{S}}(t+dt)$ in the reference configuration, say at time $t = 0$.

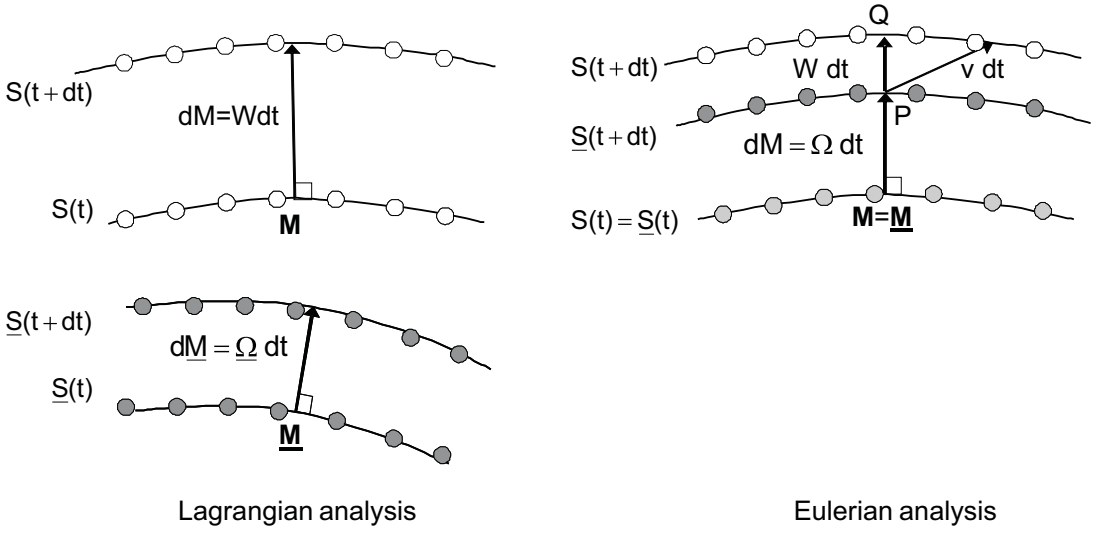

Fig. 11.1.2: Lagrangian and Eulerian analyses of wave propagation. Sketch illustrating the difference between Ω, the normal speed of propagation of the wave with respect to the material, and W, the normal speed of displacement of the wave.

Referring to Fig. 11.1.2, consider a particular point $\mathbf{M}$ on $\mathcal{S}(t)$ and its position $\underline{\mathbf{M}}(t) \in \underline{\mathcal{S}}(t)$ in the reference configuration. This point sits at time $t+dt$ on the surface $\mathcal{S}(t+dt)$ and its position in the reference configuration is $\underline{\mathbf{M}}(t+dt) \in \underline{\mathcal{S}}(t+dt)$. A distinction should be made between the *normal speed of propagation of the wave with*

respect to the material in its reference configuration,

$$\underline{\Omega} = \frac{d\underline{\mathbf{M}}}{dt} \cdot \underline{\mathbf{n}}\,, \tag{11.1.3}$$

and the *normal speed of displacement of the wave*,

$$W = \frac{d\mathbf{M}}{dt} \cdot \mathbf{n}\,. \tag{11.1.4}$$

Here $\underline{\mathbf{n}} = \underline{\mathbf{n}}(t)$ and $\mathbf{n} = \mathbf{n}(t)$ are the unit vectors that indicate the local direction of propagation of the surface in the reference configuration and current configuration, respectively. Both $\underline{\Omega}$ and W may vary in time and space, and $\underline{\Omega}$ depends clearly on the choice of the reference configuration.

In an updated Lagrangian analysis, the current configuration is taken as reference. Then, with $\mathbf{v}$ the particle velocity,

$$W = \Omega + \mathbf{v} \cdot \mathbf{n}\,, \tag{11.1.5}$$

where $\Omega = d\mathbf{M}/dt \cdot \mathbf{n}$ is the *normal speed of propagation of the wave with respect to the material in its current configuration*. Since the normal speed W is an absolute entity, its discontinuity vanishes,

$$[\![W]\!](\mathbf{x},t) = [\![\Omega + \mathbf{v} \cdot \mathbf{n}]\!](\mathbf{x},t) = 0\,. \tag{11.1.6}$$

From now on, to simplify the notation, the space and time dependences of jumps will be indicated only if necessary to the understanding.

11.1.3 Hadamard's compatibility relations in the current configuration

Hadamard's compatibility relations[11.1] are derived in an updated Lagrangian formalism, where the current configuration is taken as reference.

Let $\phi(\mathbf{x},t)$ be a scalar function which is *continuous across the wave front* that propagates at speed Ω in the direction $\mathbf{n}(\mathbf{x},t)$, and differentiable on both sides of the front. However, some of its derivatives suffer a discontinuity across the wave front.

Hadamard's compatibility relations indicate that there exists a scalar η such that

$$\left[\!\!\left[\frac{\partial \phi}{\partial \mathbf{x}}\right]\!\!\right] = \eta\ \mathbf{n}\,, \quad \left[\!\!\left[\frac{d\phi}{dt}\right]\!\!\right] = -\Omega\,\eta\,, \tag{11.1.7}$$

and therefore the discontinuities of the space and time derivatives of a continuous function obey the relation,

$$\left[\!\!\left[\frac{\partial \phi}{\partial \mathbf{x}}\right]\!\!\right] = -\frac{1}{\Omega}\ \left[\!\!\left[\frac{d\phi}{dt}\right]\!\!\right]\ \mathbf{n}\,. \tag{11.1.8}$$

These relations extend to a *continuous* vector or tensor $\boldsymbol{\phi}(\mathbf{x},t)$,

$$\left[\!\!\left[\frac{\partial \boldsymbol{\phi}}{\partial \mathbf{x}}\right]\!\!\right] = \boldsymbol{\eta} \otimes \mathbf{n}\,, \quad \left[\!\!\left[\frac{d\boldsymbol{\phi}}{dt}\right]\!\!\right] = -\Omega\,\boldsymbol{\eta}\,, \quad \left[\!\!\left[\frac{\partial \boldsymbol{\phi}}{\partial \mathbf{x}}\right]\!\!\right] = -\frac{1}{\Omega}\ \left[\!\!\left[\frac{d\boldsymbol{\phi}}{dt}\right]\!\!\right] \otimes \mathbf{n}\,. \tag{11.1.9}$$

Indeed, let us consider the differential increments of $\phi(\mathbf{x},t)$ on both sides of the singular surface,

$$d\phi_{\pm} = \frac{\partial \phi}{\partial \mathbf{x}}_{\pm} \cdot d\mathbf{x} + \frac{d\phi}{dt}_{\pm}\, dt\,. \tag{11.1.10}$$

For points along the singular surface $\mathbf{n} \cdot d\mathbf{x} - \Omega\, dt = 0$, the difference between the two differentials in front of and behind the singular surface yields, since ϕ is continuous,

$$\begin{aligned} [\![d\phi]\!] = 0 \quad &= \quad \left[\!\!\left[\frac{\partial \phi}{\partial \mathbf{x}}\right]\!\!\right] \cdot d\mathbf{x} + \left[\!\!\left[\frac{d\phi}{dt}\right]\!\!\right] dt \\ &= \quad \left(\left[\!\!\left[\frac{\partial \phi}{\partial \mathbf{x}}\right]\!\!\right] + \frac{1}{\Omega}\ \left[\!\!\left[\frac{d\phi}{dt}\right]\!\!\right] \mathbf{n} \right) \cdot d\mathbf{x}\,, \end{aligned} \tag{11.1.11}$$

which holds for any $d\mathbf{x}$, whence the relations (11.1.8) □.

[11.1] Named after the French mathematician Jacques Salomon Hadamard (1865-1963).

The Eulerian version of (11.1.7) applied to the continuous scalar function $\psi(\mathbf{x},t)$,

$$\left[\!\left[\frac{\partial\psi}{\partial\mathbf{x}}\right]\!\right] = \eta\,\mathbf{n}\,, \quad \left[\!\left[\frac{\partial\psi}{\partial t}\right]\!\right] = -W\,\eta\,, \tag{11.1.12}$$

deduces similarly by considering points on the current position of the singular surface such that $\mathbf{n}\cdot d\mathbf{x} - W\,dt = 0$. In fact, for $\phi(\underline{\mathbf{x}},t) = \psi(\mathbf{x},t)$, then $\partial\phi(\underline{\mathbf{x}},t)/\partial t = d\psi(\mathbf{x},t)/dt$ with $d\psi(\mathbf{x},t)/dt$ the material derivative, namely $d\psi(\mathbf{x},t)/dt = \partial\psi(\mathbf{x},t)/\partial t + \partial\psi(\mathbf{x},t)/\partial\mathbf{x}\cdot\mathbf{v}$. Therefore in an updated Lagrangian formalism, (11.1.12) implies (11.1.7), namely $[\![d\psi(\mathbf{x},t)/dt]\!] = -\Omega\,\eta$.

Note that relations similar to Hadamard's compatibility relations hold also for phase waves. Indeed, let $\psi(\mathbf{x},t) = \psi(\mathbf{x}\cdot\mathbf{n} - W\,t)$. Then $\partial\psi/\partial\mathbf{x} = \psi'\mathbf{n}$ and $\partial\psi/\partial t = -W\,\psi'$, with ψ' denoting the derivative of ψ with respect to its argument.

The existence of 3 or more kinematical constraints on the displacement vector may prevent the existence of propagating discontinuities: indeed, these constraints spill over the 3-component vector $\boldsymbol{\eta}$.

11.1.4 Conservation laws in a solid domain with a crossing discontinuity

Consider a singular surface $\mathcal{S}$ moving through a solid of volume V with absolute normal speed W and with a speed Ω with respect to the material in its current configuration. Material points move with velocity $\mathbf{v}$, in such way that $W = \Omega + \mathbf{v}\cdot\mathbf{n}$. As indicated in Fig. 11.1.3, V_- denotes the part of the volume behind the singular surface, V_+ denotes the part of the volume ahead of the singular surface.

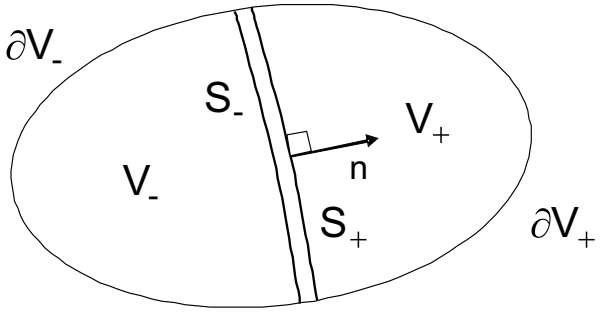

Fig. 11.1.3: A singular surface moving across a body V in the direction $\mathbf{n}$.

The generalized Reynolds theorem (2.7.5) can be applied separately to the volumes V_- and V_+ to any field $\phi = \phi(\mathbf{x},t)$ which is differentiable on each side of the surface. Let $dS = \mathbf{n}\cdot d\mathbf{S}$ be the increment of area over the singular surface. For the volume behind the singular surface,

$$\begin{aligned}\frac{d}{dt}\int_{V_-}\phi\,dV &= \int_{V_-}\frac{\partial\phi}{\partial t}\,dV + \int_{\partial V_-\cup\mathcal{S}_-}\phi\,\mathbf{v}\cdot d\mathbf{S} + \int_{\mathcal{S}}\phi\,\Omega\,dS \\ &= \int_{V_-}\frac{\partial\phi}{\partial t} + \operatorname{div}(\phi\,\mathbf{v})\,dV + \int_{\mathcal{S}}\phi\,\Omega\,dS\,,\end{aligned} \tag{11.1.13}$$

while changing the algebraic incremental area dS to $-dS$ for the volume in front of the singular surface,

$$\frac{d}{dt}\int_{V_+}\phi\,dV = \int_{V_+}\frac{\partial\phi}{\partial t} + \operatorname{div}(\phi\,\mathbf{v})\,dV - \int_{\mathcal{S}}\phi\,\Omega\,dS\,. \tag{11.1.14}$$

The integral over the whole volume $V = V_-\cup V_+$, obtained by summation of the two above partial integrals,

$$\frac{d}{dt}\int_{V}\phi\,dV = \int_{V}\frac{\partial\phi}{\partial t} + \operatorname{div}(\phi\,\mathbf{v})\,dV - \int_{\mathcal{S}}[\![\phi\,\Omega]\!]\,dS\,, \tag{11.1.15}$$

highlights the contribution of the singular surface.

We now explore in a thermodynamically closed solid the consequences of this result for the balances of mass, momentum, energy and entropy.

11.1.4.1 Conservation of mass across a strong discontinuity

Let ϕ be equal to the mass density ρ. The volume being assumed to be closed, global conservation of mass implies the left-hand side of (11.1.15) to vanish. Local conservation of mass $\partial\rho/\partial t + \operatorname{div}(\rho\,\mathbf{v}) = 0$ implies the volume integral in the right-hand side of (11.1.15) to vanish as well. Therefore, across a strong discontinuity, $\rho\,\Omega$ is continuous,

$$[\![\rho\,\Omega]\!] = 0\,. \tag{11.1.16}$$

Note 11.1 on the contribution of mass supplies.

If the solid was open, a field (volume) mass supply $\hat{\rho}$ could be present, but it would not contribute to the mass balance across a first order surface, even if it was discontinuous, as long as the discontinuity is finite. Indeed, in a one-dimensional context, let v be the velocity. The contribution of a generic term ϕ to the mass balance $\partial\rho/\partial t + d(\rho\,v)/dx = \hat{\rho}$ is obtained by integration across the surface, namely $\lim_{dx\to 0}\ \phi\,dx$: (a) the term $\phi = d(\rho\,v)/dx$ yields an integral equal to $(\rho v)_+ - (\rho v)_-$; (b) the singular surface has moved an absolute distance $dx = W\,dt$ in a time interval dt. The term $\phi = \partial\rho/\partial t$ integrates to $\phi\,dx = \phi\,W\,dt = (\rho_- - \rho_+)\,W$; (c) finally $\lim_{dx\to 0}\ \hat{\rho}\,dx = 0$, whence the relation $[\![\rho\,\Omega]\!] = 0$.

11.1.4.2 Conservation of momentum across a strong discontinuity

Let ϕ be equal to the momentum $\rho\,\mathbf{v}$. Let us first observe that local conservation of mass simplifies (11.1.15) to,

$$\frac{d}{dt}\int_V \rho\,\mathbf{v}\;dV \;=\; \int_V \rho\,\frac{d\mathbf{v}}{dt}\;dV - \int_{\mathcal{S}} [\![(\rho\,\Omega)\,\mathbf{v}]\!]\,dS\,. \tag{11.1.17}$$

Next, the local conservation of momentum $\operatorname{div}\boldsymbol{\sigma} + \rho\,\mathbf{b} = \rho\,d\mathbf{v}/dt$, with $\mathbf{b}$ body force per unit mass, is integrated by parts separately over the volumes V_- and V_+. The sum of the two integrals,

$$\int_V \rho\,\frac{d\mathbf{v}}{dt}\;dV \;=\; \int_V \rho\,\mathbf{b}\;dV + \int_{\partial V} \boldsymbol{\sigma}\cdot d\mathbf{S} - \int_{\mathcal{S}} [\![\boldsymbol{\sigma}]\!]\cdot\mathbf{n}\,dS\,, \tag{11.1.18}$$

may be contrasted with the global conservation of momentum over the volume V as a whole, Eqn (4.5.4)

$$\frac{d}{dt}\int_V \rho\,\mathbf{v}\;dV \;=\; \int_V \rho\,\mathbf{b}\;dV + \int_{\partial V} \boldsymbol{\sigma}\cdot d\mathbf{S}\,. \tag{11.1.19}$$

The combination of these three equations provides the jump of the traction across a first order wave as a function of the velocity jump,

$$[\![\boldsymbol{\sigma}]\!]\cdot\mathbf{n} + (\rho\,\Omega)\,[\![\mathbf{v}]\!] = \mathbf{0}\,. \tag{11.1.20}$$

The continuity of $\rho\,\Omega$ across the wave front has been used to rewrite the second term on the left hand side of the above relation.

Note that the jump of $\partial\mathbf{u}/\partial\mathbf{x}$ is equal to the jump of the deformation gradient $\mathbf{F} = \mathbf{I} + \partial\mathbf{u}/\partial\mathbf{x}$. Then, as a consequence of (11.1.9) and (11.1.20), the jump of the traction and the jump of the deformation gradient obey the Rankine-Hugoniot relations[11.2],

$$[\![\boldsymbol{\sigma}]\!]\cdot\mathbf{n} = (\rho\,\Omega^2)\;[\![\mathbf{F}]\!]\cdot\mathbf{n}, \quad [\![\mathbf{F}]\!] = \frac{1}{\rho\,\Omega^2}\,[\![\boldsymbol{\sigma}]\!]\cdot\mathbf{n}\otimes\mathbf{n}\,. \tag{11.1.21}$$

Note 11.2 on a direct proof of the momentum balance across a first order surface.

The result (11.1.20) can also be obtained by the following qualitative argument. Consider a piece of material of unit area. During the time interval dt, the wave front has moved a distance $\Omega\,dt$ with respect to the matter, and it has changed the velocity $\mathbf{v}$ of a mass $\rho\,\Omega\,dt$, which was ahead at time t and is behind at time $t + dt$, to $\mathbf{v} - [\![\mathbf{v}]\!]$. The resulting acceleration of this mass is thus $-[\![\mathbf{v}]\!]/dt$. The force per unit area required to induce this acceleration is equal to the mass $\rho\,\Omega\,dt$ times the acceleration $-[\![\mathbf{v}]\!]/dt$, namely $-(\rho\,\Omega)\,[\![\mathbf{v}]\!]$.

Note 11.3 on the contribution of body forces and momentum supplies.

A body force does not contribute to the relation (11.1.20) even if it is discontinuous, as long as the discontinuity is finite. The rule would apply to field (volume) momentum supplies which could be present if the solid was open. Indeed, in a one-dimensional context, let σ be the stress and v the velocity. The contribution of a generic term ϕ to the momentum balance $d\sigma/dx + \rho\,b - \rho\,dv/dt = 0$ is obtained by integration across the surface, namely $\lim_{dx\to 0}\ \phi\,dx$. (a) the term $\phi = d\sigma/dx$ yields an integral equal to $\sigma_+ - \sigma_-$; (b) the singular surface has moved a relative distance $dx = \Omega\,dt$ with respect to the matter in a time interval dt. Let v_- be the velocity of a point in front of the wave, and v_+ the velocity of this same point after it has been crossed by the wave. Then the term $\phi = -\rho\,dv/dt$ integrates to $\phi\,dx = \phi\,\Omega\,dt = -\big((\rho\,\Omega\,v)_- - (\rho\,\Omega\,v)_+\big)$, whence, using (11.1.16), the one-dimensional relation $[\![\sigma]\!] + (\rho\,\Omega)\,[\![v]\!] = 0$.

[11.2] Named after the Scot engineer and physicist William John Macquorn Rankine (1820-1872) and the French engineer Pierre Henri Hugoniot (1851-1887).

11.1.4.3 Conservation of energy across a strong discontinuity

Let ϕ be equal to the sum of the internal and kinetic energies, $\phi = \rho\,(u + \frac{1}{2}\,\mathbf{v}^2)$. Let us first observe that local conservation of mass simplifies (11.1.15) to,

$$\frac{d}{dt}\int_V \rho\,(u+\tfrac{1}{2}\,\mathbf{v}^2)\;dV \;=\; \int_V \rho\,\frac{d}{dt}\,(u+\tfrac{1}{2}\,\mathbf{v}^2)\;dV - \int_{\mathcal{S}} [\![(\rho\,\Omega)\,(u+\tfrac{1}{2}\,\mathbf{v}^2)]\!]\,dS\,. \tag{11.1.22}$$

Next, the local conservation of energy $\rho\,du/dt - \boldsymbol{\sigma} : \boldsymbol{\nabla}\mathbf{v} - \Theta + \operatorname{div}\mathbf{Q} = 0$ is integrated by parts separately over the volumes V_- and V_+. The sum of the two integrals,

$$\int_V \rho\,\frac{du}{dt}\;dV \;=\; \int_V -\operatorname{div}\boldsymbol{\sigma}\cdot\mathbf{v} + \Theta\;dV + \int_{\partial V}(\mathbf{v}\cdot\boldsymbol{\sigma}-\mathbf{Q})\cdot d\mathbf{S} - \int_{\mathcal{S}} [\![\mathbf{v}\cdot\boldsymbol{\sigma}-\mathbf{Q}]\!]\cdot\mathbf{n}\,dS\,, \tag{11.1.23}$$

may be transformed, with help of the local balance of momentum, to

$$\int_V \rho\,\frac{du}{dt}\;dV \;=\; \int_V \rho\,(\mathbf{b}-\frac{d\mathbf{v}}{dt})\cdot\mathbf{v} + \Theta\;dV + \int_{\partial V}(\mathbf{v}\cdot\boldsymbol{\sigma}-\mathbf{Q})\cdot d\mathbf{S} - \int_{\mathcal{S}} [\![\mathbf{v}\cdot\boldsymbol{\sigma}-\mathbf{Q}]\!]\cdot\mathbf{n}\,dS\,. \tag{11.1.24}$$

Finally, global conservation of energy on the volume V as a whole (4.6.10) simplifies for a closed solid to,

$$\frac{d}{dt}\int_V \rho\,(u+\tfrac{1}{2}\,\mathbf{v}^2)\;dV \;=\; \int_V \rho\,\mathbf{b}\cdot\mathbf{v} + \Theta\;dV + \int_{\partial V}(\mathbf{v}\cdot\boldsymbol{\sigma}-\mathbf{Q})\cdot d\mathbf{S}\,. \tag{11.1.25}$$

Combining the three equations (11.1.22), (11.1.24) and (11.1.25) provides the jump of energy across a first order wave as a function of the jumps of mechanical and thermal fluxes,

$$(\rho\,\Omega)\,[\![u+\tfrac{1}{2}\,\mathbf{v}^2]\!] + [\![\mathbf{v}\cdot\boldsymbol{\sigma}-\mathbf{Q}]\!]\cdot\mathbf{n} = 0\,, \tag{11.1.26}$$

accounting for the continuity of $\rho\,\Omega$ across the wave front.

The displacement is continuous across a strong discontinuity. Thus the gradient of displacement might be discontinuous but it remains finite. As a consequence, we have

Proposition 11.1 on the continuity of temperature across a singular surface in a Fourier's heat conductor.

If the internal energy depends only on the gradient of displacement and temperature, and if the material is a conductor (at least in the direction of the propagation), then the temperature itself can not undergo a jump across the singular surface.

Therefore, for the temperature to undergo a jump across the singular surface, the thermal conductivity across the surface should vanish.

The proof of the proposition rests on the fact that all terms in the energy conservation (11.1.26) are bounded except possibly the heat exchange which is the ratio of the thermal conductivity times the jump of temperature over the width of the singular surface, which actually vanishes. Therefore either the temperature jump or the thermal conductivity along the normal to the singular surface should vanish.

11.1.4.4 Entropy inequality across a strong discontinuity

Let ϕ be equal to the entropy per unit volume, $\phi = \rho\,s$. The local conservation of mass simplifies (11.1.15) to,

$$\frac{d}{dt}\int_V \rho\,s\;dV \;=\; \int_V \rho\,\frac{ds}{dt}\;dV - \int_{\mathcal{S}} [\![(\rho\,\Omega)\,s]\!]\,dS\,, \tag{11.1.27}$$

Next, the global entropy inequality on the volume V as a whole (4.7.14) is integrated by parts over the two subvolumes,

$$\begin{aligned}\frac{d}{dt}\int_V \rho\,s\;dV \;&\geq\; \int_V \frac{\Theta}{T}\;dV - \int_{\partial V}\frac{\mathbf{Q}}{T}\cdot d\mathbf{S}\\ &\geq\; \int_V \frac{\Theta}{T} - \operatorname{div}\frac{\mathbf{Q}}{T}\;dV - \int_{\mathcal{S}} [\![\frac{\mathbf{Q}}{T}]\!]\cdot\mathbf{n}\,dS\,.\end{aligned} \tag{11.1.28}$$

Combining the two above relations yields the inequality,

$$\int_V \rho\,\frac{ds}{dt} - \frac{\Theta}{T} + \operatorname{div}\frac{\mathbf{Q}}{T}\;dV + \int_{\mathcal{S}} [\![\frac{\mathbf{Q}}{T}]\!]\cdot\mathbf{n} - [\![(\rho\,\Omega)\,s]\!]\,dS \;\geq 0\,, \tag{11.1.29}$$

whence the inequality at any regular point in the volume $\hat{S}_{(\mathrm{i})} = \rho\,ds/dt - \Theta/T + \operatorname{div}(\mathbf{Q}/T) \geq 0$, and the inequality,

$$\hat{S}_{(\mathrm{i})\|} = [\![\frac{\mathbf{Q}}{T}]\!]\cdot\mathbf{n} - (\rho\,\Omega)\,[\![s]\!] \geq 0\,, \tag{11.1.30}$$

at a point on the singular surface. The thermal source Θ does not contribute as long as its jump is finite. The very definition of the discontinuity operator (11.1.1) matters to interpret this inequality. Indeed, $[\![a]\!]$ denotes the difference between the values of a ahead and behind the wave front. Therefore, under adiabatic conditions, the entropy increases through the wave front.

11.1.4.5 Incremental work on a singular surface

Let $\delta\mathbf{u}$ be a virtual displacement field which is continuous and differentiable on both sides of a surface $\mathcal{S}$ that separates the volume V in the two subdomains V_- and V_+ as displayed in Fig. 11.1.3. The actual velocity field $\mathbf{v}$ is in dynamic equilibrium with the stress field $\boldsymbol{\sigma}$ and the body force $\mathbf{b}$, and therefore,

$$\int_V \Big(\operatorname{div}\boldsymbol{\sigma} + \rho\,(\mathbf{b} - \frac{d\mathbf{v}}{dt})\Big)\cdot\delta\mathbf{u}\;dV = 0\,. \tag{11.1.31}$$

Integration by parts over each subdomain highlights the contribution of the singular surface,

$$\int_V -\boldsymbol{\sigma} : \boldsymbol{\nabla}(\delta\mathbf{u}) + \rho\,(\mathbf{b} - \frac{d\mathbf{v}}{dt})\cdot\delta\mathbf{u}\;dV + \int_{\partial V}\delta\mathbf{u}\cdot\boldsymbol{\sigma}\cdot d\mathbf{S} - \int_{\mathcal{S}}[\![\delta\mathbf{u}\cdot\boldsymbol{\sigma}]\!]\cdot\mathbf{n}\,dS = 0\,. \tag{11.1.32}$$

11.1.4.6 Lagrangian version of the discontinuity relations

The (totally) Lagrangian version of the Hadamard's compatibility relations for a scalar (11.1.7) and (11.1.8) can be cast in the format,

$$\left[\!\!\left[\frac{\partial\phi}{\partial\underline{\mathbf{x}}}\right]\!\!\right] = \underline{\eta}\,\underline{\mathbf{n}}\,,\quad \left[\!\!\left[\frac{d\phi}{dt}\right]\!\!\right] = -\underline{\Omega}\,\underline{\eta}\quad\Rightarrow\quad \left[\!\!\left[\frac{\partial\phi}{\partial\underline{\mathbf{x}}}\right]\!\!\right] = -\frac{1}{\underline{\Omega}}\left[\!\!\left[\frac{d\phi}{dt}\right]\!\!\right]\underline{\mathbf{n}}\,, \tag{11.1.33}$$

with $\underline{\Omega}$ defined as follows,

$$\frac{\underline{\Omega}}{\Omega} = |\underline{\mathbf{n}}\cdot\mathbf{F}^{-1}| = \frac{1}{|\mathbf{n}\cdot\mathbf{F}|}\,. \tag{11.1.34}$$

The relation (11.1.33) is obtained by observing that points along the singular surface obey the relation $\mathbf{n}\cdot d\mathbf{x} - \Omega\,dt = 0$ which, using Nanson's rule of change of the normal to a surface $\mathbf{n} = \underline{\mathbf{n}}\cdot\mathbf{F}^{-1}/|\underline{\mathbf{n}}\cdot\mathbf{F}^{-1}|$, transforms to $\underline{\mathbf{n}}\cdot d\underline{\mathbf{x}}/|\underline{\mathbf{n}}\cdot\mathbf{F}^{-1}| - \Omega\,dt = 0$.

Moreover, Nanson's rule of change of the surface $d\underline{\mathbf{S}}$, Eqn (2.6.9), yielding $d\mathbf{S}_\pm = \det\mathbf{F}_\pm\,d\underline{\mathbf{S}}\cdot\mathbf{F}_\pm^{-1}$ implies that the area $d\mathbf{S}$ maps identically on both sides of the discontinuity even if the deformation gradient may be discontinuous, namely, Bowen [1989], p. 91,

$$[\![(\det\mathbf{F})\,\underline{\mathbf{n}}\cdot\mathbf{F}^{-1}]\!] = \mathbf{0},\quad [\![d\mathbf{S}]\!] = \mathbf{0},\quad [\![\mathbf{n}]\!] = \mathbf{0}\,. \tag{11.1.35}$$

The proof relies on the fact that the discontinuity is dyadic, as indicated by (11.1.33) applied to a vector, say $\mathbf{F}_+ = \mathbf{F}_- + \underline{\boldsymbol{\eta}}\otimes\underline{\mathbf{n}}$, and on Sherman-Morrison formula (2.3.20) and (2.3.21). As a consequence of (11.1.34), $\underline{\rho}\,\underline{\Omega} = \rho\,\Omega\,(\det\mathbf{F})\,|\underline{\mathbf{n}}\cdot\mathbf{F}^{-1}|$ and therefore, as a consequence of $(11.1.35)_1$, $[\![\underline{\rho}\,\underline{\Omega}]\!] = 0$ □.

The extension of the relation (11.1.33) to a vector or a tensor is immediate, for example, for the deformation gradient,

$$[\![\mathbf{F}]\!] = \underline{\boldsymbol{\eta}}\otimes\underline{\mathbf{n}},\quad [\![\mathbf{v}]\!] = -\underline{\Omega}\,\underline{\boldsymbol{\eta}},\quad [\![\mathbf{F}]\!] = -\frac{1}{\underline{\Omega}}\,[\![\,\mathbf{v}\,]\!]\otimes\underline{\mathbf{n}}\,. \tag{11.1.36}$$

The three other discontinuity relations deduce similarly from their updated Lagrangian versions,

$$\begin{aligned}
&\text{balance of momentum} && [\![\underline{\boldsymbol{\tau}}]\!]\cdot\underline{\mathbf{n}} + (\underline{\rho}\,\underline{\Omega})\,[\![\mathbf{v}]\!] = \mathbf{0}\,,\\
&\text{balance of energy} && (\underline{\rho}\,\underline{\Omega})\,[\![u + \tfrac{1}{2}\,\mathbf{v}^2]\!] + [\![\mathbf{v}\cdot\underline{\boldsymbol{\tau}} - \underline{\mathbf{Q}}]\!]\cdot\underline{\mathbf{n}} = 0\,,\\
&\text{entropy inequality} && [\![\underline{\mathbf{Q}}/T]\!]\cdot\underline{\mathbf{n}} - (\underline{\rho}\,\underline{\Omega})\,[\![s]\!] \geq 0\,.
\end{aligned} \tag{11.1.37}$$

Here $\underline{\boldsymbol{\tau}} = \det\mathbf{F}\,\boldsymbol{\sigma}\cdot\mathbf{F}^{-\mathrm{T}}$ is the 1st Piola-Kirchhoff stress, and the heat flux $\underline{\mathbf{Q}} = \det\mathbf{F}\,\mathbf{F}^{-1}\cdot\mathbf{Q}$ is transported from the current configuration as indicated by (2.6.13). The updated Lagrange and (totally) Lagrange versions of the Rankine-Hugoniot relation (11.1.21) compare as,

$$\rho\,\Omega^2 = \frac{\mathbf{n}\cdot[\![\boldsymbol{\sigma}]\!]\cdot\mathbf{n}}{\mathbf{n}\cdot[\mathbf{F}]\cdot\mathbf{n}},\quad \underline{\rho}\,\underline{\Omega}^2 = \frac{\mathbf{n}\cdot[\![\underline{\boldsymbol{\tau}}]\!]\cdot\underline{\mathbf{n}}}{\mathbf{n}\cdot[\mathbf{F}]\cdot\underline{\mathbf{n}}}\,. \tag{11.1.38}$$

11.1.4.7 Discontinuity relations of order 1 for a solid: summary

We start by listing the kinematic relation linking the wave-speeds (11.1.5), the three equations of balance across the strong discontinuity (11.1.16), (11.1.20), (11.1.26), and the entropy constraint (11.1.30), namely

$$\begin{aligned}
&\text{kinematic relation} && W = \Omega + \mathbf{v}\cdot\mathbf{n}, \quad [\![W]\!] = 0\,,\\
&\text{balance of mass} && [\![\rho\,\Omega]\!] = 0\,,\\
&\text{balance of momentum} && [\![\boldsymbol{\sigma}]\!]\cdot\mathbf{n} + (\rho\,\Omega)\,[\![\mathbf{v}]\!] = \mathbf{0}\,,\\
&\text{balance of energy} && (\rho\,\Omega)\,[\![u + \tfrac{1}{2}\,\mathbf{v}^2]\!] + [\![\mathbf{v}\cdot\boldsymbol{\sigma} - \mathbf{Q}]\!]\cdot\mathbf{n} = 0\,,\\
&\text{entropy inequality} && [\![\mathbf{Q}/T]\!]\cdot\mathbf{n} - (\rho\,\Omega)\,[\![s]\!] \geq 0\,.
\end{aligned} \tag{11.1.39}$$

Here, $\mathbf{n}$ indicates the direction of the wave displacement, W is the normal speed of displacement of the wave, Ω is the normal speed of propagation of the wave relative to the material in its current configuration, ρ the mass density, T the temperature, $\mathbf{v}$ the particle velocity, u and s the internal energy and the entropy per unit mass respectively. Under adiabatic conditions, the heat flux $\mathbf{Q}$ vanishes.

For definiteness, the domains ahead and behind the wave are denoted by 1 and 2, respectively. With help of (11.1.2) and $(11.1.39)_3$, the jump of internal internal energy $(11.1.39)_4$ may be expressed in the format,

$$(\rho\,\Omega)\,[\![u]\!] + \tfrac{1}{2}\,[\![\mathbf{v}]\!]\cdot(\boldsymbol{\sigma}_1 + \boldsymbol{\sigma}_2)\cdot\mathbf{n} - [\![\mathbf{Q}]\!]\cdot\mathbf{n} = 0\,, \tag{11.1.40}$$

an expression that can be sharpened for an ideal fluid. In fact, when the velocity is decomposed into a contribution along the wave direction $\mathbf{n}$ and a contribution along the orthogonal direction $\mathbf{t}$, then,

$$(\rho\,\Omega)\,[\![u]\!] + \tfrac{1}{2}\,\Big((\rho\,\Omega)\,(w_2 - w_1)\,\mathbf{n} + ([\![\mathbf{v}]\!]\cdot\mathbf{t})\,\mathbf{t}\Big)\cdot(\boldsymbol{\sigma}_1 + \boldsymbol{\sigma}_2)\cdot\mathbf{n} - [\![\mathbf{Q}]\!]\cdot\mathbf{n} = 0\,, \tag{11.1.41}$$

where $w = 1/\rho$ is the specific volume. Since $\underline{\boldsymbol{\tau}} : [\![\mathbf{F}]\!] = -\underline{\Omega}^{-1}\,[\![\mathbf{v}]\!]\cdot\underline{\boldsymbol{\tau}}\cdot\underline{\mathbf{n}}$, the Lagrangian version of the relation (11.1.40) has the form,

$$[\![u]\!] - \frac{1}{2\,\underline{\rho}}\,(\underline{\boldsymbol{\tau}}_1 + \underline{\boldsymbol{\tau}}_2) : [\![\mathbf{F}]\!] - \frac{[\![\underline{\mathbf{Q}}]\!]\cdot\underline{\mathbf{n}}}{\underline{\rho}\,\underline{\Omega}} = 0\,. \tag{11.1.42}$$

Given a state 1 ahead of the wave, the states 2 that satisfy the relations (11.1.40) or (11.1.42) are said to lie on 'the Hugoniot'.

11.1.4.8 Adiabatic Hugoniot curve for an ideal compressible fluid

For an ideal barotropic fluid, the stress $\boldsymbol{\sigma} = -p\,\mathbf{I}$ is isotropic, with $p = p(\rho,\,T)$ the fluid pressure. Consequently, the particle velocity jump is aligned with the propagation direction, namely $[\![\mathbf{v}]\!] = -[\![\Omega]\!]\,\mathbf{n}$. If the working axes are taken to be attached to the wave, namely $W = 0$, then $\mathbf{v}\cdot\mathbf{n} = -\Omega$, and in fact $\mathbf{v} = -\Omega\,\mathbf{n}$. The four entities, namely pressure p, mass density ρ, normal speed Ω and particle velocity $\mathbf{v}$, are thus subjected to the jump relations,

$$\begin{aligned}
&\text{balance of mass} && [\![\rho\,\Omega]\!] = 0\,,\\
&\text{balance of momentum} && [\![\mathbf{v} + \Omega\,\mathbf{n}]\!] = \mathbf{0}, \quad [\![p + \rho\,\Omega^2]\!] = 0\,,\\
&\text{balance of energy} && [\![h + \tfrac{1}{2}\,\Omega^2]\!] = 0\,,\\
&\text{entropy inequality} && [\![s]\!] \leq 0\,.
\end{aligned} \tag{11.1.43}$$

where $h = u + p/\rho$ is the enthalpy per unit mass.

The slope of the 'Rayleigh line' that links the points 1 and 2 is obtained by some manipulations as,

$$-\,(\rho\,\Omega)^2 = \frac{p_2 - p_1}{w_2 - w_1} = 2\,\frac{h_2 - h_1}{w_2^2 - w_1^2}\,. \tag{11.1.44}$$

The first equality in (11.1.44) involves only mass and momentum balances, and is in fact a particular expression of the Rankine-Hugoniot relation (11.1.38) for a fluid. The changes of enthalpy and internal energy across the wave deduce from (11.1.44),

$$h_2 - h_1 = \frac{1}{2}\,(p_2 - p_1)\,(w_1 + w_2), \quad u_2 - u_1 = \frac{1}{2}\,(p_2 + p_1)\,(w_1 - w_2)\,. \tag{11.1.45}$$

Since $dh = w\,dp + T\,ds$, then as a further consequence of (11.1.44),

$$\int_1^2 T\,ds = \frac{1}{2}\,(p_2 - p_1)\,(w_2 + w_1) - \int_1^2 w\,dp = \frac{1}{12}\,w_1''\,(p_2 - p_1)^3 + O\big((p_2 - p_1)^4\big)\,. \tag{11.1.46}$$

The estimation in the right-hand side is obtained through a Taylor expansion of the specific volume $w = w(p) = w_1 + w_1'\,(p - p_1) + w_1''\,(p - p_1)^2/2 + \cdots$ around the pressure p_1. Now, the constitutive relation $w = w(p)$ is assumed to be convex with respect to the origin and it is characterized by the inequalities,

$$0 > \frac{dw}{dp} = -\frac{1}{\rho^2}\,\frac{d\rho}{dp}, \quad 0 < \frac{d^2w}{dp^2} = \frac{2}{\rho^3}\,\Big(\frac{d\rho}{dp}\Big)^2 - \frac{1}{\rho^2}\,\frac{d^2\rho}{dp^2}\,. \tag{11.1.47}$$

The entropy inequality (11.1.43) requires the jump $[\![s]\!] = s_1 - s_2$ to be negative, that is, the entropy *increases* across the wave, $s_2 > s_1$, and in fact the relation applies between any slice of the shock, so that $ds \geq 0$. Therefore, the integral (11.1.46) should be positive, which implies that

only compression waves ($p_2 > p_1$, $\rho_2 > \rho_1$) propagate in a stable manner in a barotropic fluid.

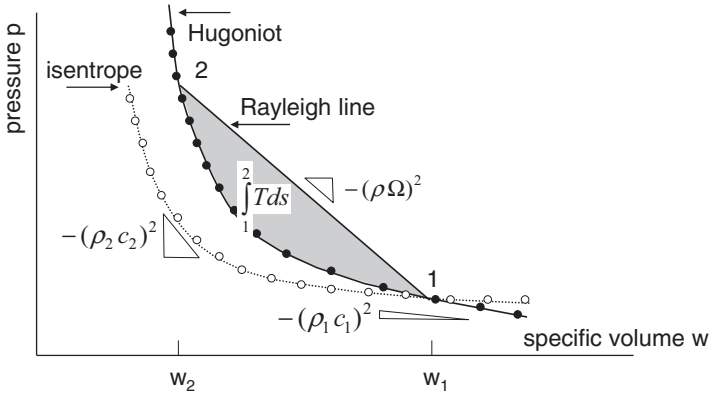

Fig. 11.1.4: Typical relation (Hugoniot) linking the pressure and the specific volume for a barotropic fluid, and Rayleigh line. c speed of sound, Ω wave-speed relative to the material. The grey area delimited by the Rayleigh line and the Hugoniot is equal to $\int_1^2 T\,ds$. Under a compression path where the specific volume decreases from w_1, the Hugoniot is above the isentrope. Under a release where the specific volume increases from w_2, the Hugoniot is below the isentrope.

Let c be the isentropic speed of sound in the fluid, namely $c^2 = dp/d\rho$. The slopes of the curve $p = p(w)$ at points 1 and 2 and of the chord between the two points (the Rayleigh line) in Fig. 11.1.4 may be shown to range in the following order,

$$\frac{dp}{dw}(p_2) = -(\rho\,c)_2^2 < \frac{p_2 - p_1}{w_2 - w_1} = -(\rho\,\Omega)^2 < \frac{dp}{dw}(p_1) = -(\rho\,c)_1^2\,. \tag{11.1.48}$$

Hence, since $\rho\,\Omega$ is continuous, the speed of propagation of the wave is supersonic ahead of the wave, i.e. faster than the sound speed, $\Omega_1 > c_1$, and subsonic behind the wave, i.e., slower than the sound speed, $\Omega_2 < c_2$.

For a perfect gas, the change of enthalpy h across the wave can be expressed as,

$$h_2 - h_1 = c_{\rm p}\,(T_2 - T_1) = \frac{\gamma}{\gamma - 1}\,(p_2\,w_2 - p_1\,w_1)\,, \tag{11.1.49}$$

with $c_{\rm p}$ the heat capacity at constant pressure, and $\gamma > 1$ the adiabatic coefficient, see Section 3.3.2. Insertion of this relation in (11.1.44) yields,

$$\frac{w_2}{w_1} = \frac{(\gamma - 1)\,p_2 + (\gamma + 1)\,p_1}{(\gamma + 1)\,p_2 + (\gamma - 1)\,p_1}\,, \quad \frac{p_2}{p_1} = \frac{(\gamma + 1)\,w_1 - (\gamma - 1)\,w_2}{(\gamma + 1)\,w_2 - (\gamma - 1)\,w_1}\,. \tag{11.1.50}$$

A Taylor expansion shows that the Hugoniot $p = p_{\rm H}(w)$ and the isentrope $p = p_{\rm I}(w)$ differ at 3rd order in the neighborhood $w_2 = w_1 + dw$ of the reference common point (w_1, p_1),

$$p_{\rm H} - p_{\rm I} = \frac{1}{12}\,\gamma\,(\gamma^2 - 1)\left(\frac{dw}{w_1}\right)^3 . \tag{11.1.51}$$

The Hugoniot is above the isentrope for specific volumes lower (pressures higher) than the reference.

11.1.4.9 Nonadiabatic shock wave

If the propagation is not adiabatic, the energy conservation across the wave front,

$$\text{balance of energy} \quad [\![h + \tfrac{1}{2}\,\Omega^2]\!] + q_n = 0\,, \tag{11.1.52}$$

involves the normal heat flux released by the shock per unit mass $q_n = -[\![\mathbf{Q}]\!]\cdot\mathbf{n}/(\rho\,\Omega)$ [unit : J/kg].

The energy output of explosives and fuel oil/air burn ranges from 4 to 5 MJ/kg. Detonation through an explosive involves the propagation of a shock which transforms the unreacted explosive (in a solid form) in front of the wave to gas products (behind the wave). What distinguishes explosives from other materials (say otherwise, explosions from other exothermic reactions) is the rate at which this energy is released, namely the quantity of interest is $[\![\mathbf{Q}]\!]\cdot\mathbf{n}$ [unit : W/m^2] rather than q_n. In fact, for typical explosives, the speed of the shock reaches 6000 to 8000 m/s and the released power is as high as 10^{13} W/m^2 while it is only 10^5 W/m^2 for fuel oil/air burn.

11.1.5 Conservation laws in a mixture with a crossing discontinuity

Across a first order wave front, the equations of balance of mass, momentum, energy and entropy for a saturated porous medium are deduced from the relations for a solid exposed in Sections 11.1.4.1 to 11.1.4.4. As indicated in Section 11.1.4, field (volume) supplies do not contribute to the discontinuity relations as long as their discontinuity (if any) is finite. Still, for each constituent k, additional surface supplies *along* the discontinuity may exist, namely

- a supply of mass $\hat\rho^k_\parallel$;
- a supply of momentum $\hat{\boldsymbol\pi}^k_\parallel$;
- a supply of internal energy $\hat{\mathcal{U}}^k_\parallel$;
- a supply of entropy $\hat{\mathcal{S}}^k_\parallel$.

If the mixture is a closed system, these supplies represent actually internal exchanges among constituents, and they are subjected to closure relations. The supplied mass of the constituent k comes with a velocity $\tilde{\mathbf{v}}_k$, an internal energy $\tilde u_k$, and an entropy $\tilde s_k$ which are not necessarily equal to their existing counterparts $\mathbf{v}_k$, u_k, and s_k at the point of the discontinuity line where they are supplied. These quantities should be specified.

Hadamard's compatibility relations (11.1.9) applied to a *continuous* vector or tensor $\boldsymbol\phi_k(\mathbf{x}, t)$ transform to,

$$\left[\!\!\left[\frac{\partial\boldsymbol\phi_k}{\partial\mathbf{x}}\right]\!\!\right] = \boldsymbol\eta_k\otimes\mathbf{n}\,,\quad \left[\!\!\left[\frac{d^k\boldsymbol\phi_k}{dt}\right]\!\!\right] = -\Omega_k\,\boldsymbol\eta_k\,,\quad \left[\!\!\left[\frac{\partial\boldsymbol\phi_k}{\partial\mathbf{x}}\right]\!\!\right] = -\frac{1}{\Omega_k}\left[\!\!\left[\frac{d^k\boldsymbol\phi_k}{dt}\right]\!\!\right]\otimes\mathbf{n}\,. \tag{11.1.53}$$

In the above relations and in the balance equations listed below for each constituent, the speed of propagation of the discontinuity relative to constituent k is denoted by $\Omega_k = W - \mathbf{v}_k\cdot\mathbf{n}$, W being the absolute speed of displacement of the discontinuity.

The conservation relations are listed below for each constituent:

◦ Balance of mass for constituent k

$$[\![\rho^k\,\Omega_k]\!] + \hat\rho^k_\parallel = 0\,, \tag{11.1.54}$$

subjected to the closure relation

$$\sum_k\ \hat\rho^k_\parallel = 0\,. \tag{11.1.55}$$

◦ Balance of momentum for constituent k

$$[\![\boldsymbol\sigma^k]\!]\cdot\mathbf{n} + (\rho^k\,\Omega_k)\,[\![\mathbf{v}_k]\!] + \hat\rho^k_\parallel\,\tilde{\mathbf{v}}_k + \hat{\boldsymbol\pi}^k_\parallel = \mathbf{0}\,, \tag{11.1.56}$$

subjected to the closure relation

$$\sum_k \hat{\rho}^k_{\|}\,\tilde{\mathbf{v}}_k + \hat{\boldsymbol{\pi}}^k_{\|} = \mathbf{0}\,. \tag{11.1.57}$$

∘ Balance of energy for constituent k

$$[\![(\rho^k\,\Omega_k)\,(u_k + \tfrac{1}{2}\,\mathbf{v}_k^2)]\!] + [\![\mathbf{v}_k\cdot\boldsymbol{\sigma}^k - \mathbf{Q}]\!]\cdot\mathbf{n} + \hat{\rho}^k_{\|}\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2) + \hat{\boldsymbol{\pi}}^k_{\|}\cdot\mathbf{v}_k + \hat{\mathcal{U}}^k_{\|} = 0\,, \tag{11.1.58}$$

subjected to the closure relation,

$$\sum_k \hat{\rho}^k_{\|}\,(\tilde{u}_k + \tfrac{1}{2}\,\tilde{\mathbf{v}}_k^2) + \hat{\boldsymbol{\pi}}^k_{\|}\cdot\mathbf{v}_k + \hat{\mathcal{U}}^k_{\|} = 0\,. \tag{11.1.59}$$

∘ Balance of entropy for constituent k

$$\hat{S}^k_{(\mathrm{i})\|} = [\![\frac{\mathbf{Q}}{T}]\!]\cdot\mathbf{n} - [\![(\rho^k\,\Omega_k)\,s_k]\!] - \hat{\rho}^k_{\|}\,\tilde{s}_k - \hat{\mathcal{S}}^k_{\|} \geq 0\,, \tag{11.1.60}$$

subjected to the closure relation

$$\sum_k \hat{\rho}^k_{\|}\,\tilde{s}_k + \hat{\mathcal{S}}^k_{\|} = 0\,. \tag{11.1.61}$$

Eringen and Ingram [1965] provide in addition the conservation equations at the mixture level.

If the mixture is open, then the right hand sides of the closure relations do not vanish and they are contributed by the surroundings.

11.1.6 Propagation of discontinuities in a solid domain

A singular surface moves through the medium, and carries a certain discontinuity that evolves pointwise in time and space. The topic is examined with care in, e.g., Truesdell and Toupin [1960] and Bowen [1976], from where the brief summary below is extracted.

11.1.6.1 Normal speed of displacement

A moving surface is defined by a sufficiently smooth function $f(\mathbf{x},t)$ and a constant α, say $f(\mathbf{x},t)=\alpha$. If $\boldsymbol{\nabla} f \neq \mathbf{0}$, the unit normal $\mathbf{n}=\mathbf{n}(\mathbf{x},t)$ and the normal speed of displacement $W = W(\mathbf{x},t)$ are defined via the space gradient and time derivative of the function f, namely

$$\mathbf{n}(\mathbf{x},t) = \frac{\boldsymbol{\nabla} f(\mathbf{x},t)}{|\boldsymbol{\nabla} f(\mathbf{x},t)|}, \quad W(\mathbf{x},t) = -\frac{1}{|\boldsymbol{\nabla} f(\mathbf{x},t)|}\frac{\partial f}{\partial t}(\mathbf{x},t)\,. \tag{11.1.62}$$

If both $\partial f/\partial t \neq 0$ and $\boldsymbol{\nabla} f \neq \mathbf{0}$, the normal speed W is non zero and bounded, and it can be assumed to be positive.

11.1.6.2 Displacement derivative

If $\partial f/\partial t \neq 0$ at $(\mathbf{x},t)$, then the relation $f(\mathbf{x},t)=\alpha$ may be inverted to $t = t^*(\mathbf{x},\alpha)$. Now let $\phi(\mathbf{x},t)$ be an arbitrary function of space and time, and let

$$\phi^*(\mathbf{x},\alpha) = \phi(\mathbf{x},t^*)\,. \tag{11.1.63}$$

Then, since $f(\mathbf{x},t)=\alpha$,

$$\begin{aligned} \frac{\partial\phi}{\partial t}(\mathbf{x},t) &= \frac{\partial\phi^*}{\partial\alpha}(\mathbf{x},\alpha)\,\frac{\partial f}{\partial t}(\mathbf{x},t)\,,\\ \boldsymbol{\nabla}\phi(\mathbf{x},t) &= \boldsymbol{\nabla}\phi^*(\mathbf{x},\alpha) + \frac{\partial\phi^*}{\partial\alpha}(\mathbf{x},\alpha)\,\boldsymbol{\nabla} f(\mathbf{x},t)\,. \end{aligned} \tag{11.1.64}$$

Combining the two relations together with the definitions (11.1.62) yields the gradient of $\phi^*(\mathbf{x},\alpha)$,

$$\begin{aligned} \boldsymbol{\nabla}\phi^*(\mathbf{x},\alpha) &= \boldsymbol{\nabla}\phi(\mathbf{x},t) + \frac{\partial\phi}{\partial t}(\mathbf{x},t)\,\frac{\mathbf{n}}{W}\,,\\ \boldsymbol{\nabla}\phi^*(\mathbf{x},\alpha)\cdot(W\,\mathbf{n}) &= \boldsymbol{\nabla}\phi(\mathbf{x},t)\cdot(W\,\mathbf{n}) + \frac{\partial\phi}{\partial t}(\mathbf{x},t)\,. \end{aligned} \tag{11.1.65}$$

The *displacement derivative* is defined as the time derivative following a surface α, namely Truesdell and Toupin [1960], Eqn (179.8),

$$\begin{aligned} \frac{\delta\phi}{\delta t}(\mathbf{x},t) &= \boldsymbol{\nabla}\phi^*(\mathbf{x},\alpha)\cdot(W\,\mathbf{n})\\ &= \frac{\partial\phi}{\partial t}(\mathbf{x},t) + \boldsymbol{\nabla}\phi(\mathbf{x},t)\cdot(W\,\mathbf{n})\,. \end{aligned} \tag{11.1.66}$$

11.1.6.3 Gradient of the jump and jump of the gradient

For any field $\phi(\mathbf{x},t)$ which is differentiable on each side of the discontinuity, the gradient of the jump is equal to the jump of the gradient,

$$(\boldsymbol{\nabla}[\![\phi]\!])(\mathbf{x},t) = [\![\boldsymbol{\nabla}\phi]\!](\mathbf{x},t)\,. \tag{11.1.67}$$

Indeed, let $\mathbf{x}_1$ and $\mathbf{x}_2$ be two points on the discontinuity, and let the domain behind and ahead of the front be denoted by $-$ and $+$, respectively. Then

$$\begin{aligned} & (\phi(\mathbf{x}_2^+,t)-\phi(\mathbf{x}_2^-,t))-(\phi(\mathbf{x}_1^+,t)-\phi(\mathbf{x}_1^-,t)) \\ = \;& (\phi(\mathbf{x}_2^+,t)-\phi(\mathbf{x}_1^+,t))-(\phi(\mathbf{x}_2^-,t)-\phi(\mathbf{x}_1^-,t))\;\square. \end{aligned} \tag{11.1.68}$$

11.1.6.4 Kinematical condition of compatibility

Application of the property (11.1.67) to $\phi^*(\mathbf{x},\alpha)$, with the gradient $\boldsymbol{\nabla}\phi^*(\mathbf{x},\alpha)$ defined by (11.1.65) yields,

$$\begin{aligned} \boldsymbol{\nabla}[\![\phi^*]\!] &= [\![\boldsymbol{\nabla}\phi^*]\!]\,, \\ &= [\![\boldsymbol{\nabla}\phi]\!] + \left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right]\frac{\mathbf{n}}{W}\,. \end{aligned} \tag{11.1.69}$$

From (11.1.66) and (11.1.67),

$$\frac{\delta[\![\phi]\!]}{\delta t} = \boldsymbol{\nabla}[\![\phi^*]\!]\cdot(W\,\mathbf{n}) = [\![\boldsymbol{\nabla}\phi^*]\!]\cdot(W\,\mathbf{n}) = \left[\!\!\left[\frac{\delta\phi}{\delta t}\right]\!\!\right], \tag{11.1.70}$$

results the *kinematical condition of compatibility*, Truesdell and Toupin [1960], Eqn (180.2),

$$\frac{\delta[\![\phi]\!]}{\delta t} = \left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right] + [\![\boldsymbol{\nabla}\phi]\!]\cdot(W\,\mathbf{n})\,. \tag{11.1.71}$$

11.1.6.5 Iterated kinematical compatibility equation for a continuous field

If ϕ is continuous across the wave front, Hadamard's compatibility relations are recovered from (11.1.69) and (11.1.71), namely

$$[\![\boldsymbol{\nabla}\phi]\!] + \left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right]\frac{\mathbf{n}}{W} = \mathbf{0}, \quad \left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right] + [\![\boldsymbol{\nabla}\phi]\!]\cdot(W\,\mathbf{n}) = 0\,. \tag{11.1.72}$$

If the wave front travels at constant speed W in a fixed direction $\mathbf{n}$, the *iterated kinematical compatibility equation* applied to a continuous field $\phi(\mathbf{x},t)$ reads, Truesdell and Toupin [1960], Eqn (181.8),

$$2\,\frac{\delta}{\delta t}\left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right] = \left[\!\!\left[\frac{\partial^2\phi}{\partial t^2}\right]\!\!\right] - W^2\,\mathbf{n}\cdot[\![\boldsymbol{\nabla}^2\phi]\!]\cdot\mathbf{n}\,. \tag{11.1.73}$$

The proof starts from (11.1.71),

$$\begin{aligned} \frac{\delta}{\delta t}\left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right] &= \left[\!\!\left[\frac{\partial^2\phi}{\partial t^2}\right]\!\!\right] + \left[\!\!\left[\boldsymbol{\nabla}\Big(\frac{\partial\phi}{\partial t}\Big)\right]\!\!\right]\cdot(W\,\mathbf{n}) \\ \frac{\delta[\![\boldsymbol{\nabla}\phi]\!]}{\delta t} &= \left[\!\!\left[\frac{\partial}{\partial t}(\boldsymbol{\nabla}\phi)\right]\!\!\right] + [\![\boldsymbol{\nabla}^2\phi]\!]\cdot(W\,\mathbf{n}) \\ \frac{\delta}{\delta t}\left[\!\!\left[\frac{\partial\phi}{\partial t}\right]\!\!\right] - \frac{\delta[\![\boldsymbol{\nabla}\phi]\!]}{\delta t}\cdot(W\,\mathbf{n}) &= \left[\!\!\left[\frac{\partial^2\phi}{\partial t^2}\right]\!\!\right] - W^2\,\mathbf{n}\cdot[\![\boldsymbol{\nabla}^2\phi]\!]\cdot\mathbf{n}\,. \end{aligned} \tag{11.1.74}$$

The last step of the proof consists in using Hadamard's compatibility relation $(11.1.72)_2$ which applies since ϕ is continuous and to take its displacement derivative at constant W and $\mathbf{n}$.

11.1.6.6 Induced discontinuity for a continuous field

The displacement $\mathbf{u}$, its time derivative $\mathbf{v} = \partial\mathbf{u}/\partial t$ and space derivative $\boldsymbol{\nabla}\mathbf{u}$ remain continuous across the front of an acceleration wave. Repetitive applications of Hadamard's compatibility relations to the velocity and displacement gradient, namely

$$\begin{aligned} [\![\mathbf{v}]\!] &= \mathbf{0}; \qquad [\![\boldsymbol{\nabla}\mathbf{u}]\!] = \mathbf{0}; \\ [\![\boldsymbol{\nabla}\mathbf{v}]\!] &= -\left[\!\!\left[\frac{\partial \mathbf{v}}{\partial t}\right]\!\!\right] \otimes \frac{\mathbf{n}}{W}, \\ [\![\boldsymbol{\nabla}(\boldsymbol{\nabla}\mathbf{u})]\!] &= -\left[\!\!\left[\frac{\partial (\boldsymbol{\nabla}\mathbf{u})}{\partial t}\right]\!\!\right] \otimes \frac{\mathbf{n}}{W} = -\left[\!\!\left[\boldsymbol{\nabla}\Big(\frac{\partial \mathbf{u}}{\partial t}\Big)\right]\!\!\right] \otimes \frac{\mathbf{n}}{W} = \left[\!\!\left[\frac{\partial^2 \mathbf{u}}{\partial t^2}\right]\!\!\right] \otimes \frac{\mathbf{n}}{W} \otimes \frac{\mathbf{n}}{W}, \end{aligned} \tag{11.1.75}$$

lead to the definition of the induced discontinuity,

$$[\![\boldsymbol{\nabla}^2\mathbf{u}]\!] = \left[\!\!\left[\frac{\partial^2 \mathbf{u}}{\partial t^2}\right]\!\!\right] \otimes \frac{\mathbf{n}}{W} \otimes \frac{\mathbf{n}}{W}, \quad \left[\!\!\left[\frac{\partial^2 u_k}{\partial x_i \partial x_j}\right]\!\!\right] = \left[\!\!\left[\frac{\partial^2 u_k}{\partial t^2}\right]\!\!\right] \frac{n_i}{W} \frac{n_j}{W}, \tag{11.1.76}$$

and to the relations,

$$\begin{aligned} \left[\!\!\left[\frac{\partial^2 \mathbf{u}}{\partial t^2}\right]\!\!\right] &= W^2\, \mathbf{n} \cdot [\![\boldsymbol{\nabla}^2\mathbf{u}]\!] \cdot \mathbf{n}, \\ [\![\boldsymbol{\nabla}\mathrm{div}\, \mathbf{u}]\!] &= \left(\left[\!\!\left[\frac{\partial^2 \mathbf{u}}{\partial t^2}\right]\!\!\right] \cdot \frac{\mathbf{n}}{W} \right) \frac{\mathbf{n}}{W}, \\ [\![\mathrm{div}\, \boldsymbol{\nabla}\mathbf{u}]\!] &= \left[\!\!\left[\frac{\partial^2 \mathbf{u}}{\partial t^2}\right]\!\!\right] \frac{1}{W^2}. \end{aligned} \tag{11.1.77}$$

11.2 Waves in elastic solids

In a linearized analysis, no difference is made between material and partial derivatives, $d(\ )/dt$ and $\partial(\ )/\partial t$ respectively, and they will be denoted collectively by a superimposed dot $\dot{(\ )}$. As a consequence, the normal speed of displacement W, the speed of propagation relative to the material Ω and the wave-speed c are not distinguished either, and they will be denoted collectively by c.

11.2.1 Jump relations for acceleration waves

Consider a second order, or acceleration, wave front with normal $\mathbf{n}(\mathbf{x}, t)$ which moves with speed c relative to the material. At any point $\mathbf{x}$ and at any time t, the velocity $\mathbf{v}(\mathbf{x}, t)$, the stress $\boldsymbol{\sigma}(\mathbf{x}, t)$, and the mass density $\rho(\mathbf{x}, t)$ remain continuous across the wave front. Therefore, Hadamard's compatibility relations apply to these entities.

11.2.1.1 Hadamard's compatibility relations for second order discontinuities

Hadamard's compatibility relations imply that the jump $[\![\partial\mathbf{v}/\partial\mathbf{x}]\!]$ of the velocity gradient and the jump $[\![\dot{\mathbf{v}}]\!]$ of the acceleration across the wave front are not independent: there exists a discontinuity vector $\boldsymbol{\eta}{=}\boldsymbol{\eta}(\mathbf{x}, t)$ which can be viewed as the jump of the velocity gradient along the normal $\mathbf{n}$, i.e., $\boldsymbol{\eta}{=}[\![\partial\mathbf{v}/\partial(\mathbf{x}\cdot\mathbf{n})]\!]$, such that

$$\left[\!\!\left[\frac{\partial \mathbf{v}}{\partial \mathbf{x}}\right]\!\!\right] = \boldsymbol{\eta} \otimes \mathbf{n}, \quad [\![\dot{\mathbf{v}}]\!] = -c\, \boldsymbol{\eta}. \tag{11.2.1}$$

Similarly with $\boldsymbol{\zeta} = [\![\partial\boldsymbol{\sigma}/\partial(\mathbf{x}\cdot\mathbf{n})]\!]$, the normal jump of the stress gradient satisfies the relations,

$$\left[\!\!\left[\frac{\partial \boldsymbol{\sigma}}{\partial \mathbf{x}}\right]\!\!\right] = \boldsymbol{\zeta} \otimes \mathbf{n}, \quad [\![\dot{\boldsymbol{\sigma}}]\!] = -c\, \boldsymbol{\zeta}. \tag{11.2.2}$$

Consequently, if the body force per unit mass $\mathbf{b}$ is continuous, taking the jump of the balance of linear momentum,

$$\mathrm{div}\, \boldsymbol{\sigma} + \rho\, (\mathbf{b} - \dot{\mathbf{v}}) = \mathbf{0}, \tag{11.2.3}$$

yields $\mathbf{n}\cdot\boldsymbol{\zeta} = -\rho\, c\, \boldsymbol{\eta}$, that is, the jump of the traction rate is aligned with the normal jump of the velocity gradient,

$$\mathbf{n} \cdot [\![\dot{\boldsymbol{\sigma}}]\!] = \rho\, c^2\, \boldsymbol{\eta}. \tag{11.2.4}$$

11.2.1.2 Acoustic tensor, wave-speeds and eigenmodes

Let us consider a material whose constitutive equation in rate form writes

$$\dot{\boldsymbol{\sigma}} = \mathbb{E} : \dot{\boldsymbol{\epsilon}} \,. \tag{11.2.5}$$

Insertion of the rate constitutive equations (11.2.5) in the jump relation (11.2.4) yields an eigenvalue problem for the jump $\boldsymbol{\eta}$ that features the wave-speed c:

$$[\mathbf{A}(\mathbf{n}) - c^2\,\mathbf{I}] \cdot \boldsymbol{\eta} = \mathbf{0} \,. \tag{11.2.6}$$

Here $\mathbf{A} = \mathbf{A}(\mathbf{n})$ denotes the acoustic tensor[11.3],

$$\mathbf{A}(\mathbf{n}) = \mathbf{n} \cdot \frac{\mathbb{E}}{\rho} \cdot \mathbf{n} \,, \quad A_{ij} = \frac{1}{\rho}\, n_k\, \mathbb{E}_{kilj}\, n_l \,. \tag{11.2.7}$$

11.2.2 Acceleration waves in linear isotropic materials

If the rate tensor moduli $\mathbb{E}$ in (11.2.5) is constant, the material response is linear. The acoustic tensor $\mathbf{A}(\mathbf{n})$ associated with linear isotropic elasticity takes the form,

$$\mathbf{A}(\mathbf{n}) = (c_{\rm L})^2\, \mathbf{n} \otimes \mathbf{n} + (c_{\rm S})^2\, (\mathbf{I} - \mathbf{n} \otimes \mathbf{n}) \,, \tag{11.2.8}$$

which shows explicitly that there exists a single longitudinal wave with eigenmode $\boldsymbol{\eta} \sim \mathbf{n}$ and with speed $c_{\rm L}$, and two shear waves with $\boldsymbol{\eta} \sim \mathbf{n}^{\perp}$ with common speed $c_{\rm S}$, where

$$c_{\rm L}^2 = \frac{\lambda + 2\,\mu}{\rho} > c_{\rm S}^2 = \frac{\mu}{\rho} > 0 \,. \tag{11.2.9}$$

The above inequalities are consequences of the positive definiteness of the elastic tensor $\mathbb{E}$, Eqn (5.2.30). As far as terminology is concerned, the longitudinal wave is also termed dilatational, and the shear wave is also called rotational or distortional.

Setting $\boldsymbol{\epsilon} = \frac{1}{2}(\mathbf{m} \otimes \mathbf{n} + \mathbf{n} \otimes \mathbf{m})$ in $\boldsymbol{\epsilon} : \mathbb{E} : \boldsymbol{\epsilon}$ shows that positive definiteness of the elastic tensor implies positive definiteness of the elastic acoustic tensor, a property referred to as *strong ellipticity* (SE), and the wave-speeds are real positive. This property holds independently of the material symmetries. For isotropic elasticity,

$$\text{(SE)} \;\; \text{of} \;\; \mathbb{E} \;\; \Leftrightarrow \;\; \mathbf{m} \cdot \mathbf{A}(\mathbf{n}) \cdot \mathbf{m} = c_{\rm S}^2 + \left(c_{\rm L}^2 - c_{\rm S}^2\right) (\mathbf{m} \cdot \mathbf{n})^2 > 0 \,, \quad \forall\, \mathbf{m} \text{ and } \mathbf{n} \text{ unit vectors} \,. \tag{11.2.10}$$

Since $\mathbb{E}$ is endowed with the major symmetry, its strong ellipticity is equivalent to its *ellipticity* (E), or, in other words, the positive definiteness of the elastic acoustic tensor implies its invertibility:

$$\text{(E) of } \mathbb{E} \quad \Leftrightarrow \quad \det \mathbf{A}(\mathbf{n}) = c_{\rm L}^2\, (c_{\rm S}^2)^2 \neq 0 \,, \quad \forall\, \mathbf{n} \text{ unit vector} \,. \tag{11.2.11}$$

Note that the elastic acoustic tensor (11.2.8) is, to within a multiplicative term, a rank one modification of the identity, as defined in Section 2.3.5. Therefore it remains form-invariant when raised to any power $a \in \mathbb{R}$,

$$\big(\mathbf{A}(\mathbf{n})\big)^a = (c_{\rm L}^2)^a\, \mathbf{n} \otimes \mathbf{n} + (c_{\rm S}^2)^a\, (\mathbf{I} - \mathbf{n} \otimes \mathbf{n}) \,. \tag{11.2.12}$$

11.2.3 Acoustic tensor of a linear elastic orthotropic material

With the stiffness matrix in component form (5.2.39), the acoustic tensor (11.2.7) expresses componentwise in the orthotropy axes $\mathbf{e}_a$,

$$\rho\, A_{jl} = \frac{\lambda_{ab}}{2}\, n_a\, n_b\, (e_{aj}\, e_{bl} + e_{bj}\, e_{al}) + \frac{\mu_a}{2}\, (n_a^2\, I_{jl} + n_a\, (n_j\, e_{al} + n_l\, e_{aj}) + e_{aj}\, e_{al}) \,, \tag{11.2.13}$$

or in matrix form, via the notation (5.2.41),

$$\rho\, \mathbf{A} = \begin{bmatrix} c_{11}\, n_1^2 + c_{66}\, n_2^2 + c_{55}\, n_3^2 & (c_{12} + c_{66})\, n_1\, n_2 & (c_{13} + c_{55})\, n_1\, n_3 \\ (c_{12} + c_{66})\, n_1\, n_2 & c_{22}\, n_2^2 + c_{66}\, n_1^2 + c_{44}\, n_3^2 & (c_{23} + c_{44})\, n_2\, n_3 \\ (c_{13} + c_{55})\, n_1\, n_3 & (c_{23} + c_{44})\, n_2\, n_3 & c_{55}\, n_1^2 + c_{44}\, n_2^2 + c_{33}\, n_3^2 \end{bmatrix} . \tag{11.2.14}$$

[11.3] At first glance, the acoustic tensor does not look like the product of a fourth order tensor by a second order tensor. Now consider the tensor $\rho\, \tilde{A}_{ij} = \tilde{E}_{ijkl}\, n_k\, n_l$ with $\tilde{E}_{ijkl} = \frac{1}{2}\, (E_{ikjl} + E_{iljk})$. Then $\rho\, \tilde{\mathbf{A}} = \tilde{\mathbb{E}} : (\mathbf{n} \otimes \mathbf{n})$ and $\mathbf{A} = \tilde{\mathbf{A}}$, Norris [2006].

11.2.4 Acoustic tensor of a linear transversely isotropic material

The elastic material displays transverse isotropy around the axis $\mathbf{e}_3$, and the stiffness $\mathbb{E}$ is assumed to be positive definite. With the notation (5.2.51), the acoustic tensor (11.2.14) specializes to

$$\rho\,\mathbf{A} = \begin{bmatrix} c_{11}\,n_1^2 + \frac{1}{2}(c_{11}-c_{12})\,n_2^2 + c_{44}\,n_3^2 & \frac{1}{2}(c_{11}+c_{12})\,n_1\,n_2 & (c_{13}+c_{44})\,n_1\,n_3 \\ \frac{1}{2}(c_{11}+c_{12})\,n_1\,n_2 & c_{11}\,n_2^2 + \frac{1}{2}(c_{11}-c_{12})\,n_1^2 + c_{44}\,n_3^2 & (c_{13}+c_{44})\,n_2\,n_3 \\ (c_{13}+c_{44})\,n_1\,n_3 & (c_{13}+c_{44})\,n_2\,n_3 & c_{44}\,(n_1^2+n_2^2) + c_{33}\,n_3^2 \end{bmatrix} . \tag{11.2.15}$$

Alternatively, one may start from the expression of $\mathbb{E}$ given in (5.E.27) in terms of the coefficients a's. The positive definiteness conditions (5.E.31) where the coefficients c's are defined by (5.E.28) restrict the coefficients a's. The acoustic tensor can be cast into the tensor form,

$$\rho\,\mathbf{A} = \alpha_1\,\mathbf{I} + \alpha_2\,\mathbf{n}\otimes\mathbf{n} + \alpha_3\,(\mathbf{e}_3\otimes\mathbf{n} + \mathbf{n}\otimes\mathbf{e}_3) + \alpha_4\,\mathbf{e}_3\otimes\mathbf{e}_3 \tag{11.2.16}$$

which involves the four scalars α_i, $i\in[1,4]$:

$$\alpha_1 = \frac{a_2}{2} + \frac{a_5}{2}(\mathbf{e}_3\cdot\mathbf{n})^2 > 0,\quad \alpha_2 = a_1 + \frac{a_2}{2},\quad \alpha_3 = \Big(a_3 + \frac{a_5}{2}\Big)(\mathbf{e}_3\cdot\mathbf{n}),\quad \alpha_4 = \frac{a_5}{2} + a_4(\mathbf{e}_3\cdot\mathbf{n})^2\,. \tag{11.2.17}$$

The sign of α_1 is implied by the positive definiteness of the elastic stiffness. The determinant of the acoustic tensor can be factorized as $\det(\rho\,\mathbf{A}) = \alpha_1\,\Delta$, and thus

$$\Delta = (\alpha_1 + \alpha_4 + \alpha_3\,(\mathbf{e}_3\cdot\mathbf{n}))\,(\alpha_1 + \alpha_2 + \alpha_3\,(\mathbf{e}_3\cdot\mathbf{n})) - (\alpha_3 + \alpha_4\,(\mathbf{e}_3\cdot\mathbf{n}))\,(\alpha_3 + \alpha_2\,(\mathbf{e}_3\cdot\mathbf{n})) > 0\,, \tag{11.2.18}$$

is strictly positive as well for all directions $\mathbf{n}$.

The inverse of the elastic acoustic tensor takes a form similar to that of the acoustic tensor itself:

$$\det(\rho\,\mathbf{A})\;(\rho\,\mathbf{A})^{-1} = \beta_1\,\mathbf{I} + \beta_2\,\mathbf{n}\otimes\mathbf{n} + \beta_3\,(\mathbf{e}_3\otimes\mathbf{n} + \mathbf{n}\otimes\mathbf{e}_3) + \beta_4\,\mathbf{e}_3\otimes\mathbf{e}_3 \tag{11.2.19}$$

with

$$\begin{gathered} \beta_1 = \Delta,\quad \beta_2 = -\alpha_2\,(\alpha_1+\alpha_4) + \alpha_3^2, \\ \beta_3 = -\alpha_1\,\alpha_3 + (\alpha_2\,\alpha_4 - \alpha_3^2)\,(\mathbf{e}\cdot\mathbf{n}),\quad \beta_4 = -\alpha_4\,(\alpha_1+\alpha_2) + \alpha_3^2. \end{gathered} \tag{11.2.20}$$

11.2.5 Acceleration waves in materials with fabric anisotropy

11.2.5.1 Materials with fabric anisotropy: the eigenvalue problem

Materials with fabric anisotropy defined by a symmetric, positive definite, second order tensor $\mathbf{B}$ are described in Section 5.2.11. The acoustic tensor $\mathbf{A}(\mathbf{n})$ associated with the elastic tensor $\mathbb{E}$, Eqn (5.2.72), takes the form,

$$\mathbf{A}(\mathbf{n}) = \frac{\lambda+\mu}{\rho}\,\mathbf{B}\cdot\mathbf{n}\otimes\mathbf{B}\cdot\mathbf{n} + \frac{\mu}{\rho}\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mathbf{B}\,. \tag{11.2.21}$$

For $\mathbf{B}=\mathbf{I}$, $\mathbf{A}(\mathbf{n})$ boils down to the isotropic acoustic tensor $\mathbf{A}^{\rm iso}(\mathbf{n})$, associated with the isotropic tensor moduli $\mathbb{E}^{\rm iso}$. It is given by (11.2.8), and can be recast in the form,

$$\mathbf{A}^{\rm iso}(\mathbf{n}) = \frac{\lambda+\mu}{\rho}\,\mathbf{n}\otimes\mathbf{n} + \frac{\mu}{\rho}\,\mathbf{I}\,. \tag{11.2.22}$$

Since the elastic tensors $\mathbb{E}^{\rm iso}$ and $\mathbb{E}$ are assumed to be positive definite, they are strongly elliptic and therefore the associated acoustic tensors are positive definite. Thus, they are invertible, indeed

$$\det\mathbf{A}(\mathbf{n}) = \det\mathbf{B}\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})^3\,(\frac{\mu}{\rho})^2\,\frac{\lambda+2\mu}{\rho} \tag{11.2.23}$$

and

$$\mathbf{A}^{-1}(\mathbf{n}) = -\frac{\rho}{\mu}\frac{\lambda+\mu}{\lambda+2\mu}\frac{\mathbf{n}\otimes\mathbf{n}}{(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})^2} + \frac{\rho}{\mu}\frac{\mathbf{B}^{-1}}{\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n}}\,. \tag{11.2.24}$$

Let us consider an acceleration wave that propagates through the elastic material in a direction $\mathbf{n}$. The propagation is governed by the eigenvalue problem, Eqn (11.2.6),

$$[\mathbf{A}(\mathbf{n}) - c^2\,\mathbf{I}]\cdot\boldsymbol{\eta} = \mathbf{0}, \tag{11.2.25}$$

where c is the normal wave-speed and $\boldsymbol{\eta}$ the mode of propagation.

It is instrumental to introduce the modified entities,

$$\tilde{\mathbf{n}} = \frac{\mathbf{B}^{\frac{1}{2}}\cdot\mathbf{n}}{\|\,\mathbf{B}^{\frac{1}{2}}\,\mathbf{n}\,\|}\,, \quad \tilde{\boldsymbol{\eta}} = \mathbf{B}^{\frac{1}{2}}\cdot\boldsymbol{\eta}\,. \tag{11.2.26}$$

Let

$$\mathbf{B} = \sum_{i=1}^{3} b_i\,\mathbf{B}_i, \quad \text{with } \mathbf{B}_i \equiv \mathbf{b}_i\otimes\mathbf{b}_i\,, \tag{11.2.27}$$

be the spectral representation of the fabric tensor $\mathbf{B}$. Its square root $\mathbf{B}^{\frac{1}{2}}$ can be given an explicit expression,

$$\mathbf{B} = \mathbf{B}^{\frac{1}{2}}\cdot\mathbf{B}^{\frac{1}{2}}, \quad \mathbf{B}^{\frac{1}{2}} = \sum_{i=1}^{3}\sqrt{b_i}\,\mathbf{B}_i\,, \tag{11.2.28}$$

but an alternative expression has been proposed in Section 2.3.6.

The elastic acoustic tensor can then be recast in terms of its underlying isotropic counterpart,

$$\mathbf{A}(\mathbf{n}) = (\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\;\mathbf{B}^{\frac{1}{2}}\cdot\mathbf{A}^{\text{iso}}(\tilde{\mathbf{n}})\cdot\mathbf{B}^{\frac{1}{2}}\,. \tag{11.2.29}$$

The strong ellipticity property of the underlying isotropic tensor is inherited by the anisotropic tensor. Indeed, let $\mathbf{x}\neq\mathbf{0}$ be an arbitrary vector, and $\tilde{\mathbf{x}} = \mathbf{B}^{\frac{1}{2}}\cdot\mathbf{x}$. Then, from (11.2.29),

$$\mathbf{x}\cdot\mathbf{A}(\mathbf{n})\cdot\mathbf{x} = (\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\;\tilde{\mathbf{x}}\cdot\mathbf{A}^{\text{iso}}(\tilde{\mathbf{n}})\cdot\tilde{\mathbf{x}} > 0\,. \tag{11.2.30}$$

With help of (11.2.29), the eigenvalue problem for the wave-speeds (11.2.25) can be transformed to a generalized eigenvalue problem relying on the *isotropic* elastic acoustic tensor, Bigoni and Loret [1999],

$$\left[\mathbf{A}^{\text{iso}}(\tilde{\mathbf{n}}) - c^2\frac{\mathbf{B}^{-1}}{\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n}}\right]\cdot\tilde{\boldsymbol{\eta}} = \mathbf{0}\,. \tag{11.2.31}$$

11.2.5.2 Materials with fabric anisotropy: wave-speeds

In the orthotropy axes, i.e. eigendirections of $\mathbf{B}$, the acoustic tensor (11.2.14) becomes,

$$\rho\,\mathbf{A} = \begin{bmatrix} (\lambda+\mu)\,b_1^2\,n_1^2 + (\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mu\,b_1 & (\lambda+\mu)\,b_1\,b_2\,n_1\,n_2 & (\lambda+\mu)\,b_1\,b_3\,n_1\,n_3 \\ (\lambda+\mu)\,b_1\,b_2\,n_1\,n_2 & (\lambda+\mu)\,b_2^2\,n_2^2 + (\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mu\,b_2 & (\lambda+\mu)\,b_2\,b_3\,n_2\,n_3 \\ (\lambda+\mu)\,b_1\,b_3\,n_1\,n_3 & (\lambda+\mu)\,b_2\,b_3\,n_2\,n_3 & (\lambda+\mu)\,b_3^2\,n_3^2 + (\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mu\,b_3 \end{bmatrix}. \tag{11.2.32}$$

The squares of the wave-speeds are the roots of the cubic equation,

$$(c^2)^3 - a_1\,(c^2)^2 + a_2\,c^2 - a_3 = 0\,, \tag{11.2.33}$$

where the coefficients a are defined by the expressions,

$$\begin{aligned} \rho\;a_1 &= (\lambda+\mu)\,(\mathbf{n}\cdot\mathbf{B}^2\cdot\mathbf{n}) + \mu\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\text{tr}\,\mathbf{B}\,, \\ \rho^2\,a_2 &= \mu\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\left((\lambda+2\,\mu)\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,I_2(\mathbf{B}) - (\lambda+\mu)\,I_3(\mathbf{B})\right), \\ \rho^3\,a_3 &= \mu^2\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})^3\,(\lambda+2\,\mu)\,I_3(\mathbf{B})\,. \end{aligned} \tag{11.2.34}$$

The Cayley-Hamilton relation has been used to establish these expressions, namely

$$\mathbf{B}^3 - I_1(\mathbf{B})\,\mathbf{B}^2 + I_2(\mathbf{B})\,\mathbf{B} - I_3(\mathbf{B})\,\mathbf{I} = \mathbf{0}\,, \tag{11.2.35}$$

where $I_1(\mathbf{B}) = \operatorname{tr}\mathbf{B}$, $I_2(\mathbf{B}) = ((\operatorname{tr}\mathbf{B})^2 - \operatorname{tr}\mathbf{B}^2)/2$, and $I_3(\mathbf{B}) = \det\mathbf{B}$ are the three isotropic scalar invariants of $\mathbf{B}$, Section 2.2.

The eigenvectors $\boldsymbol{\eta}$ satisfy the relations,

$$\begin{aligned} \rho\,\mathbf{A}\cdot\boldsymbol{\eta} &= (\lambda+\mu)\,(\boldsymbol{\eta}\cdot\mathbf{B}\cdot\mathbf{n})\,\mathbf{B}\cdot\mathbf{n} + \mu\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mathbf{B}\cdot\boldsymbol{\eta} = \rho\,c^2\,\boldsymbol{\eta}\,,\\ \boldsymbol{\eta} &= (\lambda+\mu)\,(\boldsymbol{\eta}\cdot\mathbf{B}\cdot\mathbf{n})\left(\rho\,c^2\,\mathbf{I} - \mu\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mathbf{B}\right)^{-1}\cdot\mathbf{B}\cdot\mathbf{n}\,. \end{aligned} \tag{11.2.36}$$

The tensor to be inverted can be expressed, once again via the Cayley-Hamilton relation, in terms of $\mathbf{I}$, $\mathbf{B}$, $\mathbf{B}^2$. Thus the eigenmode $\boldsymbol{\eta}$ can be expressed as $(\alpha\,\mathbf{I} + \beta\,\mathbf{B} + \gamma\,\mathbf{B}^2)\cdot\mathbf{n}$. The coefficients α, β, γ are obtained by re-insertion of the latter expression in $(11.2.36)_1$, yielding finally

$$\boldsymbol{\eta} \simeq \left(I_3(\mathbf{B})\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\frac{\mu}{\rho\,c^2}\,\mathbf{I} + (\frac{\rho\,c^2}{\mu}\,\frac{1}{(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})} - I_1(\mathbf{B}))\,\mathbf{B} + \mathbf{B}^2\right)\cdot\mathbf{n}\,. \tag{11.2.37}$$

Observe, from $(11.2.36)_1$, that, unless $\mathbf{B} = \mathbf{I}$, there is no longitudinal wave in directions distinct from the orthotropy axes, since $\rho\,\mathbf{A}\cdot\mathbf{n} = (\lambda + 2\,\mu)\,(\mathbf{n}\cdot\mathbf{B}\cdot\mathbf{n})\,\mathbf{B}\cdot\mathbf{n}$.

In the orthotropy directions $\mathbf{b}_i$, $i \in [1,3]$, the analysis is elementary,

$$\mathbf{n} = \mathbf{b}_i,\ i\in[1,3]\ :\ \begin{cases} \boldsymbol{\eta} = \mathbf{b}_i, & \rho\,c^2 = (\lambda+2\,\mu)\,b_i^2: & \text{longitudinal wave-speed,}\\ \boldsymbol{\eta} = \mathbf{b}_j,\ j\neq i, & \rho\,c^2 = \mu\,b_i\,b_j: & \text{shear wave-speed.} \end{cases} \tag{11.2.38}$$

11.2.6 Wave motions and Helmholtz potentials in isotropic elastic solids

This section addresses infinitesimal deformations of an elastic solid with Lamé moduli λ and μ and makes no distinction between the partial and total derivatives with respect to time which are both denoted by a superimposed dot. In presence of a body force per unit mass $\mathbf{b}$, the equations of balance of momentum express in terms of the displacement vector $\mathbf{u}$ in the format,

$$(\lambda+\mu)\,\boldsymbol{\nabla}\,\operatorname{div}\,\mathbf{u} + \mu\,\Delta\,\mathbf{u} + \rho\,\mathbf{b} = \rho\,\ddot{\mathbf{u}}\,, \tag{11.2.39}$$

where $\Delta = \boldsymbol{\nabla}\operatorname{div} - \boldsymbol{\nabla}\wedge(\boldsymbol{\nabla}\wedge)$ is the Laplacian operator.

As indicated in Section 2.4.1.1, the displacement vector can be defined in terms of two potentials, referred to as Helmholtz potentials, namely a scalar potential ϕ contributing an irrotational vector field, and a vector potential $\boldsymbol{\psi}$ contributing the solenoidal part,

$$\mathbf{u} = \boldsymbol{\nabla}\phi + \boldsymbol{\nabla}\wedge\,\boldsymbol{\psi}\,,\quad u_k = \frac{\partial\phi}{\partial x_k} + e_{krs}\,\frac{\partial\psi_s}{\partial x_r}\,. \tag{11.2.40}$$

Since the displacement vector has three independent components, a restriction is imposed on the two potential functions, namely $\operatorname{div}\boldsymbol{\psi} = 0$.

With help of (2.4.4) and (2.4.5),

$$\begin{aligned} &e = \operatorname{div}\,\mathbf{u} = \Delta\phi,\quad \boldsymbol{\omega} = \frac{1}{2}\,\boldsymbol{\nabla}\wedge\mathbf{u} = -\frac{1}{2}\,\Delta\boldsymbol{\psi}\\ &\Delta\mathbf{u} = (\boldsymbol{\nabla}\operatorname{div} - \boldsymbol{\nabla}\wedge\,\boldsymbol{\nabla}\wedge)\,\mathbf{u} = \boldsymbol{\nabla}\Delta\phi + \boldsymbol{\nabla}\wedge(\Delta\boldsymbol{\psi})\,. \end{aligned} \tag{11.2.41}$$

In an infinitesimal strain context, e is interpreted as the volume change. We may also adopt the Helmholtz decomposition for the body force $\mathbf{b} = \boldsymbol{\nabla}b_{\text{L}} + \boldsymbol{\nabla}\wedge\mathbf{b}_{\text{S}}$ with $\operatorname{div}\mathbf{b}_{\text{S}} = 0$, see Achenbach [1975] for justifications. Then the fact that the balance of momentum may be recast in terms of the potentials,

$$(\lambda+2\,\mu)\,\boldsymbol{\nabla}\,\Delta\phi + \mu\,\boldsymbol{\nabla}\wedge\Delta\boldsymbol{\psi} + \rho\,(\boldsymbol{\nabla}b_{\text{L}} + \boldsymbol{\nabla}\wedge\,\mathbf{b}_{\text{S}}) = \rho\,(\boldsymbol{\nabla}\ddot{\phi} + \boldsymbol{\nabla}\wedge\,\ddot{\boldsymbol{\psi}})\,, \tag{11.2.42}$$

motivates a split in a longitudinal (irrotational) part and in a rotational (solenoidal) part, namely

$$\ddot{\phi} - c_{\text{L}}^2\,\Delta\,\phi = b_{\text{L}}\,,\quad \ddot{\boldsymbol{\psi}} - c_{\text{S}}^2\,\Delta\,\boldsymbol{\psi} = \mathbf{b}_{\text{S}}\,. \tag{11.2.43}$$

Note that the above equations hold as well for e and $\boldsymbol{\omega}$,

$$\ddot{e} - c_{\text{L}}^2\,\Delta\,e = \Delta\,b_{\text{L}}\,,\quad \ddot{\boldsymbol{\omega}} - c_{\text{S}}^2\,\Delta\,\boldsymbol{\omega} = -\frac{1}{2}\,\Delta\,\mathbf{b}_{\text{S}}\,. \tag{11.2.44}$$

These relations indicate that the dilatational wave associated with the scalar potential ϕ propagates at speed c_{L} while the shear wave propagates at speed c_{S}. The split implies that the two motions are independent. In general however, the two potentials are coupled via boundary conditions.

11.3 Acceleration waves in thermoelastic solids

The state variables defining the thermoelastic solids considered are the strain and the temperature. Heat conductors and non conductors enjoy distinct, although parallel, dynamic properties which may be compared systematically.

11.3.1 Acceleration waves in solid conductors obeying Fourier's heat law

The thermal conduction obeys Fourier's heat law, namely $\mathbf{Q} = -\mathbf{k}_{\mathrm{T}} \cdot \boldsymbol{\nabla} T$, where the thermal conductivity $\mathbf{k}_{\mathrm{T}}$ is a strictly positive definite symmetric second order tensor.

According to Proposition 11.1, the temperature is continuous across a first order wave front propagating at speed $c \neq 0$ in a Fourier's heat conductor. The property holds as well across a second order wave front, by which we are concerned here. Consequently, the state variables are continuous, and so are the internal energy, entropy, stress and velocity. The jump of energy (11.1.26) reduces to,

$$[\![\mathbf{Q}]\!] \cdot \mathbf{n} = 0\,. \tag{11.3.1}$$

Since the temperature is continuous, Hadamard's compatibility relations (11.1.7) apply and imply that the jump of its gradient is aligned with the normal to the wave front, namely $[\![\boldsymbol{\nabla} T]\!] = \eta\ \mathbf{n}$, and consequently $[\![\mathbf{Q}]\!] = -\eta\, \mathbf{k}_{\mathrm{T}} \cdot \mathbf{n}$. Therefore if the normal conductivity $\mathbf{k}_{\mathrm{T}} \cdot \mathbf{n}$ does not vanish, then $\eta = 0$, and, again due to Hadamard's compatibility relations, $[\![\dot{T}]\!] = -c\,\eta = 0$.

We have thus reached *Duhem's first theorem* for a solid conductor obeying Fourier's heat law: the temperature, its spatial and time derivatives remain continuous across a second order wave front,

$$[\![\, T\,]\!] = 0, \quad [\![\, \boldsymbol{\nabla} T\,]\!] = \mathbf{0}, \quad [\![\, \dot{T}\,]\!] = 0\,. \tag{11.3.2}$$

Hadamard's compatibility relations apply to the gradient of temperature which is continuous, and there exists a vector $\boldsymbol{\eta}_T = \mathbf{n} \cdot [\![\, \boldsymbol{\nabla}(\boldsymbol{\nabla} T)\,]\!]$ which can be interpreted as the normal jump of the second gradient of the temperature such that

$$[\![\, \boldsymbol{\nabla}(\boldsymbol{\nabla} T)\,]\!] = \boldsymbol{\eta}_T \otimes \mathbf{n}, \quad [\![\, \overline{\dot{\boldsymbol{\nabla} T}}\,]\!] = -c\,\boldsymbol{\eta}_T\,. \tag{11.3.3}$$

Similarly, since $\dot{T}$ is continuous, there exists a scalar η_T such that,

$$[\![\, \boldsymbol{\nabla} \dot{T}\,]\!] = \eta_T\, \mathbf{n}, \quad [\![\, \ddot{T}\,]\!] = -c\,\eta_T\,. \tag{11.3.4}$$

The partial derivatives with respect to time and space commute, $\overline{\dot{\boldsymbol{\nabla} T}} = \boldsymbol{\nabla} \dot{T}$, and therefore $-c\,\boldsymbol{\eta}_T = \eta_T\, \mathbf{n}$. Consequently,

$$[\![\, \boldsymbol{\nabla}(\boldsymbol{\nabla} T)\,]\!] = [\![\, \ddot{T}\,]\!]\, \frac{\mathbf{n}}{c} \otimes \frac{\mathbf{n}}{c}\,. \tag{11.3.5}$$

Note incidentally that a result of the same flavor is derived in Section 11.1.6.6.

As an example, let us consider the thermoelastic material defined by (9.1.5). The jumps of time and spatial derivatives of the strain and temperature gradient should satisfy the jump equations deriving from the balance of momentum and energy conservation. Let $\boldsymbol{\eta} = \mathbf{n} \cdot [\![\boldsymbol{\nabla} \mathbf{v}]\!]$ be the normal jump of the velocity gradient, so that $[\![\boldsymbol{\nabla} \mathbf{v}]\!] = \boldsymbol{\eta} \otimes \mathbf{n}$ and $[\![\dot{\mathbf{v}}]\!] = -c\,\boldsymbol{\eta}$. Since the jump of the time rate of temperature vanishes, the jump of the balance of momentum (11.2.4) keeps its isothermal format, and reduces to an eigenvalue problem for the normal jump $\boldsymbol{\eta}$, namely

$$(\mathbf{A} - c^2\, \mathbf{I}) \cdot \boldsymbol{\eta} = \mathbf{0}\,, \tag{11.3.6}$$

and the acoustic tensor $\mathbf{A} = \mathbf{A}^{\mathrm{isoth}} = \mathbf{n} \cdot (\rho^{-1}\, \mathbb{E}) \cdot \mathbf{n}$ is built from the isothermal tensor moduli $\mathbb{E}$.

The jump of the energy equation (9.1.25),

$$-\,T\,(\mathbf{c}_{\mathrm{T}} : \mathbb{E} \cdot \mathbf{n}) \cdot \frac{[\![\dot{\mathbf{v}}]\!]}{c} \;-\; \frac{[\![\, \ddot{T}\,]\!]}{c^2}\, \mathbf{n} \cdot \mathbf{k}_{\mathrm{T}} \cdot \mathbf{n} = 0\,, \tag{11.3.7}$$

couples the mechanical and thermal jumps. The wave-speeds being known from the isothermal eigenvalue problem as well as the directions of the jump of acceleration, the above equation should be seen as providing the associated jumps of the second time derivative of temperature, given that $\mathbf{n} \cdot \mathbf{k}_{\mathrm{T}} \cdot \mathbf{n}$ is strictly positive. This jump next enters the spatial jump in (11.3.5).

The picture is different for a rigid conductor, or when the mechanical contribution can be neglected in the energy equation. Then only the second term survives in the energy equation,

$$-\;\frac{[\![\, \ddot{T}\,]\!]}{c^2}\, \mathbf{n} \cdot \mathbf{k}_{\mathrm{T}} \cdot \mathbf{n} = 0\,. \tag{11.3.8}$$

For the jump not to vanish, the wave-speed is unboundedly large, namely $c \to \infty$, which is typical of a partial differential equation of parabolic type. This eigenmode is purely thermal, in the sense that the associated mechanical jump vanishes, that is $\boldsymbol{\eta} = \mathbf{0}$.

11.3.2 Acceleration waves in solid conductors obeying Cattaneo's heat law

The models briefly exposed in Section 9.1.4 aim at transforming the parabolic equation of heat energy to a hyperbolic equation, in which thermal and mechanical signals propagate at finite speeds.

Indeed, for a rigid conductor or in the uncoupled case, the jump of the energy equation associated with Cattaneo's heat conductor (9.1.38),

$$C_\epsilon \, t_{\rm Cat} \, [\![\ddot{T}]\!] \; - \; \frac{[\![\ddot{T}]\!]}{c^2} \, \mathbf{n} \cdot \mathbf{k}_{\rm T} \cdot \mathbf{n} = 0 \, , \tag{11.3.9}$$

delivers a finite wave-speed with square,

$$c^2 = \frac{1}{t_{\rm Cat}} \, \mathbf{n} \cdot \frac{\mathbf{k}_{\rm T}}{C_\epsilon} \cdot \mathbf{n} > 0 \, , \tag{11.3.10}$$

proportional to the thermal diffusivity $\mathbf{k}_{\rm T}/C_\epsilon$ and inversely proportional to the relaxation time $t_{\rm Cat}$.

11.3.3 Acceleration waves in nonconductor thermoelastic solids

For a nonconductor (actually, if the conductivity in the direction of propagation vanishes), the normal heat flux vanishes, namely $\mathbf{Q} \cdot \mathbf{n} = 0$. For thermoelastic solids, the mechanical entropy production $\hat{S}_{(\rm i,1)} = \rho \, \dot{s} - \Theta/T + (\operatorname{div} \mathbf{Q})/T = 0$ vanishes. In absence of heat source, namely $\Theta = 0$, the vanishing of the jump of mechanical entropy production $[\![\hat{S}_{(\rm i,1)}]\!] = 0$ implies the rate of entropy to vanish,

$$[\![\dot{s}]\!] = 0 \, , \tag{11.3.11}$$

since the mass density is continuous across a second order wave front. This result is sometimes referred to as *Duhem's second theorem*.

As indicated by Proposition 11.1, the temperature might not be continuous in a non conductor. If it is, so will be the entropy of a thermoelastic solid. Then, according to Duhem's second theorem and Hadamard's compatibility relation, both the time rate and spatial gradient of the entropy vanish across a non stationary acceleration wave, namely $[\![\dot{s}]\!] = 0$, $[\![\boldsymbol{\nabla} s]\!] = \mathbf{0}$.

For the thermoelastic material defined by (9.1.5), in view of (11.3.11), the jump of the time rate of temperature expresses in terms of the jump of strain rate. Consequently the jump of the stress rate expresses in terms of the jump of the strain rate via the isentropic tensor moduli $\mathbb{E}^{\rm isen}$ given by (9.1.7). The eigenvalue problem yielding the wave-speeds and mechanical eigenmode has the format (11.3.6) but the acoustic tensor $\mathbf{A} = \mathbf{A}^{\rm isen} = \mathbf{n} \cdot (\rho^{-1} \, \mathbb{E}^{\rm isen}) \cdot \mathbf{n}$ is built from the isentropic tensor moduli $\mathbb{E}^{\rm isen}$. Accurate developments would distinguish a process at constant entropy per unit volume from a process at constant entropy per unit mass. The distinction is not addressed in this linearized analysis.

Isothermal and isentropic wave-speeds are shown to interlace in Section 11.5.4.2.

11.4 Acceleration waves and acoustic waves in fluids

11.4.1 Acceleration waves in a frictionless ideal fluid

For a frictionless ideal fluid, also referred to as barotropic fluid, the stress $\boldsymbol{\sigma}$,

$$\boldsymbol{\sigma} = -p \, \mathbf{I} \, , \tag{11.4.1}$$

expresses in terms of the thermodynamic pressure $p = p(\rho, T)$ which is a function of the mass density ρ if the fluid is compressible, and of temperature T if the fluid is thermally expansible. Therefore the normal jump of the stress rate,

$$\dot{\boldsymbol{\sigma}} = -\Big(\frac{\partial p}{\partial \rho} \dot{\rho} + \frac{\partial p}{\partial T} \dot{T} \Big) \, \mathbf{I} \, , \tag{11.4.2}$$

across a second order wave, reduces to,

$$\mathbf{n} \cdot [\![\dot{\boldsymbol{\sigma}}]\!] = K [\![\operatorname{tr} \dot{\boldsymbol{\epsilon}}]\!] \, \mathbf{n} \, , \tag{11.4.3}$$

where

$$K = \rho \, \big(\frac{\partial p}{\partial \rho} \big)_{|T} \, , \tag{11.4.4}$$

is the isothermal bulk modulus of the fluid. Indeed $\dot\rho/\rho = -\mathrm{tr}\,\dot{\boldsymbol\epsilon}$ due to the mass balance, and, for a conductor fluid, $[\![\dot T]\!] = 0$ according to (11.3.2). Therefore the acoustic tensor $\mathbf{A}(\mathbf{n}) = K\,\mathbf{n}\otimes\mathbf{n}$ that governs the eigenvalue problem $(\mathbf{A} - \rho\,c^2\,\mathbf{I})\cdot\boldsymbol\eta = \mathbf{0}$ for the jump of the velocity gradient is singular. Dilatational waves with $\boldsymbol\eta \sim \mathbf{n}$ propagate at speed c with square,

$$c^2 = \frac{K}{\rho}\,, \tag{11.4.5}$$

while shear waves, with $\boldsymbol\eta \perp \mathbf{n}$, $\boldsymbol\eta \neq \mathbf{0}$ but $[\![\dot{\mathbf{v}}]\!] = \mathbf{0}$, are stationary, i.e. $c = 0$.

The same conclusion would be reached for a non conductor fluid with constitutive equation of the form $p = p(\rho, s)$, in view of (11.3.11).

This phenomenon is at variance with the situation in elastic solids. Indeed, it is shown in Section 11.5.3 that stationary discontinuities are excluded for thermoelastic solids and mixtures as long as their tensor moduli, and acoustic tensors, are symmetric definite positive. On the other hand, stationary discontinuities are a well-known mode of failure in a number of engineering materials, also referred to as strain-localization: as the mechanical information can no longer propagate in some direction, it is deflected orthogonally, and its pile up gives rise to shear bands of intense straining. The failure of the positive definiteness of the acoustic tensors in these materials is to be traced to a strong constitutive or geometrical nonlinearity.

Returning to the wave-speed c, which for a barotropic fluid is usually referred to as *speed of sound*, some further information may be gained for a perfect gas under isentropic condition, namely from (3.3.13),

$$c^2 = \gamma\,\frac{p_0}{\rho_0}\Big(\frac{\rho}{\rho_0}\Big)^{\gamma-1} = \gamma\,\frac{p}{\rho}\,. \tag{11.4.6}$$

For example, for dry air at temperature T_0=20 °C and under atmospheric pressure $p_0 = 0.101\,\mathrm{MPa}$, the mass density ρ_0 is equal to $1.20\,\mathrm{kg/m^3}$ and the adiabatic coefficient to $\gamma = 1.4$. The speed of sound c_0 is therefore about $343.3\,\mathrm{m/s}$, while, under a pressure $p = 1.01\,\mathrm{MPa}$, c is equal to $477\,\mathrm{m/s}$.

The speed of sound in water depends on pressure, temperature and salinity. In distilled water, it increases from $1407\,\mathrm{m/s}$ at 0 °C up to about $1560\,\mathrm{m/s}$ at 70 °C, but it is anomalous, e.g., Fung [1977], p. 215. At 20 °C, it is equal to $1484\,\mathrm{m/s}$: with a mass density $\rho \sim 10^3\,\mathrm{kg/m^3}$, the associated isothermal bulk modulus $K = \rho\,c^2$ is found equal to $2.2\,\mathrm{GPa}$, which is indeed the standard static value. Interestingly, both the bulk modulus and mass density of water are orders of magnitude larger than in air but the speeds of sound result to be comparable.

11.4.2 Acoustic waves in a frictionless ideal fluid

The wave-speed c defined by (11.4.5) governs also the speed of propagation of small acoustic waves in barotropic fluids where $p = p(\rho)$. Indeed, let us consider small perturbations around the mass density ρ, and linearize the balance of momentum $-\boldsymbol\nabla p - \rho\,\dot{\mathbf{v}} = \mathbf{0}$, and the balance of mass $\dot\rho + \rho\,\mathrm{div}\,\mathbf{v} = 0$. Since around the reference state $dp = c^2\,d\rho$, then both $\psi = p$ and $\psi = \rho$ are found to satisfy the wave equation,

$$c^2\,\Delta\psi - \ddot\psi = 0\,, \tag{11.4.7}$$

while the velocity satisfies the equation $c^2\,\boldsymbol\nabla\mathrm{div}\,\mathbf{v} - \ddot{\mathbf{v}} = 0$. However for irrotational motions, $\mathbf{v}(\mathbf{x},t) = \boldsymbol\nabla\phi(\mathbf{x},t)$, this equation for the velocity transforms to $\boldsymbol\nabla(c^2\,\Delta\phi - \ddot\phi) = \mathbf{0}$. Hence $c^2\,\Delta\phi - \ddot\phi$ is a function of time only, say, equal to $\dot\phi_1(t)$, but $\phi(\mathbf{x},t)$ and $\phi(\mathbf{x},t)+\phi_1(t)$ yield the same velocity irrespective of the time dependent function ϕ_1. Therefore the potential ϕ is also a solution of (11.4.7).

The solutions of (11.4.7) are contributed by the sum of waves traveling at speeds c and $-c$ along the axis x, namely $\phi = \phi_+(x - c\,t) + \phi_-(x + c\,t)$, with $\phi_\pm$ arbitrary twice differentiable functions.

11.4.3 Regimes in the steady irrotational flow in a barotropic fluid

Consider steady state flow where the partial derivatives with respect to time vanish. Then the steady state flow of a barotropic fluid is governed by

$$\begin{aligned}
&\text{its balance of mass} && \mathrm{div}\,\rho\,\mathbf{v} = \mathbf{0};\\
&\text{its balance of momentum} && -\frac{\boldsymbol\nabla p}{\rho} + \mathbf{b} = \mathbf{v}\cdot\boldsymbol\nabla\mathbf{v};\\
&\text{its mechanical behavior} && p = p(\rho)\,.
\end{aligned} \tag{11.4.8}$$

To simplify the presentation, the flow is assumed to take place in the plane (x, y) and to be irrotational, and the body force $\mathbf{b}$ vanishes. For an irrotational flow, the velocity $\mathbf{v}$ may be taken equal to the gradient $\boldsymbol{\nabla}\phi$ of a scalar potential ϕ. With c the wave-speed defined by (11.4.4) and (11.4.5), namely $c^2 = dp/d\rho$, the balance of mass may be recast in the format,

$$\begin{aligned} & c^2 \operatorname{div} \mathbf{v} - \mathbf{v} \cdot (\mathbf{v} \cdot \boldsymbol{\nabla}\mathbf{v}) = 0; \\ & \Big(c^2 - (\frac{\partial \phi}{\partial x})^2\Big) \frac{\partial^2 \phi}{\partial x^2} - 2 \frac{\partial \phi}{\partial x} \frac{\partial \phi}{\partial y} \frac{\partial^2 \phi}{\partial x \partial y} + \Big(c^2 - (\frac{\partial \phi}{\partial y})^2\Big) \frac{\partial^2 \phi}{\partial y^2} = 0 \,. \end{aligned} \tag{11.4.9}$$

Along standard mathematical textbooks, e.g., Courant and Hilbert [1953,1962], the last equation is recognized as a quasi-linear second order partial differential equation, of the form

$$A \frac{\partial^2 \phi}{\partial x^2} + 2\, B \frac{\partial^2 \phi}{\partial x \partial y} + C \frac{\partial^2 \phi}{\partial y^2} = 0 \,, \tag{11.4.10}$$

where the coefficients A, B and C may depend on the coordinates, on ϕ and on its first derivatives. The mathematical type of this equation relies on the sign of $B^2 - A\,C$, which here is equal to $c^2\,(|\mathbf{v}|^2 - c^2)$. The partial differential equation is said to be hyperbolic, elliptic or parabolic according to the conventions shown in Table 11.4.1.

Table 11.4.1: Classification of second order partial differential equations.

Type of the Equation	$B^2 - A\,C$	*Mach nb.* $\lvert\mathbf{v}\rvert/c$	*Regime of the Flow*
Hyperbolic	> 0	> 1	Supersonic
Elliptic	< 0	< 1	Subsonic
Parabolic	$= 0$	$= 1$	Transonic

The implications of this classification are fundamental for an understanding of the physical meaning of partial differential equations. Basic examples of parabolic and hyperbolic equations describing diffusion of heat and mass are worked out in Chapter 15. The issue is also of key concern for the energy equation, Section 11.3.2: when the material obeys Fourier's heat law of conduction, the energy equation is of parabolic type, while it is of hyperbolic type when the material obeys Cattaneo's heat law, which endows the diffusion phenomenon with a finite relaxation time.

In a gas, there is a single speed of sound c, namely $c^2 = \gamma\, p/\rho$ according to Eqn (11.4.6). Interestingly, subsonic flows modify little the air pressure. Indeed, according to Section (15.7.2), the relative change in pressure p due to flow $\frac{1}{2}\,\rho\,\mathbf{v}^2 = \frac{1}{2}\,\gamma\,p\,(\mathbf{v}/c)^2$ is less than 1% if the Mach number is less than $0.1\,\sqrt{2/\gamma} \sim 0.1$.

Elastic solids and elastic saturated porous media display respectively two and three body wave-speeds. Therefore the classification of the regimes is somehow more complex. For saturated porous media, the classification is reported in Table 11.5.1 and the dependence on porosity and the relative order of the three body wave-speeds are displayed in Fig. 11.5.2. The flow regime is also addressed in Section 11.10, where the entity that plays the role of the particle velocity is the speed of a crack tip that moves through the material.

11.4.4 A Newtonian viscous fluid

For a Newtonian viscous fluid, the effective stress $\boldsymbol{\sigma} + p\,\mathbf{I}$ expresses linearly in terms of the strain rate $\dot{\boldsymbol{\epsilon}}$,

$$\boldsymbol{\sigma} + p\,\mathbf{I} = K_{\mathrm{v}} \operatorname{tr} \dot{\boldsymbol{\epsilon}} + 2\,\mu_{\mathrm{v}} \operatorname{dev} \dot{\boldsymbol{\epsilon}} \,, \tag{11.4.11}$$

via the bulk viscosity $K_{\mathrm{v}} \geq 0$ and the shear viscosity $\mu_{\mathrm{v}} \geq 0$. The thermodynamic pressure $p = p(\rho, T)$ is in general a function of the mass density ρ and temperature T. A thermodynamic exposition of the constitutive equation is found in Bowen [1989], p. 96.

Thus we are lead to distinguish the following subcases:

(a) bulk viscosity $K_{\mathrm{v}} \neq 0$ and shear viscosity $\mu_{\mathrm{v}} \neq 0$.

In order to address the existence of acceleration waves, it is instrumental to attempt to rewrite the constitutive equation in the format $\dot{\boldsymbol{\epsilon}} = \dot{\boldsymbol{\epsilon}}(\boldsymbol{\sigma}, \rho, T)$. The constitutive equation is indeed invertible,

$$\dot{\boldsymbol{\epsilon}} = \frac{1}{K_{\mathrm{v}}} \Big(\frac{\operatorname{tr} \boldsymbol{\sigma}}{3} + p\Big) \frac{\mathbf{I}}{3} + \frac{1}{2\,\mu_{\mathrm{v}}} \operatorname{dev} \boldsymbol{\sigma} \,. \tag{11.4.12}$$

Across an acceleration wave front, the right hand side of (11.4.12) is continuous, so that the jump of the strain rate vanishes.

(b) bulk viscosity $K_{\rm v} = 0$ but shear viscosity $\mu_{\rm v} \neq 0$.

Then the constitutive equation is invertible in the form,

$$\operatorname{dev} \dot{\boldsymbol{\epsilon}} = \frac{1}{2\,\mu_{\rm v}} \operatorname{dev} \boldsymbol{\sigma}, \quad p = -\frac{\operatorname{tr} \boldsymbol{\sigma}}{3}\,. \tag{11.4.13}$$

The jump of the deviatoric part of the strain rate vanishes according to the first relation (11.4.13), which actually implies the jump of the velocity gradient to vanish[11.4]. As a consequence, a Newtonian viscous fluid with non vanishing shear viscosity cannot propagate acceleration waves.

11.5 Acceleration waves in saturated porous media

The constitutive equations are derived within the general framework of mixture theory, e.g., Truesdell and Toupin [1960], Green and Naghdi [1969], Bowen [1976]. The body of the theory has been exposed in Chapters 4 and 7, but the basic elements used in the dynamic analysis are summarized below. Emphasis is placed on second order (acceleration) waves which are discontinuity waves. First order waves are considered in Section 11.10. The speeds of propagation and eigenmodes of acceleration waves are controlled by the mechanical constitutive equations. On the other hand, the diffusion phenomenon comes into picture in the propagation of these waves, Section 11.6, as well as in harmonic waves, Section 11.9. Diffusion introduces a viscous effect in the field equations, and by the same token, a length scale.

11.5.1 The characteristic equation for the wave-speeds

We consider here porous media which are made up of two constituents, a solid and a fluid, namely water, which are viewed as two independent overlapping continua. Phases (solid (s) and fluid (w)) represent the constituents when viewed as part of the mixture. The solid phase is usually referred to as *solid skeleton*. Each constituent has a mass M_α and a volume V_α, $\alpha = \mathrm{s}, \mathrm{w}$, which make up the total mass $M{=}M_{\rm s}{+}M_{\rm w}$ and the total volume $V{=}V_{\rm s}{+}V_{\rm w}$ of the mixture.

At each point of each phase, we define *intrinsic* or *true* quantities, labeled by subscripts, and *apparent* or *partial* quantities, labeled by superscripts. For example, the intrinsic mass density is defined as $\rho_\alpha{=}M_\alpha/V_\alpha$, whereas the apparent mass density is defined by $\rho^\alpha{=}M_\alpha/V$; hence $\rho^\alpha{=}n^\alpha\,\rho_\alpha$ where $n^\alpha = V_\alpha/V$ is the volume fraction of phase α. Since we consider fluid-saturated porous media, the volume fractions satisfy the constraint,

$$n^{\rm s} + n^{\rm w} = 1\,. \tag{11.5.1}$$

The equations of balance of momentum of the phases involve two (symmetric) *partial stress tensors* $\boldsymbol{\sigma}^{\rm s}$ and $\boldsymbol{\sigma}^{\rm w}$, which make up the total stress tensor of the mixture,

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\rm s} + \boldsymbol{\sigma}^{\rm w}\,, \tag{11.5.2}$$

when the contribution due to diffusion is neglected. With each partial stress tensor $\boldsymbol{\sigma}^\alpha$ is associated an *intrinsic stress tensor* $\boldsymbol{\sigma}_\alpha$ defined as $\boldsymbol{\sigma}_\alpha{=}\boldsymbol{\sigma}^\alpha/n^\alpha$. The partial stress tensor of the fluid phase, associated with a linear compressible fluid, is defined in terms of its partial $p^{\rm w}$ or intrinsic $p_{\rm w}$ pressure as,

$$\boldsymbol{\sigma}^{\rm w} = -p^{\rm w}\,\mathbf{I} = -n^{\rm w} p_{\rm w}\,\mathbf{I}\,. \tag{11.5.3}$$

Each phase α is endowed with its own apparent (infinitesimal) strain tensor $\boldsymbol{\epsilon}^\alpha$ defined as the symmetrized gradient of its macroscopic displacement field. As for constituents, they are generally compressible. Incompressibility of one or both constituents can be viewed as a limit case. If both solid and fluid constituents are incompressible, the equations of mass balance imply that the rates of volume change must satisfy the constraint (7.2.23), which for a binary mixture simplifies to,

$$n^{\rm s}\,\operatorname{div} \mathbf{v}_{\rm s} + n^{\rm w}\,\operatorname{div} \mathbf{v}_{\rm w} = \frac{\hat{\rho}^{\rm s}}{\rho_{\rm s}} + \frac{\hat{\rho}^{\rm w}}{\rho_{\rm w}}\,. \tag{11.5.4}$$

[11.4] Indeed let $[\![\operatorname{dev} \dot{\boldsymbol{\epsilon}}]\!] = \frac{1}{2}\,(\boldsymbol{\eta}\otimes\mathbf{n} + \mathbf{n}\otimes\boldsymbol{\eta}) - \frac{1}{3}\,\boldsymbol{\eta}\cdot\mathbf{n}\,\mathbf{I} = \mathbf{0}$. Scalar product by $\mathbf{n}\otimes\mathbf{n}$ implies $\boldsymbol{\eta}\cdot\mathbf{n} = 0$. Hence $\boldsymbol{\eta}\otimes\mathbf{n} + \mathbf{n}\otimes\boldsymbol{\eta} = \mathbf{0}$. Since $\boldsymbol{\eta}$ is orthogonal to $\mathbf{n}$, scalar product by $\mathbf{n}$ implies in turn $\boldsymbol{\eta} = \mathbf{0}$.

For a closed mixture, the mass supplies $\hat{\rho}^\alpha$ satisfy the condition (4.4.3), namely here $\hat{\rho}^{\rm s} + \hat{\rho}^{\rm w} = 0$.

For each phase of the porous medium, the balance of momentum (4.5.5),

$$\text{div}\ \boldsymbol{\sigma}^\alpha + \rho^\alpha \left(\mathbf{b}_\alpha - \frac{d^\alpha \mathbf{v}_\alpha}{dt}\right) = \hat{\rho}^\alpha \left(\mathbf{v}_\alpha - \tilde{\mathbf{v}}_\alpha\right) - \hat{\boldsymbol{\pi}}^\alpha, \quad \alpha = \text{s, w}\,, \tag{11.5.5}$$

involves, in addition to the usual terms present in single phase solids, namely the divergence of the stress tensor, the body force per unit mass $\mathbf{b}_\alpha$ and the acceleration $d^\alpha \mathbf{v}_\alpha/dt$, the apparent mass density ρ^α and the momentum supply $\hat{\boldsymbol{\pi}}^\alpha$ to the phase α by the rest of the mixture. Momentum supplies, defined by (7.3.10), introduce the diffusion of the fluid through the solid skeleton via the coefficient of Stokes' drag $k_{\rm Sd}$,

$$\hat{\rho}^{\rm w}(\tilde{\mathbf{v}}_{\rm w} - \mathbf{v}_{\rm w}) + \hat{\boldsymbol{\pi}}^{\rm w} = p_{\rm w} \boldsymbol{\nabla} n^{\rm w} + k_{\rm Sd}\left(\mathbf{v}_{\rm s} - \mathbf{v}_{\rm w}\right). \tag{11.5.6}$$

For a closed mixture, momentum supplies satisfy the constraint (4.5.2), namely,

$$\sum_{\alpha={\rm s,w}} \hat{\rho}^\alpha\, \tilde{\mathbf{v}}_\alpha + \hat{\boldsymbol{\pi}}^\alpha = \mathbf{0}\,, \tag{11.5.7}$$

where $\tilde{\mathbf{v}}_\alpha$ is the velocity of the mass transferred to phase α.

The balance of momentum holds pointwise, except along a singular surface of order 1 where it is replaced by the jump relation (11.1.56). Singular surfaces of order 1 display a velocity discontinuity, while, across singular surfaces of order 2, the velocity is continuous but the acceleration and the velocity gradient are not.

The analysis below involves a number of simplifications. First, it assumes that no mass transfer takes place between constituents, namely $\hat{\rho}^\alpha = 0$, $\alpha =$ s, w. In addition, since we envisage a linearized analysis around an equilibrium state, the volume fractions and mass densities are fixed to their reference values. Moreover, we shall make no difference between partial and material time derivatives, and denote them by a superimposed dot. Therefore we shall not distinguish the speed of displacement W along its direction of propagation $\mathbf{n}$, and the two speeds of propagation $c_\alpha = W - \mathbf{v}_\alpha \cdot \mathbf{n}$ of an acceleration wave with respect to the particles of each of the two phases $\alpha =$ s, w.

Note also that, in a linearized analysis, the buoyancy term associated with the gradient of volume fraction disappears from the momentum supplies. Therefore the remaining terms in the momentum supplies involve only a velocity difference, which is continuous across singular surfaces of order 2. Finally, the rates of the body forces $\mathbf{b}_\alpha$, $\alpha =$ s, w, are also assumed to be continuous across the wave front.

Consider an acceleration wave that propagates through the porous medium at speed c. Hadamard's compatibility relations (11.1.9) apply to the two phases independently. e.g., for $\boldsymbol{\phi} = \boldsymbol{\sigma}^\alpha$ the partial stress of phase $\alpha =$ s, w,

$$\left[\!\!\left[\frac{\partial \boldsymbol{\sigma}^\alpha}{\partial \mathbf{x}} \right]\!\!\right] = -\frac{1}{c}\left[\dot{\boldsymbol{\sigma}}^\alpha\right] \otimes \mathbf{n}\,. \tag{11.5.8}$$

and, for $\boldsymbol{\phi} = \mathbf{v}_\alpha$ the velocity of phase α,

$$\left[\!\!\left[\frac{\partial \mathbf{v}_\alpha}{\partial \mathbf{x}} \right]\!\!\right] = \boldsymbol{\eta}_\alpha \otimes \mathbf{n}\,, \quad \left[\!\left[\, \dot{\mathbf{v}}_\alpha \,\right]\!\right] = -c\,\boldsymbol{\eta}_\alpha\,. \tag{11.5.9}$$

As a consequence of the above assumptions on the entities involved in momentum balances, the jump across the front of an acceleration wave of the rate of traction is proportional to the normal jump of the velocity gradient,

$$\mathbf{n} \cdot \left[\!\left[\dot{\boldsymbol{\sigma}}^\alpha \right]\!\right] = \rho^\alpha\, c^2\, \boldsymbol{\eta}_\alpha\,, \quad \alpha = \text{s, w}\,. \tag{11.5.10}$$

As an immediate consequence, we have

Proposition 11.2 on the kinematics of the acceleration wave in the fluid phase.

The normal jump of the velocity gradient in the fluid phase $\boldsymbol{\eta}_{\rm w}$, Eqn (11.2.1), is aligned with the wave normal $\mathbf{n}$,

$$\boldsymbol{\eta}_{\rm w} = \eta_{\rm w}\, \mathbf{n}\,. \tag{11.5.11}$$

The proof simply uses Hadamard's compatibility relation for the fluid phase, (11.5.10), accounting for the fact that the fluid stress is isotropic, that is

$$\mathbf{n} \cdot \left[\!\left[-\dot{p}^{\rm w}\, \mathbf{I} \,\right]\!\right] = \rho^{\rm w}\, c^2\, \boldsymbol{\eta}_{\rm w}\,. \tag{11.5.12}$$

Still it might be worth mentioning that Proposition 11.2 does not hold in presence of inertial coupling: the issue is elaborated in Section 11.5.5.

The form of the poroelastic constitutive equations that is convenient in the analysis of acceleration waves is detailed in Section 7.3.6 together with the central concept of underlying drained solid. Insertion of the constitutive equations (7.3.28) in the discontinuity relations (11.5.10) provides a 4×4 generalized eigenvalue problem for the wave-speeds c^2 in terms of a constitutive matrix $[\mathbf{A}^\#]$, of a diagonal mass matrix $[\mathbf{R}^\#] = \mathrm{diag}\,[\rho^\mathrm{s},\, \rho^\mathrm{s},\, \rho^\mathrm{s},\, \rho^\mathrm{w}]$ and of an eigenvector $[\boldsymbol{\eta}^\#] = [\boldsymbol{\eta}_\mathrm{s},\, \eta_\mathrm{w}]^\mathrm{T}$,

$$\begin{gathered}\left[\mathbf{A}^\# - c^2\mathbf{R}^\#\right]\left[\boldsymbol{\eta}^\#\right] = \mathbf{0}\,,\\ \left[\begin{array}{cc} \mathbf{n}\cdot\mathbb{E}^{\mathrm{ss}}\cdot\mathbf{n} - c^2\,\rho^\mathrm{s}\mathbf{I} & \mathbf{n}\cdot\lambda^{\mathrm{sw}}\,\boldsymbol{\lambda}_\mathrm{w} \\ \lambda^{\mathrm{sw}}\,(\boldsymbol{\lambda}_\mathrm{w}\cdot\mathbf{n})^\mathrm{T} & \lambda^{\mathrm{ww}} - c^2\rho^\mathrm{w} \end{array}\right]\left[\begin{array}{c} \boldsymbol{\eta}_\mathrm{s} \\ \eta_\mathrm{w} \end{array}\right] = \left[\begin{array}{c} \mathbf{0} \\ 0 \end{array}\right].\end{gathered} \tag{11.5.13}$$

Through simple manipulations, the generalized eigenvalue problem can be transformed into a standard eigenvalue problem,

$$\left[\mathbf{A} - c^2\mathbf{I}_4\right]\left[\boldsymbol{\eta}\right] = [\mathbf{0}]\,, \tag{11.5.14}$$

where $[\mathbf{I}_4]$ is the identity matrix over the set of 4×4 matrices. The block structure of the problem emanates from the mechanical constitutive equations of the constituents,

$$\left[\begin{array}{cc} \mathbf{A}^{\mathrm{ss}} - c^2\,\mathbf{I} & \mathbf{a}^{\mathrm{sw}} \\ (\mathbf{a}^{\mathrm{sw}})^\mathrm{T} & c_\mathrm{w}^2 - c^2 \end{array}\right]\left[\begin{array}{c} \sqrt{\rho^\mathrm{s}}\,\boldsymbol{\eta}_\mathrm{s} \\ \sqrt{\rho^\mathrm{w}}\,\eta_\mathrm{w} \end{array}\right] = \left[\begin{array}{c} \mathbf{0} \\ 0 \end{array}\right], \tag{11.5.15}$$

and, in explicit form,

$$\left[\begin{array}{cc} \mathbf{n}\cdot\dfrac{\mathbb{E}^{\mathrm{ss}}}{\rho^\mathrm{s}}\cdot\mathbf{n} - c^2\,\mathbf{I} & \mathbf{n}\cdot\boldsymbol{\lambda}_\mathrm{w}\dfrac{\lambda^{\mathrm{sw}}}{\sqrt{\rho^\mathrm{s}\,\rho^\mathrm{w}}} \\ \dfrac{\lambda^{\mathrm{sw}}}{\sqrt{\rho^\mathrm{s}\,\rho^\mathrm{w}}}\,(\boldsymbol{\lambda}_\mathrm{w}\cdot\mathbf{n})^\mathrm{T} & \dfrac{\lambda^{\mathrm{ww}}}{\rho^\mathrm{w}} - c^2 \end{array}\right]\left[\begin{array}{c} \sqrt{\rho^\mathrm{s}}\,\boldsymbol{\eta}_\mathrm{s} \\ \sqrt{\rho^\mathrm{w}}\,\eta_\mathrm{w} \end{array}\right] = \left[\begin{array}{c} \mathbf{0} \\ 0 \end{array}\right]. \tag{11.5.16}$$

Consequently, there are at most four possible modes of propagation, each one associated with a solution c^2 of (11.5.13) or of (11.5.16). In addition, (11.5.16) shows clearly that the major symmetry of the constitutive equations is inherited by the acoustic matrix $[\mathbf{A}]$. Thus, the eigenvalue problem is symmetric and, therefore, the squares of the wave-speeds and the eigenvectors are real.

Mechanical coupling between the solid and fluid phases assumes $\lambda^{\mathrm{sw}} \neq 0$. Then the eigenmodes affect in general both phases. An eigenmode that does not affect the fluid phase, namely $\eta_\mathrm{w} = 0$, satisfies the relation $\boldsymbol{\eta}_\mathrm{s}\cdot\boldsymbol{\lambda}_\mathrm{w}\cdot\mathbf{n} = 0$.

Given that the fluid jump is necessarily parallel to the normal $\mathbf{n}$, a wave is said to be *longitudinal* if the solid jump $\boldsymbol{\eta}_\mathrm{s}$ is also parallel to the normal $\mathbf{n}$, and *transversal* if the solid jump is orthogonal to $\mathbf{n}$.

For isotropic mixtures with compressible constituents, the analysis below ranks the elastic wave-speeds, according to the material parameters. The wave-speeds correspond to a shear wave-speed of double multiplicity which affects only the solid phase, and to two longitudinal wave-speeds, so-called Biot's first and second waves, which affect both the solid and fluid phases. When both solid and fluid constituents are incompressible, the largest longitudinal wave-speed becomes unbounded, so that there are only two finite wave-speeds.

11.5.2 Acceleration wave-speeds in isotropic porous media

11.5.2.1 Relative order of acceleration wave-speeds

For an isotropic elastic mixture, the constitutive equations of Section 7.3.6 linking the partial stresses to the partial strains simplify to,

$$\begin{aligned} \boldsymbol{\sigma}^\mathrm{s} &= \lambda^{\mathrm{ss}}\ \mathrm{tr}\ \boldsymbol{\epsilon}^\mathrm{s}\,\mathbf{I} \ +\ 2\,\mu\,\boldsymbol{\epsilon}^\mathrm{s} \ +\ \lambda^{\mathrm{sw}}\,\mathrm{tr}\ \boldsymbol{\epsilon}^\mathrm{w}\,\mathbf{I}\,,\\ -n^\mathrm{w}\,p_\mathrm{w} &= \lambda^{\mathrm{sw}}\,\mathrm{tr}\ \boldsymbol{\epsilon}^\mathrm{s} \ +\ \lambda^{\mathrm{ww}}\ \mathrm{tr}\ \boldsymbol{\epsilon}^\mathrm{w}\,. \end{aligned} \tag{11.5.17}$$

The four constitutive moduli have been identified in the above section in terms of measurable quantities. The eigenvalue problem,

$$\left[\begin{array}{cc} c_\mathrm{s}^2\,\mathbf{n}\otimes\mathbf{n} + c_3^2\,(\mathbf{I} - \mathbf{n}\otimes\mathbf{n}) - c^2\,\mathbf{I} & c_{\mathrm{sw}}^2\,\mathbf{n} \\ c_{\mathrm{sw}}^2\,\mathbf{n}^\mathrm{T} & c_\mathrm{w}^2 - c^2 \end{array}\right]\left[\begin{array}{c} \sqrt{\rho^\mathrm{s}}\,\boldsymbol{\eta}_\mathrm{s} \\ \sqrt{\rho^\mathrm{w}}\,\eta_\mathrm{w} \end{array}\right] = \left[\begin{array}{c} \mathbf{0} \\ 0 \end{array}\right], \tag{11.5.18}$$

is advantageously expressed in the cartesian axes $(\mathbf{n},\, \mathbf{t}_1,\, \mathbf{t}_2)$,

$$\begin{bmatrix} c_{\rm s}^2 - c^2 & 0 & 0 & c_{\rm sw}^2 \\ 0 & c_3^2 - c^2 & 0 & 0 \\ 0 & 0 & c_3^2 - c^2 & 0 \\ c_{\rm sw}^2 & 0 & 0 & c_{\rm w}^2 - c^2 \end{bmatrix} \begin{bmatrix} \sqrt{\rho^{\rm s}}\, \eta_{\rm s1} \\ \sqrt{\rho^{\rm s}}\, \eta_{\rm s2} \\ \sqrt{\rho^{\rm s}}\, \eta_{\rm s3} \\ \sqrt{\rho^{\rm w}}\, \eta_{\rm w} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} . \tag{11.5.19}$$

Some notation has been introduced, namely

$$c_{\rm s}^2 = \frac{\lambda^{\rm ss} + 2\,\mu}{\rho^{\rm s}} > 0\,, \quad c_{\rm w}^2 = \frac{\lambda^{\rm ww}}{\rho^{\rm w}} > 0\,, \quad c_{\rm ms}^2 = \frac{\lambda^{\rm sw}}{\rho^{\rm s}}\,, \quad c_{\rm mw}^2 = \frac{\lambda^{\rm sw}}{\rho^{\rm w}}\,, \quad c_{\rm sw}^2 = \frac{\lambda^{\rm sw}}{\sqrt{\rho^{\rm s}\rho^{\rm w}}}\,. \tag{11.5.20}$$

The signs of $c_{\rm s}^2$ and $c_{\rm w}^2$ are implied by the positive definiteness of the poroelastic energy, Eqn (7.3.45). Note that only the squares $c_{\rm ms}^2$, $c_{\rm mw}^2$ and $c_{\rm sw}^2$ are used, not the square-roots themselves, and the sign of the coefficient of mechanical coupling $\lambda^{\rm sw}$, although significant from a mechanical point of view, is arbitrary. Actually, for most materials, the coefficient $\lambda^{\rm sw}$ is positive. In particular, the property holds when the solid constituent is incompressible, Eqn (7.3.51).

As a general property, positive definiteness of the poroelastic energy (7.3.45) implies strong ellipticity, and the existence of a real shear wave-speed c_3 of double multiplicity, with a non zero jump in the solid phase only,

$$c_3^2 = \frac{\mu}{\rho^{\rm s}}, \quad \boldsymbol{\eta}_{\rm s} \perp \mathbf{n}, \quad \boldsymbol{\eta}_{\rm w} = \mathbf{0}\,, \tag{11.5.21}$$

and of two real longitudinal wave-speeds, $c_1 \geq c_2$, of single multiplicity,

$$\left.\begin{matrix} c_1^2 \\ c_2^2 \end{matrix}\right\} = \tfrac{1}{2}\,(c_{\rm s}^2 + c_{\rm w}^2) \pm \tfrac{1}{2}\left((c_{\rm s}^2 - c_{\rm w}^2)^2 + 4\,c_{\rm sw}^4\right)^{1/2}, \tag{11.5.22}$$

with eigenmodes,

$$\boldsymbol{\eta}_{\rm s} = (\boldsymbol{\eta}_{\rm s}\cdot\mathbf{n})\,\mathbf{n}, \quad \boldsymbol{\eta}_{\rm w} = \frac{\sqrt{\rho^{\rm s}}}{\sqrt{\rho^{\rm w}}}\,\frac{c^2 - c_{\rm s}^2}{c_{\rm sw}^2}\,\boldsymbol{\eta}_{\rm s} = \frac{\sqrt{\rho^{\rm s}}}{\sqrt{\rho^{\rm w}}}\,\frac{c_{\rm sw}^2}{c^2 - c_{\rm w}^2}\,\boldsymbol{\eta}_{\rm s}\,. \tag{11.5.23}$$

The squares of the longitudinal wave-speeds are solutions of the polynomial

$$F(c^2) = (c^2)^2 - (c_{\rm s}^2 + c_{\rm w}^2)\,c^2 + c_{\rm s}^2\,c_{\rm w}^2 - c_{\rm sw}^4 = 0\,, \tag{11.5.24}$$

and they obey the relations,

$$c_1^2 + c_2^2 = c_{\rm s}^2 + c_{\rm w}^2\,, \tag{11.5.25}$$

and

$$c_{\rm sw}^4 = c_{\rm s}^2\,c_{\rm w}^2 - c_1^2\,c_2^2 = \left(c_1^2 - c_{\rm s}^2\right)\left(c_{\rm s}^2 - c_2^2\right) = \left(c_1^2 - c_{\rm w}^2\right)\left(c_{\rm w}^2 - c_2^2\right). \tag{11.5.26}$$

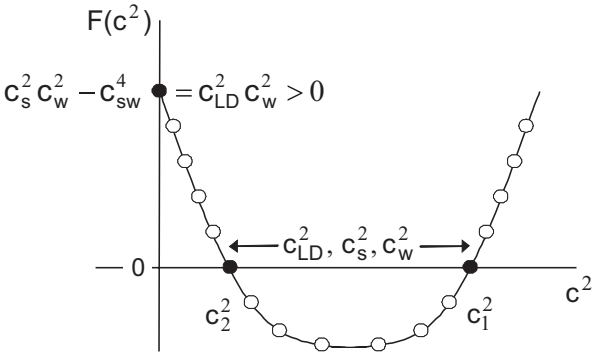

Fig. 11.5.1: Relative positions of entities involved in the analysis of the longitudinal wave-speeds in an isotropic poroelastic body.

Irrespective of the material parameters, the wave-speeds satisfy the inequalities that can be read from Fig. 11.5.1,

$$\max\{c_2,\, c_3\} \leq c_1, \quad c_2 \leq \min\{c_{\rm s},\, c_{\rm w}\} \leq \max\{c_{\rm s},\, c_{\rm w}\} \leq c_1\,. \tag{11.5.27}$$

Indeed,

$$F(c_{\rm w}^2) = F(c_{\rm s}^2) = -c_{\rm sw}^4 \leq 0\,, \tag{11.5.28}$$

and

$$F(c_3^2) = \frac{1}{\rho^{\rm s}\rho^{\rm w}}\left((\lambda_0^{\rm sw})^2 - (\lambda^{\rm sw})^2\right), \tag{11.5.29}$$

with $(\lambda_0^{\rm sw})^2$ defined by the relation,

$$\frac{(\lambda_0^{\rm sw})^2}{\rho^{\rm s}\rho^{\rm w}} = (c_{\rm s}^2 - c_3^2)\,(c_{\rm w}^2 - c_3^2)\,. \tag{11.5.30}$$

Then, the more detailed inequalities result,

$$\begin{aligned} &c_3 < c_2 = c_1 \quad \text{if} \quad c_{\rm s} = c_{\rm w} \quad \text{and} \quad \lambda^{\rm sw} = 0\,,\\ &c_3 < c_2 < c_1 \quad \text{if} \quad (\lambda_0^{\rm sw})^2 > (\lambda^{\rm sw})^2\,,\\ &c_3 = c_2 < c_1 \quad \text{if} \quad (\lambda_0^{\rm sw})^2 = (\lambda^{\rm sw})^2\,,\\ &c_2 < c_3 < c_1 \quad \text{if} \quad (\lambda_0^{\rm sw})^2 < (\lambda^{\rm sw})^2\,. \end{aligned} \tag{11.5.31}$$

The relative order of the three poroelastic wave-speeds delineates, in the plane of porosity $n^{\rm w}$ versus speed c, three intersonic regions denoted by (i), (ii) and (iii), defined in explicit form in Table 11.5.1.

Table 11.5.1: The subsonic, intersonic and supersonic regions in a saturated porous medium.

Region	Range of Speed c
Subsonic	$c < \min(c_2, c_3)$
Intersonic (i)	$\max(c_2, c_3) < c < c_1$
Intersonic (ii)	$c_3 < c < c_2 < c_1$
Intersonic (iii)	$c_2 < c < c_3 < c_1$
Supersonic	$c_1 < c$

11.5.2.2 Dry materials and drained materials

For dry materials, the moduli involved are those of the solid skeleton, say bulk modulus $K = \lambda + 2\,\mu$ and shear modulus μ. Then the longitudinal and shear wave-speeds boil down to their counterparts in the single phase solid defined by the above moduli and the *apparent* mass density of the skeleton,

$$c_{\rm LD}^2 = \frac{\lambda + 2\,\mu}{\rho^{\rm s}} = \frac{K + 4\,\mu/3}{\rho^{\rm s}}, \quad c_{\rm SD}^2 = \frac{\mu}{\rho^{\rm s}}\,. \tag{11.5.32}$$

These wave-speeds are also the wave-speeds of the underlying drained solid. Indeed setting the pressure to zero in (11.5.17), and eliminating the fluid strain yields a relation linking the partial solid stress and apparent solid strain,

$$\boldsymbol{\sigma}^{\rm s} = \lambda\,{\rm tr}\,\boldsymbol{\epsilon}^{\rm s}\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon}^{\rm s}\,, \tag{11.5.33}$$

with help of the relation $\lambda = \lambda^{\rm ss} - (\lambda^{\rm sw})^2/\lambda^{\rm ww}$, Eqn (7.3.44). Insertion of this constitutive equation in the jump of the momentum balance of the solid phase (11.5.10) yields an eigenvalue problem for the drained acoustic tensor. The elastic acoustic tensor of the drained solid is defined as for a single phase solid,

$$\mathbf{A}^{\rm D} = \mathbf{n}\cdot\frac{\mathbb{E}}{\rho^{\rm s}}\cdot\mathbf{n} = (c_{\rm LD})^2\,\mathbf{n}\otimes\mathbf{n} + (c_{\rm SD})^2\,(\mathbf{I} - \mathbf{n}\otimes\mathbf{n})\,, \tag{11.5.34}$$

which delivers the longitudinal wave-speed $c_{\rm LD}$ with single multiplicity and the shear wave-speed $c_{\rm SD}$ with double multiplicity.

The longitudinal wave-speed $c_{\rm LD}$ of the drained solid is smaller than the first longitudinal wave-speed c_1 of the porous medium, and larger than the second longitudinal wave-speed c_2. Indeed, $c_{\rm s}^2\,c_{\rm w}^2 - c_{\rm sw}^4$ can be shown to be equal to $c_{\rm LD}^2\,c_{\rm w}^2$, and the function $F(c_{\rm LD}^2)$ defined by (11.5.24) is negative, indeed equal to $-c_{\rm sw}^4\,c_{\rm LD}^2/c_{\rm w}^2$. This separation property is generalized to any type of mechanical anisotropy in Section 11.5.4.3.

11.5.2.3 Undrained wave-speeds

Two additional wave-speeds are relevant, namely

$$c_{\rm LU}^2 = \frac{\lambda^{\rm U} + 2\,\mu}{\rho} = \frac{K^{\rm U} + 4\,\mu/3}{\rho}, \quad c_{\rm SU}^2 = \frac{\mu}{\rho}\,, \tag{11.5.35}$$

where $\rho = \rho^{\rm s} + \rho^{\rm w}$ is the mass density of the porous medium, and

$$\lambda^{\rm U} = \lambda^{\rm ss} + \lambda^{\rm ww} + 2\lambda^{\rm sw}, \quad K^{\rm U} = \lambda^{\rm U} + 2\,\mu/3\,, \tag{11.5.36}$$

are undrained moduli. Using the definitions (11.5.20), $c_{\rm LU}^2$ may also be cast in the format,

$$c_{\rm LU}^2 = \frac{\rho^{\rm s}}{\rho}\,(c_{\rm s}^2 + c_{\rm ms}^2) + \frac{\rho^{\rm w}}{\rho}\,(c_{\rm w}^2 + c_{\rm mw}^2)\,. \tag{11.5.37}$$

Indeed, the speeds defined by (11.5.35) are the undrained wave-speeds. They can be viewed also as the low frequency limits of harmonic waves-speeds, i.e. the viscosity of the fluid implying the solid and fluid to move together, their displacements $\mathbf{u} = \mathbf{u}_{\rm s} = \mathbf{u}_{\rm w}$, and therefore their strains $\boldsymbol{\epsilon} = \boldsymbol{\epsilon}(\mathbf{u}) = \boldsymbol{\epsilon}(\mathbf{u}_{\rm s}) = \boldsymbol{\epsilon}(\mathbf{u}_{\rm w})$ being equal. The total stress $\boldsymbol{\sigma}$ obtained by summation of the two partial stresses in (11.5.17) expresses in terms of the strain $\boldsymbol{\epsilon}$,

$$\boldsymbol{\sigma} = \lambda^{\rm U}\,{\rm tr}\,\boldsymbol{\epsilon}\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon}\,, \tag{11.5.38}$$

and the balance of momentum reduces to a single equation,

$$\text{div}\,\boldsymbol{\sigma} - \rho\,\ddot{\mathbf{u}} = \mathbf{0}\,. \tag{11.5.39}$$

Thus the medium behaves like a solid, and admits one longitudinal wave-speed $c_{\rm LU}$ and one shear wave-speed $c_{\rm SU}$ with double multiplicity, and its acoustic tensor reads,

$$\mathbf{A}^{\rm U} = \mathbf{n}\cdot\frac{\mathbb{E}^{\rm U}}{\rho}\cdot\mathbf{n} = c_{\rm LU}^2\,\mathbf{n}\otimes\mathbf{n} + c_{\rm SU}^2\,(\mathbf{I} - \mathbf{n}\otimes\mathbf{n})\,. \tag{11.5.40}$$

Note that the total mass density ρ is involved since the fluid and solid are endowed with identical kinematics. The above undrained relations are sometimes referred to as Gassmann relations.

Using $(7.3.44)_4$ for $\lambda^{\rm ss}$, $(7.3.44)_3$ for $\lambda^{\rm sw}$, and $(7.3.44)_1$ for $\lambda^{\rm ww}$, the undrained bulk modulus may be phrased in terms of these moduli,

$$K^{\rm U} = K + (\frac{\lambda^{\rm sw}}{\lambda^{\rm ww}} + 1)^2\,\lambda^{\rm ww} = K + \frac{(K_{\rm s} - K)^2}{(\frac{1-n^{\rm w}}{K_{\rm s}} + \frac{n^{\rm w}}{K_{\rm w}})\,K_{\rm s}^2 - K}\,. \tag{11.5.41}$$

Note that

$$\lim_{n^{\rm w}\to 0} K^{\rm U} = K_{\rm s}, \quad \lim_{n^{\rm w}\to 1} K^{\rm U} = K_{\rm w}\,, \tag{11.5.42}$$

the second limit assuming that $\lim_{n^{\rm w}\to 1} K = 0$.

As an alternative format, the undrained bulk modulus $K^{\rm U}$ and undrained Poisson's ratio $\nu^{\rm U}$ might be considered as measurable entities, and then

$$\lambda^{\rm U} = 3\,\frac{\nu^{\rm U}}{1+\nu^{\rm U}}\,K^{\rm U}\,, \quad \mu = \frac{3}{2}\,\frac{1-2\,\nu^{\rm U}}{1+\nu^{\rm U}}\,K^{\rm U}, \quad \lambda^{\rm U} + 2\,\mu = 3\,\frac{1-\nu^{\rm U}}{1+\nu^{\rm U}}\,K^{\rm U}\,. \tag{11.5.43}$$

The inequalities (7.4.43) ensure the undrained wave-speeds (11.5.35) to be real and the undrained longitudinal wave-speed to be larger than the undrained shear wave-speed, namely $c_{\rm LU} > c_{\rm SU}$.

11.5.2.4 The frozen mixture

Let c_0 be the wave-speed defined by the relation,

$$\min(c_{\rm s}^2+c_{\rm ms}^2,\, c_{\rm w}^2+c_{\rm mw}^2) \le c_0^2 = \tfrac{1}{2}\,(c_{\rm s}^2+c_{\rm ms}^2+c_{\rm w}^2+c_{\rm mw}^2) \le \max(c_{\rm s}^2+c_{\rm ms}^2,\, c_{\rm w}^2+c_{\rm mw}^2)\,. \tag{11.5.44}$$

When the relation of *dynamic compatibility* is satisfied, Biot [1956],

$$c_{\rm s}^2+c_{\rm ms}^2 = c_{\rm w}^2+c_{\rm mw}^2\,, \tag{11.5.45}$$

then, the common value c_0^2 is easily checked to be a root of (11.5.24), and therefore c_0 is a longitudinal wave-speed, in fact the largest one. Under this condition, this wave-speed is also easily checked to be equal to the undrained wave-speed $c_{\rm LU}$,

$$c_1^2 = c_0^2 = c_{\rm s}^2+c_{\rm ms}^2 = c_{\rm w}^2+c_{\rm mw}^2 = c_{\rm LU}^2, \quad c_2^2 = c_{\rm s}^2-c_{\rm mw}^2 = c_{\rm w}^2-c_{\rm ms}^2\,. \tag{11.5.46}$$

According to (11.5.23), the solid and fluid jumps on the longitudinal wave enjoy the relations,

$$\begin{aligned} c=c_1\,:&\quad \boldsymbol{\eta}_{\rm w}=\boldsymbol{\eta}_{\rm s},\\ c=c_2\,:&\quad \boldsymbol{\eta}_{\rm w}=-\frac{\rho^{\rm s}}{\rho^{\rm w}}\,\boldsymbol{\eta}_{\rm s}\,. \end{aligned} \tag{11.5.47}$$

Then the fastest longitudinal wave turns out to be non dissipative, the solid and fluid jumps being equal. This argument led Biot to call the wave-speed c_0 the wave-speed of the *frozen mixture*. The second longitudinal wave is, on the other hand, strongly dissipative, i.e., it dies out at short distances.

11.5.2.5 Incompressible constituents

When both constituents are incompressible, the second order discontinuities $\boldsymbol{\eta}_\alpha$ are constrained by the rate form of the incompressibility condition (11.5.4), namely:

$$n^{\rm s}\,(\boldsymbol{\eta}_{\rm s}\cdot\mathbf{n}) + n^{\rm w}\,(\boldsymbol{\eta}_{\rm w}\cdot\mathbf{n}) = 0\,. \tag{11.5.48}$$

Therefore the number of independent modes of propagation is now at most three. The associated eigenvalue problem can be obtained using the limit procedure (7.3.54), or directly following Loret and Harireche [1991]: first the jump of the stress $\boldsymbol{\sigma}' = \boldsymbol{\sigma}^{\rm s} + n^{\rm s}\,p_{\rm w}\,\mathbf{I}$ is formed by combining the two relations (11.5.10), and, second, the jump of the fluid velocity gradient $\boldsymbol{\eta}_{\rm w}$ is eliminated with help of the constraint (11.5.48). The rate constitutive equations $\dot{\boldsymbol{\sigma}}' = \mathbb{E}:\dot{\boldsymbol{\epsilon}}^{\rm s}$ then yield a generalized eigenvalue problem for the solid jump,

$$\big(\mathbf{A}^{\rm D} - c^2\,\mathbf{I}(r)\,\big)\cdot\boldsymbol{\eta}_{\rm s} = \mathbf{0}\,, \tag{11.5.49}$$

which involves the elastic acoustic tensor of the drained solid. However, the second order tensor $\mathbf{I}(r)$ differs from the identity $\mathbf{I}$=$\mathbf{I}(1)$ due to the scalar r greater than 1 (Section 2.3.5 shows a few properties of this rank one modification of the identity):

$$\mathbf{I}(r) = \mathbf{I} + (r-1)\,\mathbf{n}\otimes\mathbf{n}\,, \quad r = 1+\left(\frac{n^{\rm s}}{n^{\rm w}}\right)^2\frac{\rho^{\rm w}}{\rho^{\rm s}} > 1\,. \tag{11.5.50}$$

The characteristic equation $\det\big(\mathbf{A}^{\rm D} - c^2\,\mathbf{I}(r)\,\big)$=0 differs from its counterpart for single phase solids. Indeed, for isotropic elasticity,

$$\det\big(\mathbf{A}^{\rm D} - c^2\,\mathbf{I}(r)\,\big) = r\,(c^2-c_3^2)^2\,(c^2-c_{2\rm I}^2)\,, \tag{11.5.51}$$

in which we have anticipated the fact that there exist one shear wave-speed c_3 of double multiplicity and a single longitudinal wave with speed $c_{2\rm I}$,

$$c_{2\rm I}^2 = \frac{1}{r}\,\frac{\lambda+2\,\mu}{\rho^{\rm s}}\,, \quad c_3^2 = \frac{\mu}{\rho^{\rm s}}\,. \tag{11.5.52}$$

In contrast to the case of single phase solids, Eqn (11.2.9), and despite the inequalities (7.3.45), the presence of the coefficient $r>1$ makes it possible for the elastic shear wave-speed to be larger than the elastic longitudinal wave-speed. This phenomenon is not at odds with the classification established in Section 11.5.2.1 for compressible porous media. In fact, one may consider incompressible porous media as a limit case of compressible media, with the bulk moduli of the solid and of the fluid tending to infinity along the scheme defined by (7.3.54). The largest longitudinal wave-speed c_1 is then observed to become unbounded while the second longitudinal wave-speed c_2 tends to the above value of $c_{2\rm I}$. And, indeed, the relative order provided in Section 11.5.2.1 indicates that the second longitudinal wave-speed c_2 may be larger or smaller than the shear wave-speed c_3, depending on the material parameters.

As a final remark, let us mention that the dynamic condition of compatibility which results in (11.5.47) and the incompressibility condition (11.5.48) are clearly at odds.

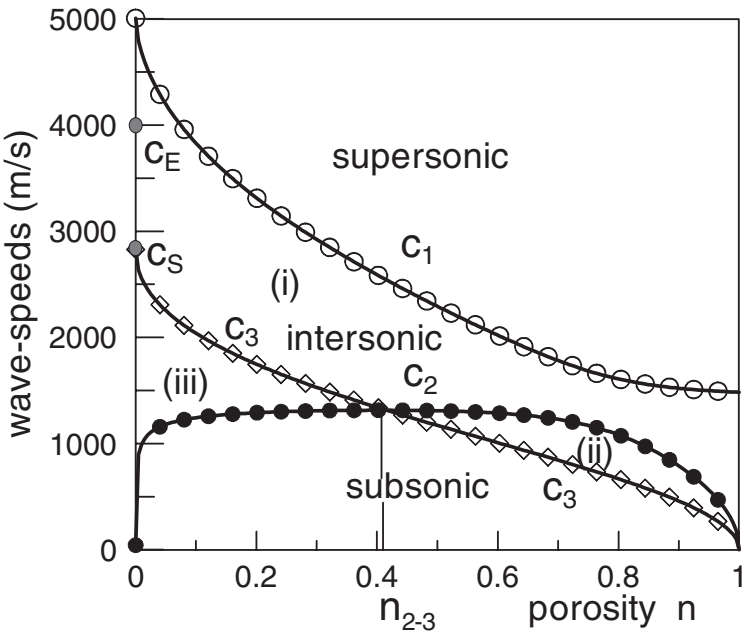

Fig. 11.5.2: Variations with porosity n of the three acceleration body wave-speeds, c_1 fast longitudinal wave-speed, c_2 slow longitudinal wave-speed and c_3 shear wave-speed, and corresponding subsonic region, supersonic region and intersonic regions (i), (ii), and (iii).

The parameters used for the solid constituent are: shear modulus $\mu_s = 20\,\text{GPa}$, bulk modulus $K_s = 36\,\text{GPa}$ (Poisson's ratio $\nu_s = 0.265$), mass density $\rho_s = 2500\,\text{kg/m}^3$, porosity dependence $n_c = 1$, $q = 0.5$; and for the fluid constituent: bulk modulus $K_w = 2.2\,\text{GPa}$, mass density $\rho_w = 1000\,\text{kg/m}^3$.

For these parameters, the wave-speed c_2 is equal to the shear wave-speed c_3 for a porosity $n = n_{2-3} \sim 0.415$.

For the solid ($n = 0$), the longitudinal wave-speed c_L is equal to 5006.7 m/s, Eshelby wave-speed $c_E = \sqrt{2}\,c_S$ to 4000 m/s and the shear wave-speed c_S to 2828.4 m/s. These theoretical variations of the wave-speeds agree qualitatively with the available experimental data shown in Fig. 11.5.3.

11.5.2.6 Wave-speeds with porosity dependent moduli

As for the dependence of the moduli in porosity, a parameter $q = 1/2$ and a limit porosity $n_c^w = 1$ are assumed so that the relation (7.3.46) simplifies to $K/K_s = \mu/\mu_s = (1 - \sqrt{n^w})^2$. This dependence implies the modulus of elastic coupling $\lambda^{sw} \geq 0$ to be positive as indicated by (7.3.49), which justifies the two definitions of c_{ms} and c_{mw} in (11.5.20). Fig. 11.5.2 illustrates the typical variations of the wave-speeds with porosity for stiff materials, like bones. Fig. 11.5.3 shows experimental data for an artificial material and for a cancellous bone.

Irrespective of the values of $q \in]0, 1[$ and n_c^w, the wave-speeds c_1 and c_3 tend, as the porosity vanishes, to their counterparts in the solid constituent,

$$c_1^2 \to c_L^2 = \frac{K_s}{\rho_s} + \frac{4}{3}\frac{\mu_s}{\rho_s}, \quad c_2^2 \to 0, \quad c_3^2 \to c_S^2 = \frac{\mu_s}{\rho_s}\,. \tag{11.5.53}$$

At small porosity, the slow longitudinal wave-speed is proportional to $(n^w)^{(1-q)/2}$, so that the initial slope dc_2/dn^w is quite large. On the other hand, in his description of ultrasonic waves, as opposed to acceleration waves of interest here, Berryman [1995] obtains a much smoother relation $c_2(n^w)$, through the high-frequency device of Biot [1956].

For linear elastic solids, the so-called Eshelby speed $c_E = \sqrt{2}\,c_S$ is below the longitudinal wave-speed c_L if Poisson's ratio ν_s is positive: indeed $c_L/c_E = (1 + \nu_s/(1 - 2\,\nu_s))^{1/2}$.

At the upper limit $n^w = n_c^w$, the situation becomes similar to that of a compressible fluid with a single longitudinal wave-speed,

$$c_1^2 \to \frac{\dfrac{1 - n_c^w}{\rho_s} + \dfrac{n_c^w}{\rho_w}}{\dfrac{1 - n_c^w}{K_s} + \dfrac{n_c^w}{K_w}}, \quad c_2^2 \to 0, \quad c_3^2 \to 0\,. \tag{11.5.54}$$

These expressions are established using the relations of Section 7.3.6.5.

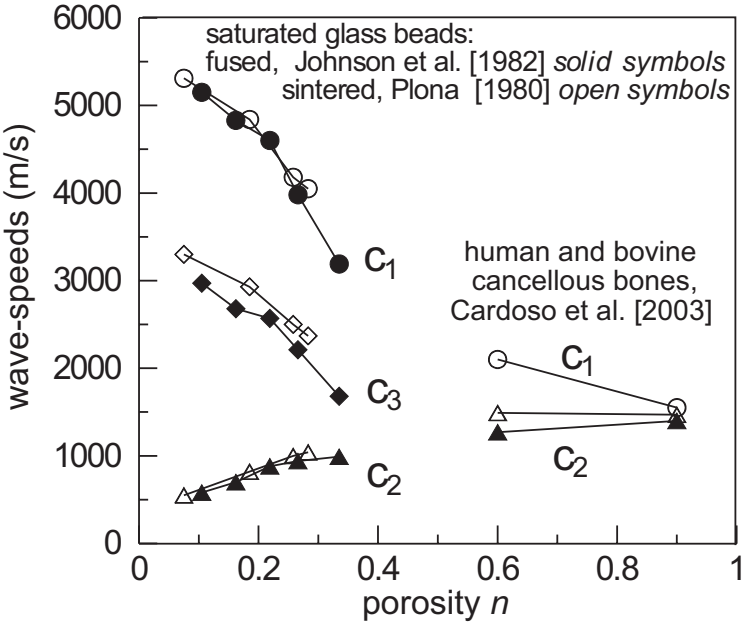

Fig. 11.5.3: Wave-speeds in porous materials in dry conditions or saturated by water: c_1 and c_2 fast and second (slow) longitudinal wave-speeds, c_3 shear wave-speed, Plona [1980], Johnson et al. [1982], Lakes et al. [1983], Cardoso et al. [2003].

11.5.3 Stationary discontinuity

Now that we have established the equations for the acceleration wave-speeds, we have the tools to study the existence of a stationary discontinuity where $c = 0$ is solution of the generalized eigenvalue problem (11.5.13). The dynamical interpretation of the phenomenon, also referred to as strain localization, is as follows: since it can not propagate any longer in the directions along which the wave-speed vanishes, the mechanical information accumulates in zones orthogonal to these directions and gives rise to a high strain gradient.

According to (11.5.10), the jump of the traction rate of each phase vanishes across a stationary discontinuity, namely $\mathbf{n} \cdot [\![\dot{\boldsymbol{\sigma}}^{\alpha}]\!] = \mathbf{0}$, $\alpha = \mathrm{s}, \mathrm{w}$. While the tangent components of the rate of the solid partial stress $\dot{\boldsymbol{\sigma}}^{\mathrm{s}}$ may be discontinuous, the fact that the fluid stress is isotropic implies trivially,

Proposition 11.3 on the jump of the rate of fluid pressure.

The jump of the rate of fluid pressure across a stationary discontinuity vanishes:

$$[\![-\dot{p}^{\mathrm{w}}]\!] = 0\,. \tag{11.5.55}$$

This simple observation indicates that, across a stationary discontinuity, the material behaves as if it was drained. In fact, setting $c = 0$ in (11.5.16), the condition for non zero jumps $\boldsymbol{\eta}_{\alpha}$, $\alpha = \mathrm{s}, \mathrm{w}$, is that the determinant of the $4{\times}4$ acoustic matrix $\mathbf{A}$ vanishes,

$$\det \mathbf{A} = \det \begin{bmatrix} \mathbf{A}^{\mathrm{ss}} & \mathbf{a}^{\mathrm{sw}} \\ (\mathbf{a}^{\mathrm{sw}})^{\mathrm{T}} & c_{\mathrm{w}}^2 \end{bmatrix} = 0\,. \tag{11.5.56}$$

Now, since the diagonal scalar c_{w}^2 is strictly positive, Exercise 11.1 shows that the singularity of $\mathbf{A}$ reduces to the singularity of its Schur complement in $\mathbf{A}$, which, due to (7.3.29), is equal to the acoustic tensor $\mathbf{A}^{\mathrm{D}}$ of the drained solid defined by (11.5.34),

$$\det \mathbf{A} = c_{\mathrm{w}}^2 \, \det \mathbf{A}^{\mathrm{D}}\,. \tag{11.5.57}$$

Therefore we have proved that stationary discontinuities are simultaneous in the porous medium and in its underlying drained solid. However, positive definiteness of the drained stiffness implies the drained wave-speeds to be strictly positive, and therefore prevents stationary discontinuities in the underlying drained solid, and consequently in the porous medium. This result was expected since the material parameters have been constrained so as to ensure the poroelastic energy to be positive definite, e.g., Section 7.4.2.

11.5.4 Interlacing and separation properties

With help of the two powerful theorems of linear algebra enounced in Section 2.2.1, the relative order of the wave-speeds of a saturated poroelastic medium, of its underlying drained solid and of its underlying undrained medium, are sorted out, Loret [1990]. The results hold for any type of mechanical anisotropy. By the same token, the isothermal and isentropic wave-speeds of a thermoelastic material are shown to interlace.

11.5.4.1 Interlacing property: drained solid and undrained medium

Let $\mathbf{A}$ be a symmetric positive definite matrix of size $m \times m$, $\mathbf{a}$ a vector of size m, and $a \geq 0$ a scalar, and let $\mathbf{A}(a)$ be a rank one modification of $\mathbf{A} = \mathbf{A}(0)$,

$$\mathbf{A}(a) = \mathbf{A} + a\,\mathbf{a} \otimes \mathbf{a}\,. \tag{11.5.58}$$

Then the eigenvalues $e_i^2(0)$ and $e_i^2(a)$, $i \in [1, m]$, of $\mathbf{A}(0)$ and $\mathbf{A}(a)$ respectively interlace, namely for $a \geq 0$,

$$e_m^2(0) \leq e_m^2(a) \leq e_{m-1}^2(0) \leq e_{m-1}^2(a) \;\cdots \leq e_1^2(0) \leq e_1^2(a)\,. \tag{11.5.59}$$

The proof goes as follows. Let $\mathbf{I}_m$ be the identity matrix of size $m \times m$. Consider the eigenvalue problem,

$$\mathbf{Z}(a) \cdot \mathbf{e} = \mathbf{0}, \quad \text{with} \quad \mathbf{Z}(a) = \mathbf{A}(a) - e^2\,\mathbf{I}_m\,, \tag{11.5.60}$$

and assume the eigenvalues to be ordered in decreasing order, namely $e_m^2(a) \leq e_{m-1}^2(a) \;\cdots \leq e_1^2(a)$. Now, using the property (2.3.20), the determinant of $\mathbf{Z}(a)$ may be cast in the useful format,

$$\begin{aligned} \mathbf{Z}(a) &= \mathbf{Z}(0) \cdot (\mathbf{I}_m + a\,\mathbf{Z}(0)^{-1} \cdot \mathbf{a} \otimes \mathbf{a}) \\ \det \mathbf{Z}(a) &= \det \mathbf{Z}(0) + a\,\mathbf{a} \cdot \operatorname{adj} \mathbf{Z}(0) \cdot \mathbf{a}\,, \end{aligned} \tag{11.5.61}$$

where $\operatorname{adj} \mathbf{Z}(0)$ is the matrix adjoint to $\mathbf{Z}(0)$, namely $\det \mathbf{Z}(0) \times \mathbf{Z}(0)^{-1}$. When expressed in the eigenspace of $\mathbf{Z}(0)$, the determinant $\det \mathbf{Z}(a)$ viewed as a function of e^2 may be further expanded as, Mandel [1962],

$$F(e^2) = \prod_{i=1}^{m} (e_i^2(0) - e^2) + a \sum_{i=1}^{m} a_i^2 \prod_{j=1, j\neq i}^{m} (e_j^2(0) - e^2)\,. \tag{11.5.62}$$

Consequently,

$$F(e_m^2(0)) \geq 0, \quad \cdots \quad (-1)^k\, F(e_{m-k}^2(0)) \geq 0, \quad \cdots \quad (-1)^{m-1}\, F(e_1^2(0)) \geq 0\,, \tag{11.5.63}$$

and this completes the proof in view of the fact that F is a polynomial of degree m in e^2 $\square$.

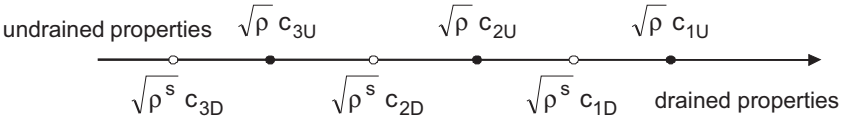

Fig. 11.5.4: Interlacing of drained and undrained characteristics.

This theorem can be applied to interlace the spectra of the drained and undrained acoustic tensors times an appropriate mass density, namely $\rho^{\mathrm{s}}\,\mathbf{A}^{\mathrm{D}} = \mathbf{n} \cdot \mathbb{E} \cdot \mathbf{n}$ and $\rho\,\mathbf{A}^{\mathrm{U}} = \mathbf{n} \cdot \mathbb{E}^{\mathrm{U}} \cdot \mathbf{n}$, respectively. Indeed, we have seen in Section 11.5.2.2 that the three drained wave-speeds are obtained by solving the eigenvalue problem,

$$(\mathbf{n} \cdot \mathbb{E} \cdot \mathbf{n} - \rho^{\mathrm{s}}\, c^2\, \mathbf{I}) \cdot \boldsymbol{\eta}_{\mathrm{s}}^{\mathrm{D}} = \mathbf{0}\,, \tag{11.5.64}$$

and in Section 11.5.2.3 that the three undrained wave-speeds are associated with the eigenvalue problem,

$$(\mathbf{n} \cdot \mathbb{E}^{\mathrm{U}} \cdot \mathbf{n} - \rho\, c^2\, \mathbf{I}) \cdot \boldsymbol{\eta}_{\mathrm{s}}^{\mathrm{U}} = \mathbf{0}\,. \tag{11.5.65}$$

Now, according to Section 7.4.2, the difference $\mathbf{n} \cdot \mathbb{E}^{\mathrm{U}} \cdot \mathbf{n} - \mathbf{n} \cdot \mathbb{E} \cdot \mathbf{n}$ is dyadic with a positive coefficient $a = M$. Therefore,

$$\rho^{\mathrm{s}}\, c_{3\mathrm{D}}^2 \leq \rho\, c_{3\mathrm{U}}^2 \leq \rho^{\mathrm{s}}\, c_{2\mathrm{D}}^2 \leq \rho\, c_{2\mathrm{U}}^2 \leq \rho^{\mathrm{s}}\, c_{1\mathrm{D}}^2 \leq \rho\, c_{1\mathrm{U}}^2\,. \tag{11.5.66}$$

The interlacing property is illustrated in Fig. 11.5.4. It holds for the square-roots of the entities involved. On the other hand, the inequalities do not hold a priori for the wave-speeds by themselves.

For isotropic poroelastic properties, the shear wave-speed has multiplicity two, and the inequalities simplify to,

$$\rho^{\mathrm{s}}\, c_{\mathrm{SD}}^2 = \rho\, c_{\mathrm{SU}}^2 \leq \rho^{\mathrm{s}}\, c_{\mathrm{LD}}^2 \leq \rho\, c_{\mathrm{LU}}^2\,, \tag{11.5.67}$$

as can be checked in Sections 7.4.2 and 11.5.2.3.

11.5.4.2 Interlacing property: isothermal and isentropic wave-speeds

In Section 11.3, the thermoelastic wave-speeds associated with a Fourier's heat conductor have been shown to be governed by the acoustic tensor of the underlying isothermal tensor moduli. By contrast, the thermoelastic wave-speeds associated with a non conductor have been shown to be governed by the acoustic tensor of the underlying isentropic tensor moduli.

The isothermal and isentropic tensor moduli are related by (9.1.7) so that their acoustic tensors differ only by a symmetric dyadic product. The interlacing property established in the previous section applies and actually can be sharpened since the mass densities associated with the two solids are identical. Indeed,

$$c_{3\text{isoth}} \leq c_{3\text{isEn}} \leq c_{2\text{isoth}} \leq c_{2\text{isEn}} \leq c_{1\text{isoth}} \leq c_{1\text{isEn}} \,. \tag{11.5.68}$$

For isotropic thermoelastic properties, the elastic shear wave-speed c_{S} has double multiplicity for both solids, and the inequalities simplify to,

$$c_{\text{S}} \leq c_{1\text{isoth}} \leq c_{1\text{isEn}} \,. \tag{11.5.69}$$

11.5.4.3 Separation property: drained solid and porous medium

The acoustic matrix $\mathbf{A}$ defining the eigenvalue problem that yields the (real) wave-speeds of the porous medium (11.5.16) has the format considered in Exercise 11.1, namely

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}^{\text{ss}} - c^2\,\mathbf{I} & \mathbf{a}^{\text{sw}} \\ (\mathbf{a}^{\text{sw}})^{\text{T}} & c_{\text{w}}^2 - c^2 \end{bmatrix} , \tag{11.5.70}$$

and therefore

$$F(c^2) \equiv \det\big[\mathbf{A} - c^2\mathbf{I}_4\big] = (c_{\text{w}}^2 - c^2)\, \det(\mathbf{A}^{\text{ss}} - c^2\,\mathbf{I}) - \mathbf{a}^{\text{sw}} \cdot \text{adj}\,(\mathbf{A}^{\text{ss}} - c^2\,\mathbf{I}) \cdot \mathbf{a}^{\text{sw}} \,. \tag{11.5.71}$$

Due to (7.3.29), the drained acoustic tensor can also be rephrased in terms of $\mathbf{A}^{\text{ss}}$, $\mathbf{a}^{\text{sw}}$ and c_{w}^2, namely

$$\mathbf{A}^{\text{D}} = \mathbf{A}^{\text{ss}} - \frac{\mathbf{a}^{\text{sw}} \otimes \mathbf{a}^{\text{sw}}}{c_{\text{w}}^2} \,. \tag{11.5.72}$$

Therefore, using again the property (2.3.20),

$$F_{\text{D}}(c_{\text{D}}^2) \equiv \det\big[\mathbf{A}^{\text{D}} - c_{\text{D}}^2\mathbf{I}_3\big] = \frac{1}{c_{\text{w}}^2}\Big(c_{\text{w}}^2\, \det(\mathbf{A}^{\text{ss}} - c_{\text{D}}^2\,\mathbf{I}) - \mathbf{a}^{\text{sw}} \cdot \text{adj}\,(\mathbf{A}^{\text{ss}} - c_{\text{D}}^2\,\mathbf{I}) \cdot \mathbf{a}^{\text{sw}}\Big) \,. \tag{11.5.73}$$

The wave-speeds c_i, $i \in [1,4]$, of the porous medium satisfy the secular equation $F(c_i^2) = 0$. Combining (11.5.71) and (11.5.73) yields,

$$F_{\text{D}}(c_i^2) = \frac{c_i^2}{c_{\text{w}}^2}\, \det(\mathbf{A}^{\text{ss}} - c_i^2\,\mathbf{I}) \,. \tag{11.5.74}$$

The sign of $\det(\mathbf{A}^{\text{ss}} - c_i^2\,\mathbf{I})$ is deduced from the theorem of algebra referred to as separation theorem enounced in Section 2.2.1:

$$F_{\text{D}}(c_4^2) \geq 0, \quad F_{\text{D}}(c_3^2) \leq 0, \quad F_{\text{D}}(c_2^2) \geq 0, \quad F_{\text{D}}(c_1^2) \leq 0 \,. \tag{11.5.75}$$

Consequently, the (squares of the) three wave-speeds of the drained solid separate the (squares of the) four wave-speeds of the porous medium as illustrated by Fig. 11.5.5,

$$c_4 \leq c_{3\text{D}} \leq c_3 \leq c_{2\text{D}} \leq c_2 \leq c_{1\text{D}} \leq c_1 \,. \tag{11.5.76}$$

For isotropic poroelastic properties, the drained shear wave-speed is smaller than the longitudinal wave-speed and it has multiplicity two, namely $c_{2\text{D}} = c_{3\text{D}} = c_{\text{SD}} < c_{1\text{D}}$. Consequently, the wave-speed c_3 of the porous medium is necessarily equal to c_{SD},

$$c_4 \leq c_3 = c_{\text{SD}} \leq c_2 \leq c_{\text{LD}} \leq c_1 \,. \tag{11.5.77}$$

In fact, the shear wave-speed has also multiplicity two for the porous medium, and either it is the smallest wave-speed,

$$c_4 = c_3 = c_{\text{SD}} \leq c_2 \leq c_{\text{LD}} \leq c_1 \,, \tag{11.5.78}$$

or the second longitudinal wave-speed is the smallest one,

$$c_4 \leq c_3 = c_{\text{SD}} = c_2 \leq c_{\text{LD}} \leq c_1 \,. \tag{11.5.79}$$

The notation is different from that of Section 11.5.2.1 where the second longitudinal wave-speed was denoted by c_2 and the shear wave-speed by c_3, while the numbers here correspond to the rank.

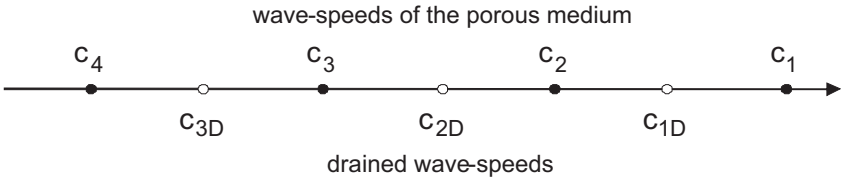

Fig. 11.5.5: The drained wave-speeds separate the wave-speeds of the saturated porous medium.

11.5.5 Inertial coupling: influence on acceleration waves

Inertial coupling has been introduced by Biot [1956] to induce an added mass effect. The idea is motivated in Section 7.3.1. Inertial coupling is often neglected because it is difficult to quantify. However, it might be necessary to take it into account, for instance for an accurate interpretation of wave-speeds in the resonant column. Actually, due to viscous coupling, the response of porous media to a general impulse is dispersive. Gajo [1996] has analyzed the relative influence of inertial and viscous couplings according to porosity and permeability.

Implications of inertial coupling on the speeds and modes of propagation of acceleration waves are reported in Loret and Rizzi [1998]. In essence, inertial coupling does not alter the structures neither of the secular polynomial yielding the wave-speeds, nor of the eigenvalue problem for the solid eigenmode. On the other hand, the structure of the fluid eigenmode is modified by inertial coupling as transverse motions in the solid phase carry over to the fluid phase. Consequently, Proposition 11.2 does not hold in presence of inertial coupling.

As a consequence of inertial coupling, the discontinuity relations across the acceleration front (11.5.10) modify to,

$$\mathbf{n}\cdot[\![\dot{\boldsymbol{\sigma}}^{\alpha}]\!]=\sum_{\beta=\mathrm{s,w}}\rho^{\alpha\beta}\,c^2\,\boldsymbol{\eta}_{\beta}\,,\quad \alpha=\mathrm{s,w}\,. \tag{11.5.80}$$

We consider in turn compressible and incompressible constituents. The analysis is restricted to isotropic mechanical properties.

11.5.5.1 Inertial coupling with compressible constituents

The generalized eigenvalue problem (11.5.13) modifies to,

$$\begin{bmatrix}(\lambda^{\mathrm{ss}}+2\mu)\,\mathbf{n}\otimes\mathbf{n}+\mu\,(\mathbf{I}-\mathbf{n}\otimes\mathbf{n}) & \lambda^{\mathrm{sw}}\,\mathbf{n}\otimes\mathbf{n}\\ \lambda^{\mathrm{sw}}\,\mathbf{n}\otimes\mathbf{n} & \lambda^{\mathrm{ww}}\,\mathbf{n}\otimes\mathbf{n}\end{bmatrix}\begin{bmatrix}\boldsymbol{\eta}_{\mathrm{s}}\\ \boldsymbol{\eta}_{\mathrm{w}}\end{bmatrix}=c^2\begin{bmatrix}\rho^{\mathrm{ss}}\,\mathbf{I} & \rho^{\mathrm{sw}}\,\mathbf{I}\\ \rho^{\mathrm{sw}}\,\mathbf{I} & \rho^{\mathrm{ww}}\,\mathbf{I}\end{bmatrix}\begin{bmatrix}\boldsymbol{\eta}_{\mathrm{s}}\\ \eta_{\mathrm{w}}\end{bmatrix}. \tag{11.5.81}$$

Positive definiteness of the elastic energy of the porous medium implies positive definiteness of the symmetric constitutive array (7.3.28), and consequently of the constitutive array appearing at the left hand side of (11.5.81). Moreover, Section 7.3.1 has restricted the coefficients of inertial coupling so that the kinetic energy and the mass array appearing at the right-hand side of (11.5.81) are positive definite as well. The generalized eigenvalue problem can then be transformed to a standard eigenvalue problem, featuring a symmetric positive definite matrix. Thus positive definiteness of the strain and kinetic energies ensures the elastic wave-speeds to be real and strictly positive.

The jump in the fluid phase $\boldsymbol{\eta}_{\mathrm{w}}$ can be eliminated in favor of the solid jump $\boldsymbol{\eta}_{\mathrm{s}}$,

$$\boldsymbol{\eta}_{\mathrm{w}}=-\Big(\frac{\rho^{\mathrm{sw}}c^2-\lambda^{\mathrm{sw}}}{\rho^{\mathrm{ww}}c^2-\lambda^{\mathrm{ww}}}\,\mathbf{n}\otimes\mathbf{n}+\frac{\rho^{\mathrm{sw}}}{\rho^{\mathrm{ww}}}(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\Big)\cdot\boldsymbol{\eta}_{\mathrm{s}}\,, \tag{11.5.82}$$

so as to obtain an equation in terms of the jump in the solid phase $\boldsymbol{\eta}_{\mathrm{s}}$ only,

$$\Big(a\,\mathbf{n}\otimes\mathbf{n}+b\,(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\Big)\cdot\boldsymbol{\eta}_{\mathrm{s}}=\mathbf{0}\,, \tag{11.5.83}$$

where

$$a=\ \lambda^{\mathrm{ss}}+2\,\mu-\rho^{\mathrm{ss}}\,c^2+\frac{(\rho^{\mathrm{sw}}c^2-\lambda^{\mathrm{sw}})^2}{\rho^{\mathrm{ww}}c^2-\lambda^{\mathrm{ww}}}\,,\quad b=\mu-\tilde{\rho}^{\mathrm{ss}}\,c^2\,, \tag{11.5.84}$$

with

$$\tilde{\rho}^{\mathrm{ss}}\equiv\rho^{\mathrm{ss}}\,\Delta\,,\quad \Delta\equiv 1-\frac{(\rho^{\mathrm{sw}})^2}{\rho^{\mathrm{ss}}\rho^{\mathrm{ww}}}>0\,. \tag{11.5.85}$$

Now

$$\det\big(a\,\mathbf{n}\otimes\mathbf{n}\;+\;b\,(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\big)=a\,b^2\,. \tag{11.5.86}$$

Thus there exist in general one shear wave-speed c_3 of double multiplicity corresponding to $b^2=0$, and two longitudinal wave-speeds $c_2\le c_1$ corresponding to $a=0$, Biot [1956]. As a characteristic of inertial coupling, the shear wave gives rise to in-phase motions in both the solid and fluid phases (remember that $\rho^{\rm sw}$ is negative),

$$c_3=\Big(\frac{\mu}{\tilde\rho^{\rm ss}}\Big)^{1/2},\quad \boldsymbol{\eta}_{\rm s}\perp\mathbf{n},\quad \boldsymbol{\eta}_{\rm w}=-\frac{\rho^{\rm sw}}{\rho^{\rm ww}}\,\boldsymbol{\eta}_{\rm s}\,. \tag{11.5.87}$$

The longitudinal wave-speeds are obtained from the sum and product of their squares:

$$\begin{aligned} c_1^2+c_2^2 &= \frac{1}{\Delta}\Big(\frac{\lambda^{\rm ss}+2\mu}{\rho^{\rm ss}}+\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}-2\,\frac{\rho^{\rm sw}\lambda^{\rm sw}}{\rho^{\rm ss}\rho^{\rm ww}}\Big)\,,\\ c_1^2\,c_2^2 &= \frac{1}{\Delta}\,\frac{\lambda+2\mu}{\rho^{\rm ss}}\,\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}\,, \end{aligned} \tag{11.5.88}$$

with the usual notation $\lambda=\lambda^{\rm ss}-(\lambda^{\rm sw})^2/\lambda^{\rm ww}$ and μ for the Lamé moduli of the underlying drained solid. Indeed, with a defined by (11.5.84), the longitudinal wave-speeds are found to be the roots of a polynomial of degree two in c^2:

$$F(c^2)=\Delta\,(c^2)^2-\Big(\frac{\lambda^{\rm ss}+2\mu}{\rho^{\rm ss}}+\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}-2\,\frac{\rho^{\rm sw}\lambda^{\rm sw}}{\rho^{\rm ss}\rho^{\rm ww}}\Big)\,c^2+\frac{\lambda+2\mu}{\rho^{\rm ss}}\,\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}\,. \tag{11.5.89}$$

The associated longitudinal jumps are linked by Eqn (11.5.82),

$$\boldsymbol{\eta}_{\rm s}=(\boldsymbol{\eta}_{\rm s}\cdot\mathbf{n})\,\mathbf{n},\quad \boldsymbol{\eta}_{\rm w}=-\frac{\rho^{\rm sw}c^2-\lambda^{\rm sw}}{\rho^{\rm ww}c^2-\lambda^{\rm ww}}\,\boldsymbol{\eta}_{\rm s}\,. \tag{11.5.90}$$

Information about the relative location of the scalar x with respect to the wave-speeds may be obtained from the sign of the function $F(x^2)$:

$$F\Big(\frac{\lambda^{\rm sw}}{\rho^{\rm sw}}\Big)=\Big(\frac{\lambda^{\rm sw}}{\rho^{\rm sw}}-\frac{\lambda^{\rm ss}+2\mu}{\rho^{\rm ss}}\Big)\Big(\frac{\lambda^{\rm sw}}{\rho^{\rm sw}}-\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}\Big)\,, \tag{11.5.91}$$

$$F\Big(\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}\Big)=-\frac{(\rho^{\rm sw})^2}{\rho^{\rm ss}\rho^{\rm ww}}\Big(\frac{\lambda^{\rm ww}}{\rho^{\rm ww}}-\frac{\lambda^{\rm sw}}{\rho^{\rm sw}}\Big)^2\le 0\,, \tag{11.5.92}$$

$$F\Big(\frac{\lambda^{\rm ss}+2\,\mu}{\rho^{\rm ss}}\Big)=-\frac{(\rho^{\rm sw})^2}{\rho^{\rm ss}\rho^{\rm ww}}\Big(\frac{\lambda^{\rm ss}+2\mu}{\rho^{\rm ss}}-\frac{\lambda^{\rm sw}}{\rho^{\rm sw}}\Big)^2\le 0\,, \tag{11.5.93}$$

$$F(c_0^2)=-\frac{(\rho^{\rm s}\rho^{\rm w})^2}{(\rho^{\rm s}+\rho^{\rm w})^2\rho^{\rm ss}\rho^{\rm ww}}\Big(\frac{\lambda^{\rm ss}+\lambda^{\rm sw}+2\mu}{\rho^{\rm s}}-\frac{\lambda^{\rm ww}+\lambda^{\rm sw}}{\rho^{\rm w}}\Big)^2\le 0\,, \tag{11.5.94}$$

where c_0,

$$c_0^2=\frac{\lambda^{\rm ss}+2\mu+\lambda^{\rm ww}+2\lambda^{\rm sw}}{\rho^{\rm s}+\rho^{\rm w}}\,, \tag{11.5.95}$$

is the *frozen mixture* wave-speed, Section 11.5.2.4. Therefore,

$$c_2^2\le\min\Big\{\frac{\lambda^{\rm ss}+2\mu}{\rho^{\rm ss}},\frac{\lambda^{\rm ww}}{\rho^{\rm ww}},c_0^2\Big\}\le\max\Big\{\frac{\lambda^{\rm ss}+2\mu}{\rho^{\rm ss}},\frac{\lambda^{\rm ww}}{\rho^{\rm ww}},c_0^2\Big\}\le c_1^2\,. \tag{11.5.96}$$

The mass densities involved in the above relations are linked by the restrictions detailed in Section 7.3.1.

When the dynamic condition of compatibility,

$$\frac{\lambda^{\rm ss}+\lambda^{\rm sw}+2\mu}{\rho^{\rm s}}=\frac{\lambda^{\rm ww}+\lambda^{\rm sw}}{\rho^{\rm w}}\,, \tag{11.5.97}$$

is satisfied, then c_0 is a wave-speed as indicated by (11.5.95), actually the larger longitudinal wave-speed c_1,

$$c_0^2=c_1^2=\frac{\lambda^{\rm ss}+\lambda^{\rm sw}+2\mu}{\rho^{\rm s}}=\frac{\lambda^{\rm ww}+\lambda^{\rm sw}}{\rho^{\rm w}}=\frac{\lambda^{\rm ss}+2\mu+\lambda^{\rm ww}+2\lambda^{\rm sw}}{\rho^{\rm s}+\rho^{\rm w}}\,. \tag{11.5.98}$$

The faster longitudinal wave then results to be non dissipative, since (11.5.82) yields $\boldsymbol{\eta}_{\rm w}=\boldsymbol{\eta}_{\rm s}$.

11.5.5.2 Inertial coupling with incompressible constituents

When both the solid and the fluid constituents are incompressible, the fluid pressure is indeterminate, the normal components of the solid and fluid jumps satisfy the relation (11.5.48), and the constitutive equations provide the effective stress as a function of the solid strain. Upon elimination of the jump of the rate of fluid pressure with help of (11.5.80) follows a relation involving the fluid and solid jumps,

$$\Big((\lambda+2\,\mu)\,\mathbf{n}\otimes\mathbf{n}+\mu\,(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\Big)\cdot\boldsymbol{\eta}_{\rm s}=c^2\,\left(\left(\rho^{\rm ss}-\frac{n^{\rm s}}{n^{\rm w}}\rho^{\rm sw}\right)\boldsymbol{\eta}_{\rm s}+\left(\rho^{\rm sw}-\frac{n^{\rm s}}{n^{\rm w}}\rho^{\rm ww}\right)\boldsymbol{\eta}_{\rm w}\right)\,. \tag{11.5.99}$$

From the discontinuity equation (11.5.48),

$$\boldsymbol{\eta}_{\rm w}=-\frac{n^{\rm s}}{n^{\rm w}}(\boldsymbol{\eta}_{\rm s}\cdot\mathbf{n})\,\mathbf{n}\;+\;\boldsymbol{\eta}_{\rm w}^{\perp}\,,\quad\text{with}\quad\boldsymbol{\eta}_{\rm w}^{\perp}\cdot\mathbf{n}=0\,. \tag{11.5.100}$$

If $c\neq 0$, Eqn (11.5.80) for the fluid phase shows the sum $\rho^{\rm sw}\boldsymbol{\eta}_{\rm s}+\rho^{\rm ww}\boldsymbol{\eta}_{\rm w}$ to be parallel to $\mathbf{n}$. Therefore, the fluid jump can be expressed in terms of the solid jump through the relation,

$$\boldsymbol{\eta}_{\rm w}=-\Big(\frac{n^{\rm s}}{n^{\rm w}}\mathbf{n}\otimes\mathbf{n}+\frac{\rho^{\rm sw}}{\rho^{\rm ww}}(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\Big)\cdot\boldsymbol{\eta}_{\rm s}\,, \tag{11.5.101}$$

which could have been derived directly from Eqn (11.5.82) using the limit process (7.3.54). Elimination of the fluid jump from (11.5.99) gives a generalized eigenvalue problem for the solid jump, which holds for any c,

$$\Big(\frac{\lambda+2\,\mu}{\tilde\rho^{\rm ss}}\,\mathbf{n}\otimes\mathbf{n}+\frac{\mu}{\tilde\rho^{\rm ss}}\,(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\Big)\cdot\boldsymbol{\eta}_{\rm s}=c^2\,\mathbf{I}(\tilde r)\cdot\boldsymbol{\eta}_{\rm s}\,, \tag{11.5.102}$$

where $\mathbf{I}(\tilde r)=\mathbf{I}+(\tilde r-1)\,\mathbf{n}\otimes\mathbf{n}$ and

$$\tilde r\equiv 1+\frac{\rho^{\rm ww}}{\tilde\rho^{\rm ss}}\Big(\frac{n^{\rm s}}{n^{\rm w}}-\frac{\rho^{\rm sw}}{\rho^{\rm ww}}\Big)^2\;>1\,. \tag{11.5.103}$$

This eigenvalue problem has exactly the same form as its counterpart without inertial coupling, as described in Section 11.5.2.5. The uncoupled wave-speeds are retrieved from the above relations by the substitutions $\tilde\rho^{\rm ss}\to\rho^{\rm s}$ and $\tilde r\to r\equiv 1+(\rho^{\rm w}/\rho^{\rm s})(n^{\rm s}/n^{\rm w})^2$. Like for compressible constituents, the shear wave-speed has double multiplicity, its value and the eigenmodes are still given by (11.5.87). However there is a single finite longitudinal wave with speed c_2,

$$c_2=\Big(\frac{1}{\tilde r}\;\frac{\lambda+2\,\mu}{\tilde\rho^{\rm ss}}\Big)^{1/2}\,, \tag{11.5.104}$$

and the associated fluid and solid jumps are linked by the relation $\boldsymbol{\eta}_{\rm w}=-\boldsymbol{\eta}_{\rm s}\,n^{\rm s}/n^{\rm w}$.

11.5.6 Waves in fluid saturated porous media: pushing the window ajar

The analysis of the existence of isothermal acceleration waves so far may be extended to include fluid saturated porous media with double porosity introduced in Section 10.6.

Table 11.5.2: Acceleration wave-speeds for isotropic solids and fluid saturated porous media. The longitudinal wave-speeds have in general single multiplicity and the shear wave-speeds double multiplicity.

Material	nb. Longitudinal Wave-Speed	nb. Shear Wave-Speed
Solid	1	1
Porous solid with single porosity	2	1
Porous solid with double porosity	3	1

Table 11.5.2 applies to fluid saturated porous media in the following context: (1) their mechanical constitutive equations are linear; (2) their mechanical constitutive equations are isotropic; (3) the fluids filling the pores are non viscous.

Harmonic waves provide a more general tool to probe mechanical and transport properties than acceleration waves. In fact, acceleration waves can be viewed as the limit of harmonic waves where the frequency tends to infinity.

11.6 Propagation of 2nd order waves in saturated porous media

In Section 11.5, we have formally defined the modes under which plane acceleration waves propagate. We shall now study how their amplitude varies in time as they propagate. We begin by establishing the differential equation governing the evolution in time of the jumps of the velocity gradients. Next, we will analyze the coefficients of growth or decay depending on the details of the constitutive equations.

To simplify the presentation, we consider only incompressible constituents, and direct the reader to Loret et al. [1997] for the compressible case. Moreover, the body forces are assumed to vanish, and the momentum supplies reduce to Darcy's law.

11.6.1 Equations of propagation

Elements of the differential equations that govern the propagation of discontinuities on a moving surface have been summarized in Section 11.1.6. They will be used in the present context of second order waves.

Upon derivation with respect to time, the linearized equations of balance of momentum (11.5.5) yield the discontinuity equations,

$$\rho^{\alpha}[\![\dot{\mathbf{v}}_{\alpha}]\!] \;=\; [\![\operatorname{div}\dot{\boldsymbol{\sigma}}^{\alpha}]\!] \;-\; \epsilon_{\alpha}\, k_{\mathrm{Sd}}\,([\![\dot{\mathbf{v}}_{\mathrm{s}}]\!] - [\![\dot{\mathbf{v}}_{\mathrm{w}}]\!])\,, \tag{11.6.1}$$

with $\epsilon_{\mathrm{s}} = 1$ and $\epsilon_{\mathrm{w}} = -1$. The evolution of the amplitude of the acceleration wave front is expressed through a differential equation in terms of the *displacement derivative*, Eqn (11.1.66),

$$\frac{\delta[\![\dot{\mathbf{v}}_{\alpha}]\!]}{\delta t} = \frac{\partial[\![\dot{\mathbf{v}}_{\alpha}]\!]}{\partial t} + \boldsymbol{\nabla}[\![\dot{\mathbf{v}}_{\alpha}]\!]\cdot(c\,\mathbf{n})\,. \tag{11.6.2}$$

Now, since the velocity is continuous across the front that travels at constant speed c in a given direction $\mathbf{n}$, the *iterated kinematical compatibility equation* (11.1.73) simplifies to

$$2\,\frac{\delta[\![\dot{\mathbf{v}}_{\alpha}]\!]}{\delta t} = [\![\ddot{\mathbf{v}}_{\alpha}]\!] - c^2\,\mathbf{n}\cdot\left[\!\left[\boldsymbol{\nabla}^2\mathbf{v}_{\alpha}\right]\!\right]\cdot\mathbf{n}\,. \tag{11.6.3}$$

Eliminating the discontinuity $[\![\ddot{\mathbf{v}}_{\alpha}]\!]$, $\alpha = \mathrm{s},\mathrm{w}$, from (11.6.1) and (11.6.3) and using the rate constitutive equations $\dot{\boldsymbol{\sigma}}' = \mathbb{E} : \dot{\boldsymbol{\epsilon}}^{\mathrm{s}}$ in terms of the effective stress $\boldsymbol{\sigma}' = \boldsymbol{\sigma}^{\mathrm{s}} - n^{\mathrm{s}}/n^{\mathrm{w}}\,\boldsymbol{\sigma}_{\mathrm{w}}$, the evolution equations for the discontinuities of acceleration $[\![\dot{\mathbf{v}}_{\alpha}]\!]$, $\alpha = \mathrm{s},\mathrm{w}$, follow,

$$\begin{aligned}
2\,\rho^{\mathrm{s}}\,\frac{\delta[\![\dot{\mathbf{v}}_{\mathrm{s}}]\!]}{\delta t} \;&=\; \rho^{\mathrm{s}}\,(\mathbf{A}^{\mathrm{D}} - c^2\,\mathbf{I})\cdot\boldsymbol{\Delta}_{\mathrm{s}} \;+\; \frac{n^{\mathrm{s}}}{n^{\mathrm{w}}}[\![\operatorname{div}\dot{\boldsymbol{\sigma}}^{\mathrm{w}}]\!] \;-\; k_{\mathrm{Sd}}\,([\![\dot{\mathbf{v}}_{\mathrm{s}}]\!] - [\![\dot{\mathbf{v}}_{\mathrm{w}}]\!])\,,\\
2\,\rho^{\mathrm{w}}\,\frac{\delta[\![\dot{\mathbf{v}}_{\mathrm{w}}]\!]}{\delta t} \;&=\; -\rho^{\mathrm{w}}c^2\,\boldsymbol{\Delta}_{\mathrm{w}} \;+\; [\![\operatorname{div}\dot{\boldsymbol{\sigma}}^{\mathrm{w}}]\!] \;+\; k_{\mathrm{Sd}}\,([\![\dot{\mathbf{v}}_{\mathrm{s}}]\!] - [\![\dot{\mathbf{v}}_{\mathrm{w}}]\!])\,,
\end{aligned} \tag{11.6.4}$$

where $\mathbf{A}^{\mathrm{D}}$ is the drained acoustic tensor and $\boldsymbol{\Delta}_{\alpha} = \mathbf{n}\cdot\left[\!\left[\boldsymbol{\nabla}^2\mathbf{v}_{\alpha}\right]\!\right]\cdot\mathbf{n}$, $\alpha = \mathrm{s},\mathrm{w}$, are the induced discontinuities. Due to Hadamard's compatibility relation (11.2.1), the relation (11.5.11) and the incompressibility condition (11.5.48) imply the discontinuity of acceleration in the fluid phase to be aligned with the wave normal $\mathbf{n}$, and

$$[\![\dot{\mathbf{v}}_{\mathrm{w}}]\!] = -\frac{n^{\mathrm{s}}}{n^{\mathrm{w}}}\big([\![\dot{\mathbf{v}}_{\mathrm{s}}]\!]\cdot\mathbf{n}\big)\,\mathbf{n}\,. \tag{11.6.5}$$

As another consequence of Hadamard's compatibility relation, the jump $[\![\operatorname{div}\dot{\boldsymbol{\sigma}}^{\mathrm{w}}]\!]$ is aligned with $\mathbf{n}$. Upon space differentiation of the incompressibility condition (11.5.4), the induced discontinuities are seen to be balanced by the condition,

$$n^{\mathrm{s}}(\boldsymbol{\Delta}_{\mathrm{s}}\cdot\mathbf{n}) \;+\; n^{\mathrm{w}}(\boldsymbol{\Delta}_{\mathrm{w}}\cdot\mathbf{n}) = 0\,. \tag{11.6.6}$$

Therefore, the projection of $(11.6.4)_2$ along $\mathbf{n}$ can be expressed as,

$$-\,2\,\rho^{\mathrm{w}}\,\frac{\delta}{\delta t}\left(\frac{n^{\mathrm{s}}}{n^{\mathrm{w}}}([\![\dot{\mathbf{v}}_{\mathrm{s}}]\!]\cdot\mathbf{n})\,\mathbf{n}\right) = [\![\operatorname{div}\dot{\boldsymbol{\sigma}}^{\mathrm{w}}]\!] + \rho^{\mathrm{w}}c^2\frac{n^{\mathrm{s}}}{n^{\mathrm{w}}}\big(\boldsymbol{\Delta}_{\mathrm{s}}\cdot\mathbf{n}\big)\,\mathbf{n} + \frac{k_{\mathrm{Sd}}}{n^{\mathrm{w}}}\,([\![\dot{\mathbf{v}}_{\mathrm{s}}]\!]\cdot\mathbf{n})\,\mathbf{n}\,. \tag{11.6.7}$$

Subtraction of Eqn (11.6.7) multiplied by $n^{\mathrm{s}}/n^{\mathrm{w}}$ from Eqn (11.6.4) yields the evolution equation for the 3-component vector $\mathbf{V} = [\![\dot{\mathbf{v}}_{\mathrm{s}}]\!]$ in the solid phase,

$$2\,\mathbf{I}(r)\cdot\frac{\delta\mathbf{V}}{\delta t} = \big(\,\mathbf{A}^{\mathrm{D}} \;-\; c^2\,\mathbf{I}(r)\,\big)\cdot\boldsymbol{\Delta}_{\mathrm{s}} \;-\; k_{\mathrm{Sd}}\,\frac{\mathbf{I}(e)}{\rho^{\mathrm{s}}}\cdot\mathbf{V}\,, \tag{11.6.8}$$

where, for any real x, the matrix $\mathbf{I}(x) = \mathbf{I} + (x-1)\,\mathbf{n}\otimes\mathbf{n}$, r is defined by (11.5.50), and $e = 1/(n^{\mathrm{w}})^2 > 1$.

Once the solid jump is known, the wave front in the fluid-phase is then given by (11.6.5).

11.6.2 The decaying wave-front

Since we assume the mechanical state on the wave front to be fixed, the unit left and right eigenvectors of the generalized eigenvalue problem (11.5.49), namely $\mathbf{e}^L$ and $\mathbf{e}^R$, are constant. Therefore, multiplication of the evolution equation (11.6.8) by the unit left eigenvector $\mathbf{e}^L$ yields a differential equation for the amplitude $|\mathbf{V}|$ that is integrated to,

$$\frac{|\mathbf{V}|(t)}{|\mathbf{V}|(0)} = \exp\Big(- \frac{k_{\rm Sd}}{2\rho^{\rm s}}\,\zeta\, t\Big), \quad \zeta = \frac{\mathbf{e}^L\cdot\mathbf{I}(e)\cdot\mathbf{e}^R}{\mathbf{e}^L\cdot\mathbf{I}(r)\cdot\mathbf{e}^R}\,. \tag{11.6.9}$$

Notice that the products by $\mathbf{e}^L$ are not inner products in the usual sense, that is, they remain unchanged even if $\mathbf{e}^L$ is complex, Wilkinson [1965], Eqn (3.10), p. 4.

Since the coefficient $k_{\rm Sd}$ is a real positive number, growth or decay of the wave front is governed by the sign of the dimensionless *decay* coefficient ζ. For a poroelastic skeleton, the generalized eigenvalue problem (11.5.49) is symmetric, the wave-speeds are real and the left and right eigenvectors are one and the same. Since the matrices $\mathbf{I}(r)$ and $\mathbf{I}(e)$ are symmetric positive definite, the coefficient ζ is then positive and propagation is accompanied by a wave front whose amplitude strictly decays: the fact that the two constituents are incompressible excludes the possibility that the fastest wave can propagate without dissipation, a situation referred to as *dynamic compatibility* by Biot [1956] and considered in Section 11.5.2.4. In fact, this remark can be sharpened.

11.6.2.1 The decay coefficient as a Rayleigh quotient

Indeed, let us transform the generalized eigenvalue problem (11.5.49) into a standard eigenvalue problem,

$$\big((\mathbf{A}^{\rm D})^{\#} - c^2\,\mathbf{I}\big)\cdot\boldsymbol{\eta}_{\rm s}^{\#} = \mathbf{0}\,, \tag{11.6.10}$$

with

$$(\mathbf{A}^{\rm D})^{\#} = \mathbf{I}(r)^{-\frac{1}{2}}\cdot\mathbf{A}^{\rm D}\cdot\mathbf{I}(r)^{-\frac{1}{2}}\,, \quad \boldsymbol{\eta}_{\rm s}^{\#} = \mathbf{I}(r)^{\frac{1}{2}}\cdot\boldsymbol{\eta}_{\rm s}\,. \tag{11.6.11}$$

If one denotes by $\mathbf{e}^{L\#} = \mathbf{I}(r)^{\frac{1}{2}}\cdot\mathbf{e}^L$ and $\mathbf{e}^{R\#} = \mathbf{I}(r)^{\frac{1}{2}}\cdot\mathbf{e}^R$ the new eigenvectors, then one obtains

Proposition 11.4 on the decay coefficient as a Rayleigh quotient, Loret et al. [1997].

The decay coefficient ζ appears in the form of a Rayleigh quotient,

$$\zeta = \frac{\mathbf{e}^{R\#}\cdot\mathbf{I}^{\#}(e)\cdot\mathbf{e}^{R\#}}{\mathbf{e}^{R\#}\cdot\mathbf{e}^{R\#}}\,, \tag{11.6.12}$$

associated with the symmetric positive definite matrix $\mathbf{I}^{\#}(e) = \mathbf{I}(r)^{-\frac{1}{2}}\cdot\mathbf{I}(e)\cdot\mathbf{I}(r)^{-\frac{1}{2}}$, which, according to (2.3.23) and (2.3.24), is equal to $\mathbf{I}(e/r)$. Consequently, it is bounded below and above by the smallest and largest eigenvalues of this matrix,

$$1 \le \zeta \le \frac{1}{r\big(n^{\rm w}\big)^2}\,. \tag{11.6.13}$$

As indicated by (2.3.25), the largest eigenvalue is associated with a longitudinal eigenmode, while the smallest one is associated with transverse eigenmodes.

The evolution equation (11.6.8) yields not only the decay coefficient but also the part of the induced discontinuity which is orthogonal to the eigenmode $\mathbf{e}^R$: in fact, when the wave-speed has single multiplicity, this part can be shown to be uniquely defined.

11.6.2.2 An alternative direct evaluation of the decay coefficient ζ

To obtain the decay coefficient for a given wave-speed c, the natural approach is to calculate first the associated left and right eigenvectors $\mathbf{e}^R$ and $\mathbf{e}^L$. However, if c is a wave-speed of single multiplicity, considerable algebraic simplifications result from the alternative procedure below. Only the eigenvalues, not the eigenmodes, of an extended problem are required.

Let $c^2(0) = c^2$ be an eigenvalue with single multiplicity of the generalized eigenproblem (11.5.49) and let $\mathbf{e}^R(0) = \mathbf{e}^R$ and $\mathbf{e}^L(0) = \mathbf{e}^L$ be the associated right and left eigenvectors. Consider now the *extended* generalized eigenvalue problem:

$$\Big(\mathbf{A}^{\rm D} + \varphi\,\mathbf{I}(e) - c^2(\varphi)\,\mathbf{I}(r)\Big)\cdot\mathbf{e}^R(\varphi) = 0\,. \tag{11.6.14}$$

For φ a sufficiently small real number, the eigenvalue $c^2(\varphi)$ is an analytic function of φ, Stoer and Bulirsch [1980], p. 389. Therefore scalar multiplication of (11.6.14) by the left eigenvector $\mathbf{e}^L(0) = \mathbf{e}^L$, differentiation with respect to φ of the resulting product and estimation of the derivative at $\varphi = 0$ lead to

Proposition 11.5 on a direct evaluation of the decay coefficient ζ, Stoer and Bulirsch [1980].

Let $c(0)$ be a solution of single multiplicity of the eigenvalue problem (11.5.49) with $\mathbf{e}^R$ and $\mathbf{e}^L$ the respective right and left eigenvectors. Then the decay coefficient associated with $c(0)$ and defined by (11.6.9) is given by the derivative of the square of the generalized wave-speed,

$$\zeta = \frac{dc^2}{d\varphi}(\varphi = 0)\,. \tag{11.6.15}$$

The procedure breaks down at an eigenvalue of multiplicity greater than one, where the nature of the eigenspace may be more complex. Let us simply consider the case of a double eigenvalue, for $\mathbf{A}^{\rm D}$ a non-symmetric matrix, a possibility that takes place for some irreversible mechanical behaviors. Then, the eigenvectors may not be unique or, if the eigenspace is defective, the left and right eigenvectors may be well-defined and then they are orthogonal with respect to the matrix $\mathbf{I}(r)$, that is, Wilkinson [1965], Eqn (7.5), p.10:

$$\mathbf{e}^L \cdot \mathbf{I}(r) \cdot \mathbf{e}^R = 0\,, \tag{11.6.16}$$

which is in strong contrast with the case of single multiplicity, where this equality occurs only for $\mathbf{e}^L$ and $\mathbf{e}^R$ associated with distinct eigenvalues. This result suggests that, in the vicinity of a wave-speed of multiplicity greater than 1, the decay coefficient for materials with a non-symmetric acoustic tensor may become unbounded, Loret et al. [1997].

11.7 Plane motions and Helmholtz potentials in poroelasticity

11.7.1 Displacements and strains in terms of Helmholtz potentials

The apparent strains $\boldsymbol{\epsilon}^\alpha$ of each phase derive from the corresponding displacements $\mathbf{u}_\alpha$,

$$\boldsymbol{\epsilon}^\alpha = \frac{1}{2}(\boldsymbol{\nabla}\mathbf{u}_\alpha + (\boldsymbol{\nabla}\mathbf{u}_\alpha)^{\rm T})\,, \quad \alpha = {\rm s},\, {\rm w}\,, \tag{11.7.1}$$

so that

$$\text{tr}\ \boldsymbol{\epsilon}^\alpha = \text{div}\ \mathbf{u}_\alpha\,, \quad \alpha = {\rm s},\, {\rm w}\,. \tag{11.7.2}$$

Henceforth, the analysis considers displacements in the plane (x_1, x_2) endowed with cartesian axes. Let $\mathbf{e}_3$ be the unit vector orthogonal to this plane. Then, as a generalization of the approach exposed for single phase solids in Section 11.2.6, the displacements are defined in terms of four potentials,

$$\mathbf{u}_\alpha = \boldsymbol{\nabla}\phi_\alpha + \boldsymbol{\nabla} \wedge (\psi_\alpha \mathbf{e}_3) \quad \text{with} \quad \text{div}\,(\psi_\alpha \mathbf{e}_3) = 0\,, \quad \alpha = {\rm s},\, {\rm w}\,, \tag{11.7.3}$$

and, in component form, for $\alpha = {\rm s},\, {\rm w}$,

$$\begin{aligned} u_{\alpha 1} &= \frac{\partial \phi_\alpha}{\partial x_1} + \frac{\partial \psi_\alpha}{\partial x_2} \\ u_{\alpha 2} &= \frac{\partial \phi_\alpha}{\partial x_2} - \frac{\partial \psi_\alpha}{\partial x_1} \end{aligned} \quad \text{and} \quad \frac{\partial \psi_\alpha}{\partial x_1} + \frac{\partial \psi_\alpha}{\partial x_2} = 0\,. \tag{11.7.4}$$

The resulting strains take the form,

$$\begin{aligned} \epsilon^\alpha_{11} &= \frac{\partial^2 \phi_\alpha}{\partial x_1^2} + \frac{\partial^2 \psi_\alpha}{\partial x_1 \partial x_2}\,, \\ \epsilon^\alpha_{22} &= \frac{\partial^2 \phi_\alpha}{\partial x_2^2} - \frac{\partial^2 \psi_\alpha}{\partial x_1 \partial x_2}\,, \\ \epsilon^\alpha_{12} &= \frac{\partial^2 \phi_\alpha}{\partial x_1 \partial x_2} + \frac{1}{2}\frac{\partial^2 \psi_\alpha}{\partial x_2^2} - \frac{1}{2}\frac{\partial^2 \psi_\alpha}{\partial x_1^2}\,. \end{aligned} \tag{11.7.5}$$

11.7.2 Poroelastic stresses in terms of Helmholtz potentials

For linear poroelasticity, the partial stresses deduce easily in terms of the Helmholtz potentials,

$$\begin{aligned}
\sigma^{\rm s}_{11} &= (\lambda^{\rm ss}+2\,\mu)\,\frac{\partial^2\phi_{\rm s}}{\partial x_1^2}+\lambda^{\rm ss}\,\frac{\partial^2\phi_{\rm s}}{\partial x_2^2}+\lambda^{\rm sw}\,\Delta\phi_{\rm w}+2\,\mu\,\frac{\partial^2\psi_{\rm s}}{\partial x_1\partial x_2}\,,\\
\sigma^{\rm s}_{22} &= \lambda^{\rm ss}\,\frac{\partial^2\phi_{\rm s}}{\partial x_1^2}+(\lambda^{\rm ss}+2\,\mu)\,\frac{\partial^2\phi_{\rm s}}{\partial x_2^2}+\lambda^{\rm sw}\,\Delta\phi_{\rm w}-2\,\mu\,\frac{\partial^2\psi_{\rm s}}{\partial x_1\partial x_2}\,,\\
\sigma^{\rm s}_{12} &= \mu\,\Big(2\,\frac{\partial^2\phi_{\rm s}}{\partial x_1\partial x_2}+\frac{\partial^2\psi_{\rm s}}{\partial x_2^2}-\frac{\partial^2\psi_{\rm s}}{\partial x_1^2}\Big)\,,\\
-n^{\rm w}\,p_{\rm w} &= \lambda^{\rm sw}\,\Delta\,\phi_{\rm s}+\lambda^{\rm ww}\,\Delta\,\phi_{\rm w}\,,
\end{aligned}\tag{11.7.6}$$

as well as the total stresses,

$$\begin{aligned}
\sigma_{11} &= (\lambda^{\rm ss}+\lambda^{\rm sw}+2\,\mu)\,\frac{\partial^2\phi_{\rm s}}{\partial x_1^2}+(\lambda^{\rm ss}+\lambda^{\rm sw})\,\frac{\partial^2\phi_{\rm s}}{\partial x_2^2}+(\lambda^{\rm ww}+\lambda^{\rm sw})\,\Delta\phi_{\rm w}+2\,\mu\,\frac{\partial^2\psi_{\rm s}}{\partial x_1\partial x_2}\,,\\
\sigma_{22} &= (\lambda^{\rm ss}+\lambda^{\rm sw})\,\frac{\partial^2\phi_{\rm s}}{\partial x_1^2}+(\lambda^{\rm ss}+\lambda^{\rm sw}+2\,\mu)\,\frac{\partial^2\phi_{\rm s}}{\partial x_2^2}+(\lambda^{\rm ww}+\lambda^{\rm sw})\,\Delta\phi_{\rm w}-2\,\mu\,\frac{\partial^2\psi_{\rm s}}{\partial x_1\partial x_2}\,,\\
\sigma_{12} &= \mu\,\Big(2\,\frac{\partial^2\phi_{\rm s}}{\partial x_1\partial x_2}+\frac{\partial^2\psi_{\rm s}}{\partial x_2^2}-\frac{\partial^2\psi_{\rm s}}{\partial x_1^2}\Big)\,.
\end{aligned}\tag{11.7.7}$$

The relation,

$$\sigma_{11}+\sigma_{22}=2\,(\lambda^{\rm ss}+\lambda^{\rm sw}+\mu)\,\Delta\,\phi_{\rm s}+2\,(\lambda^{\rm sw}+\lambda^{\rm ww})\,\Delta\,\phi_{\rm w}\,,\tag{11.7.8}$$

is worth recording as well as the divergence and Laplacian of the displacement vectors defined by (2.4.5), namely for $\alpha={\rm s},\,{\rm w}$,

$$\begin{aligned}
&{\rm div}\;\mathbf{u}_\alpha=\Delta\phi_\alpha,\\
&\Delta\mathbf{u}_\alpha=\boldsymbol{\nabla}{\rm div}\,\mathbf{u}_\alpha-\boldsymbol{\nabla}\wedge(\boldsymbol{\nabla}\wedge\mathbf{u}_\alpha)=\boldsymbol{\nabla}\Delta\phi_\alpha+\boldsymbol{\nabla}\wedge(\Delta\psi_\alpha\mathbf{e}_3)\,.
\end{aligned}\tag{11.7.9}$$

11.7.3 Field equations in terms of Helmholtz potentials

In absence of body forces, the equations of balance of momentum of the solid and fluid phases expressed in terms of displacements may be linearized to

$$\begin{aligned}
(\lambda^{\rm ss}+\mu)\,\boldsymbol{\nabla}\,{\rm div}\;\mathbf{u}_{\rm s}\;+\;\mu\,\Delta\,\mathbf{u}_{\rm s}\;+\;\lambda^{\rm sw}\,\boldsymbol{\nabla}\,{\rm div}\;\mathbf{u}_{\rm w}\;-\;k_{\rm Sd}\,(\dot{\mathbf{u}}_{\rm s}-\dot{\mathbf{u}}_{\rm w})\;&=\;\rho^{\rm s}\,\ddot{\mathbf{u}}_{\rm s}\,,\\
\lambda^{\rm sw}\,\boldsymbol{\nabla}\,{\rm div}\;\mathbf{u}_{\rm s}\;+\;\lambda^{\rm ww}\;\boldsymbol{\nabla}\,{\rm div}\;\mathbf{u}_{\rm w}\;+\;k_{\rm Sd}\,(\dot{\mathbf{u}}_{\rm s}-\dot{\mathbf{u}}_{\rm w})\;&=\;\rho^{\rm w}\,\ddot{\mathbf{u}}_{\rm w}\,,
\end{aligned}\tag{11.7.10}$$

the buoyancy term $p_{\rm w}\,\boldsymbol{\nabla}n^{\rm w}$ disappearing from the momentum supplies, see Sections 4.5.1, 7.3.1 and 7.3.2. Moreover, no distinction is made between the material time derivatives and the partial derivative with respect to time, which are all denoted by a superimposed dot.

Via (11.7.9), the two vector equations of balance of momentum (11.7.10) can be split into their longitudinal part

$$\begin{aligned}
(\lambda^{\rm ss}+2\,\mu)\,\Delta\,\phi_{\rm s}+\lambda^{\rm sw}\,\Delta\,\phi_{\rm w}-k_{\rm Sd}\,(\dot\phi_{\rm s}-\dot\phi_{\rm w})\;&=\;\rho^{\rm s}\,\ddot\phi_{\rm s}\,,\\
\lambda^{\rm sw}\,\Delta\,\phi_{\rm s}+\lambda^{\rm ww}\;\Delta\,\phi_{\rm w}+k_{\rm Sd}\,(\dot\phi_{\rm s}-\dot\phi_{\rm w})\;&=\;\rho^{\rm w}\,\ddot\phi_{\rm w}\,,
\end{aligned}\tag{11.7.11}$$

and rotational part,

$$\begin{aligned}
\mu\,\Delta\,\psi_{\rm s}-k_{\rm Sd}\,(\dot\psi_{\rm s}-\dot\psi_{\rm w})\;&=\;\rho^{\rm s}\,\ddot\psi_{\rm s}\,,\\
k_{\rm Sd}\,(\dot\psi_{\rm s}-\dot\psi_{\rm w})\;&=\;\rho^{\rm w}\,\ddot\psi_{\rm w}\,.
\end{aligned}\tag{11.7.12}$$

Note that the four field equations are still pairwise coupled.

11.7.4 Boundary conditions in a dynamic non dissipative context

As an example, let us consider the lower half-plane whose surface is free of traction and permeable to the fluid. An alternative boundary condition pertaining to the fluid phase consists in assuming that the fluid flux in the direction normal to the surface is prescribed, say, typically equal to zero.

The analysis is greatly simplified if the dissipative terms are omitted from the field equations, either because the permeability is very high, or because the fluid and solid move together for some reason.

An incident wave-motion impinges the surface, giving rise to reflected waves of all possible types in general, namely, two longitudinal waves and one shear wave, Fig. 11.7.1. It is convenient here to associate the Helmholtz potentials, not with the phases as done above, but with the waves. For example the incident motion may be due to the first longitudinal wave propagating in the direction $\mathbf{n}^I = \sin\beta_I\,\mathbf{e}_1 - \cos\beta_I\,\mathbf{e}_2$ with pulsation ω [unit : 1/s] and with associated potential,

$$\phi_I = \exp\left(i\,\omega\,(t - \frac{\mathbf{x}\cdot\mathbf{n}^I}{c_1})\right). \tag{11.7.13}$$

Each of the three reflected waves has its own direction of propagation $\mathbf{n}^{Rj} = \sin\beta_{Rj}\,\mathbf{e}_1 + \cos\beta_{Rj}\,\mathbf{e}_2$ and its own speed c_j, $j = 1, 2, 3$, but the pulsation may be shown to be inherited from the incident wave. The associated potentials assume the formats,

$$\phi_{Rj} = \exp\left(i\,\omega\,(t - \frac{\mathbf{x}\cdot\mathbf{n}^{Rj}}{c_j})\right),\ j = 1, 2; \quad \psi_{R3} = \exp\left(i\,\omega\,(t - \frac{\mathbf{x}\cdot\mathbf{n}^{R3}}{c_3})\right). \tag{11.7.14}$$

The displacements are contributed by the incident field and by the two solenoidal and single rotational reflected fields,

$$\mathbf{u}_\alpha = a_\alpha\,\boldsymbol{\nabla}\phi_I + \sum_{j=1,2} b_{\alpha j}\,\boldsymbol{\nabla}\phi_{Rj} + b_{\alpha 3}\boldsymbol{\nabla}\wedge(\psi_{R3}\mathbf{e}_3), \quad \alpha = \mathrm{s},\,\mathrm{w}\,. \tag{11.7.15}$$

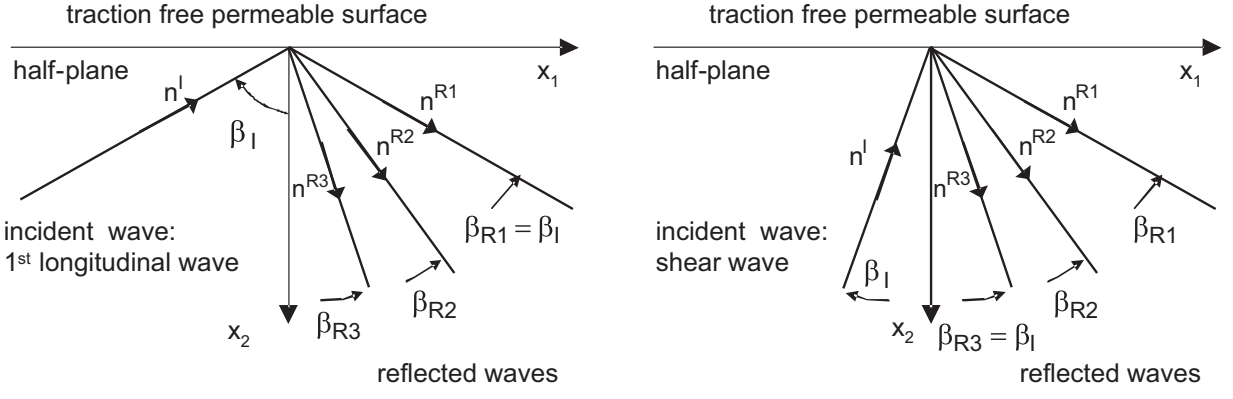

Fig. 11.7.1: To meet the boundary conditions along the free surface of the poroelastic lower half-plane, an incident plane wave triggers in general several reflected waves. The sketches assume the shear wave-speed to be smaller than the second longitudinal wave-speed so that $\beta_{R3} < \beta_{R2}$. Otherwise, the inequality is reversed.

If the incident field is associated with the second longitudinal wave, just change the index 1 to 2 in (11.7.13). If the incident wave is the shear wave, then change the incident potential (11.7.13) to

$$\psi_I = \exp\left(i\,\omega\,(t - \frac{\mathbf{x}\cdot\mathbf{n}^I}{c_3})\right), \tag{11.7.16}$$

as well as the displacements to

$$\mathbf{u}_\alpha = a_\alpha\,\boldsymbol{\nabla}\wedge(\psi_I\mathbf{e}_3) + \sum_{j=1,2} b_{\alpha j}\,\boldsymbol{\nabla}\phi_{Rj} + b_{\alpha 3}\boldsymbol{\nabla}\wedge(\psi_{R3}\mathbf{e}_3), \quad \alpha = \mathrm{s},\,\mathrm{w}\,. \tag{11.7.17}$$

From the displacements deduce the strains as in (11.7.1), and next the stresses through the poroelastic constitutive equations.

In the nondissipative case, the field equations (11.7.11) and (11.7.12) yield a relation between the amplitudes of the solid and fluid displacements of each of the four types. If the incident field is the longitudinal wave with speed c_k, $k = 1, 2$, then,

$$\frac{b_{\mathrm{w}j}}{b_{\mathrm{s}j}} = \frac{c_j^2 - c_{\mathrm{s}}^2}{c_{\mathrm{ms}}^2} = \frac{c_{\mathrm{mw}}^2}{c_j^2 - c_{\mathrm{w}}^2},\ j = 1, 2; \quad \frac{a_{\mathrm{w}}}{a_{\mathrm{s}}} = \frac{b_{\mathrm{w}k}}{b_{\mathrm{s}k}}; \quad b_{\mathrm{w}3} = 0\,. \tag{11.7.18}$$

If the incident field is the shear wave, then,

$$\frac{b_{\mathrm{w}j}}{b_{\mathrm{s}j}} = \frac{c_j^2 - c_{\mathrm{s}}^2}{c_{\mathrm{ms}}^2} = \frac{c_{\mathrm{mw}}^2}{c_j^2 - c_{\mathrm{w}}^2},\ j = 1, 2; \quad a_{\mathrm{w}} = b_{\mathrm{w}3} = 0\,. \tag{11.7.19}$$

In words, the displacements in the fluid can be considered known as soon as the solid displacements are defined. The needed information is provided by the boundary conditions, as follows.

If for example the surface is traction free and permeable, the boundary conditions at the surface $x_2 = 0$,

$$\sigma_{22}^{\mathrm{s}}(x_1, x_2 = 0, t) = 0, \quad \sigma_{12}^{\mathrm{s}}(x_1, x_2 = 0, t) = 0, \quad -n^{\mathrm{w}} p_{\mathrm{w}}(x_1, x_2 = 0, t) = 0\,, \tag{11.7.20}$$

should be satisfied for any $x_1 \in]-\infty, \infty[$. Whence the directions of the reflected waves, namely the angles β_{Rj}, $j = 1, 2, 3$. Indeed if the incident wave is oriented at the angle β_I with respect to the axis $\mathbf{e}_2$, and has speed c_j, then

$$\beta_{Rj} = \beta_I, \quad \frac{\sin\beta_{R1}}{c_1} = \frac{\sin\beta_{R2}}{c_3} = \frac{\sin\beta_{R3}}{c_3}\,. \tag{11.7.21}$$

This simple relation indicates that the angles of reflection are in proportion with the wave-speeds. For some critical incident angle(s), it might happen that one, or two, reflected angles reach 90°. Larger incident angles imply the associated wave to be reflected, no longer as a plane wave, but as a surface wave with an amplitude decreasing with depth. The phenomenon does not take place if the incident wave is the first longitudinal wave. Surface waves are addressed in Section 11.9.

Finally, the three boundary conditions constitute a linear system which provides the amplitude of the reflected waves relative to the incident amplitude, namely $b_{\mathrm{s}j}/a_{\mathrm{s}}$, $j = 1, 2, 3$.

The only case where an incident wave reflects only itself is for a normal incidence. Conversely, there exist conditions for which an incident wave is completely converted into its two sister waves. Some details may be found in Deresiewicz [1960].

More advanced configurations might be considered. If the porous medium includes two porosities, a wave impinging on a free surface will in general trigger four reflected waves, namely three longitudinal waves and one transversal wave. Reflections also take place at the interface between two layers endowed with distinct material properties, or with distinct saturations. The properties of the interface come into picture: actual situations are expected to be intermediate between a perfect interface (ensuring perfect bonding) and a frictionless interface.

11.8 Silent poroelastic boundaries

Section 11.7.4 indicates that, in a dynamic context, a signal emanating from an inner part of the body triggers one or several reflected signals in order to satisfy boundary conditions. In that line, the boundary conditions (11.7.20) may be rewritten in the form of an incident traction and of reflected traction(s),

$$\mathbf{t}^I(x_1, x_2 = 0, t) + \mathbf{t}^R(x_1, x_2 = 0, t) = \mathbf{0}\,. \tag{11.8.1}$$

Often, in analytical or computer models, only a piece of a large body is of direct interest. The boundary generated by this procedure is artificial, and it may generate spurious reflections. A number of methods aim at alleviating this undesirable feature.

Among them are methods that add supplementary tractions $\mathbf{t}^{\mathrm{supp}}$ along the boundary, in view of minimizing the reflected signals $\mathbf{t}^R$,

$$\mathbf{t}^I(x_1, x_2 = 0, t) + \mathbf{t}^R(x_1, x_2 = 0, t) + \mathbf{t}^{\mathrm{supp}}(x_1, x_2 = 0, t) = \mathbf{0}\,. \tag{11.8.2}$$

The formulation below intends to obtain a silent boundary whose viscous tractions are frequency independent. This feature makes it possible to solve the equations of motion in the time domain and to take into account a possible nonlinear constitutive response at the interior of the body.

The viscous boundary method developed below follows Zerfa and Loret [2004] where a short review of the pertinent literature is presented and the theoretical performances of the method have been tested. The method has been used in a finite element context in Zerfa and Loret [2003]. Computations show that, at no additional cost, this *drained* method is more accurate for all permeabilities than the *undrained* method, which misses the existence of the second dilatational wave.

This viscous boundary method has been challenged by the so-called paraxial methods. These methods are motivated by the following observation. The second order hyperbolic partial differential equations, that govern the field equations of solids and saturated porous media, allow waves to travel forward and backward. The idea is to replace these field equations, in regions adjacent to the boundary, by partial differential equations that generate only waves that exit the body. While the idea seems exciting, numerical issues and practical difficulties in applications in a multidimensional finite element context limit the performances of these methods.

11.8.1 Impedance matrix, general case $\lambda^{\rm sw} \neq 0$

The starting point of the viscous boundary method is the observation that Hadamard's compatibility relations for acceleration waves hold also for phase waves. Indeed, let $\phi(\mathbf{x},t) = \phi(\mathbf{x}\cdot\mathbf{n} - c\,t)$ be a scalar function. Then $\partial\phi/\partial\mathbf{x} = \eta\,\mathbf{n}$ and $\partial\phi/\partial t = -c\,\eta$, with $\eta = \phi'$ denoting the derivative of ϕ with respect to its argument. Therefore harmonic waves in a medium with *infinite* permeability propagate at the speeds of acceleration waves and along the same eigenmodes. The method can thus capitalize upon the spectral analysis of Section 11.5.2.

For the displacements fields $\mathbf{u}_\alpha(\mathbf{x}\cdot\mathbf{n} - c\,t)$, $\alpha = \mathrm{s}, \mathrm{w}$, the gradients and velocities obey the following relations,

$$\boldsymbol{\nabla}\mathbf{u}_\alpha = -\frac{1}{c}\,\mathbf{v}_\alpha \otimes \mathbf{n}, \quad \mathbf{v}_\alpha = -c\,\boldsymbol{\nabla}\mathbf{u}_\alpha \cdot \mathbf{n}\,, \tag{11.8.3}$$

and the partial stresses (11.5.17) express in terms of the velocities,

$$\begin{aligned} \boldsymbol{\sigma}^{\rm s} &= -\frac{1}{c}\left(\lambda^{\rm ss}\ \mathbf{v}_{\rm s}\cdot\mathbf{n}\,\mathbf{I} \ +\ \mu\,(\mathbf{v}_{\rm s}\otimes\mathbf{n} + \mathbf{n}\otimes\mathbf{v}_{\rm s}) \ +\ \lambda^{\rm sw}\,\mathbf{v}_{\rm w}\cdot\mathbf{n}\,\mathbf{I}\right), \\ -n^{\rm w}\,p_{\rm w} &= -\frac{1}{c}\left(\lambda^{\rm sw}\,\mathbf{v}_{\rm s}\cdot\mathbf{n} \qquad\qquad\qquad\qquad\qquad\quad +\ \lambda^{\rm ww}\ \mathbf{v}_{\rm w}\cdot\mathbf{n}\right). \end{aligned} \tag{11.8.4}$$

The eigenmodes associated with the two longitudinal wave-speeds c_1 and c_2, and single shear wave-speed with double multiplicity given in explicit form in Section 11.5.2 express in terms of the unit direction of propagation $\mathbf{n}$, and of the two orthogonal unit vectors $\mathbf{t}^{(1)}$ and $\mathbf{t}^{(2)}$:

$$\begin{aligned} \text{longitudinal mode}\quad c = c_1, c_2 \quad &:\quad \mathbf{v}_{\rm s} \sim c_{\rm ms}^2\mathbf{n}, \qquad \mathbf{v}_{\rm w} \sim (c^2 - c_{\rm s}^2)\,\mathbf{n}, \\ \text{shear mode}\quad c = c_3 \quad &:\quad \mathbf{v}_{\rm s} \sim \mathbf{t}^{(1)}, \mathbf{t}^{(2)}, \quad \mathbf{v}_{\rm w} = \mathbf{0}\,. \end{aligned} \tag{11.8.5}$$

Conversely, the velocities can be calculated in terms of the two longitudinal and two shear eigenmodes,

$$\begin{aligned} \mathbf{v}_{\rm s} &= a_1\,c_{\rm ms}^2\,\mathbf{n} \ +\ a_2\,c_{\rm ms}^2\,\mathbf{n} \ +\ (\mathbf{v}_{\rm s}\cdot\mathbf{t}^{(1)})\,\mathbf{t}^{(1)} + (\mathbf{v}_{\rm s}\cdot\mathbf{t}^{(2)})\,\mathbf{t}^{(2)}, \\ \mathbf{v}_{\rm w} &= a_1\,(c_1^2 - c_{\rm s}^2)\,\mathbf{n} \ +\ a_2\,(c_2^2 - c_{\rm s}^2)\,\mathbf{n}\,, \end{aligned} \tag{11.8.6}$$

which may be rearranged to

$$\begin{aligned} \mathbf{v}_{\rm s} &= (V_1 + V_2)\,\mathbf{n} \ +\ (\mathbf{v}_{\rm s}\cdot\mathbf{t}^{(1)})\,\mathbf{t}^{(1)} + (\mathbf{v}_{\rm s}\cdot\mathbf{t}^{(2)})\,\mathbf{t}^{(2)} \\ \mathbf{v}_{\rm w} &= (W_1 + W_2)\,\mathbf{n}\,, \end{aligned} \tag{11.8.7}$$

where

$$\begin{aligned} V_1 &= \frac{1}{c_1^2 - c_2^2}\left((c_{\rm s}^2 - c_2^2)\,\mathbf{v}_{\rm s}\cdot\mathbf{n} + c_{\rm ms}^2\,\mathbf{v}_{\rm w}\cdot\mathbf{n}\right), \quad W_1 = \frac{c_1^2 - c_{\rm s}^2}{c_{\rm ms}^2}\,V_1, \\ V_2 &= \frac{1}{c_2^2 - c_1^2}\left((c_{\rm s}^2 - c_1^2)\,\mathbf{v}_{\rm s}\cdot\mathbf{n} + c_{\rm ms}^2\,\mathbf{v}_{\rm w}\cdot\mathbf{n}\right), \quad W_2 = \frac{c_2^2 - c_{\rm s}^2}{c_{\rm ms}^2}\,V_2\,. \end{aligned} \tag{11.8.8}$$

Substituting these expressions in the partial stresses (11.8.4) yields the supplementary tractions of viscous nature in (11.8.2),

$$\left[\begin{array}{c}\mathbf{h}^{\mathrm{s}}\\ \mathbf{h}^{\mathrm{w}}\end{array}\right]=\left[\begin{array}{c}\boldsymbol{\sigma}^{\mathrm{s}}\cdot\mathbf{n}\\ \boldsymbol{\sigma}^{\mathrm{w}}\cdot\mathbf{n}\end{array}\right]=-\left[\begin{array}{cc}\mathbf{A}^{\mathrm{ss}} & \mathbf{A}^{\mathrm{sw}}\\ (\mathbf{A}^{\mathrm{sw}})^{\mathrm{T}} & \mathbf{A}^{\mathrm{ww}}\end{array}\right]\left[\begin{array}{c}\mathbf{v}_{\mathrm{s}}\\ \mathbf{v}_{\mathrm{w}}\end{array}\right], \tag{11.8.9}$$

in terms of the velocities via the impedance matrix $\mathbf{A}$ with block components,

$$\begin{aligned}\mathbf{A}^{\mathrm{ss}} &= \frac{\lambda^{\mathrm{ss}}+2\,\mu+\rho^{\mathrm{s}}\,c_1\,c_2}{c_1+c_2}\;\mathbf{n}\otimes\mathbf{n} \;+\; \frac{\mu}{c_3}\,(\overbrace{\mathbf{t}^{(1)}\otimes\mathbf{t}^{(1)}+\mathbf{t}^{(2)}\otimes\mathbf{t}^{(2)}}^{\mathbf{I}-\mathbf{n}\otimes\mathbf{n}}),\\ \mathbf{A}^{\mathrm{ww}} &= \frac{\lambda^{\mathrm{ww}}+\rho^{\mathrm{w}}\,c_1\,c_2}{c_1+c_2}\;\mathbf{n}\otimes\mathbf{n},\\ \mathbf{A}^{\mathrm{sw}} &= \frac{\lambda^{\mathrm{sw}}}{c_1+c_2}\;\mathbf{n}\otimes\mathbf{n}.\end{aligned} \tag{11.8.10}$$

11.8.2 Impedance matrix: no poromechanical coupling, $\lambda^{\mathrm{sw}}=0$

When the poroelastic coupling parameter λ^{sw} vanishes, the two longitudinal modes decouple. The eigenmode associated with the wave-speed c_{s} of square $(\lambda^{\mathrm{ss}}+2\,\mu)/\rho^{\mathrm{s}}$ affects only the solid, while the eigenmode with wave-speed c_{w} of square $\lambda^{\mathrm{ww}}/\rho^{\mathrm{w}}$ affects only the fluid.

The impedance matrix can be recalculated following the same steps as in the coupled case, or deduced as a limit case, yielding

$$\mathbf{A}^{\mathrm{ss}}=\rho^{\mathrm{s}}\,c_{\mathrm{s}}\,\mathbf{n}\otimes\mathbf{n}+\rho^{\mathrm{s}}\,c_3\,(\mathbf{I}-\mathbf{n}\otimes\mathbf{n}),\quad \mathbf{A}^{\mathrm{ww}}=\rho^{\mathrm{w}}\,c_{\mathrm{w}}\,\mathbf{n}\otimes\mathbf{n},\quad \mathbf{A}^{\mathrm{sw}}=\mathbf{0}. \tag{11.8.11}$$

As expected, the coefficients involved in the impedance are equal to the product of an apparent mass density times a wave-speed, or to a ratio of a modulus over a wave-speed, namely $\rho^{\mathrm{s}}\,c_{\mathrm{s}}=(\lambda^{\mathrm{ss}}+2\,\mu)/c_{\mathrm{s}}$, $\rho^{\mathrm{w}}\,c_{\mathrm{w}}=\lambda^{\mathrm{ww}}/c_{\mathrm{w}}$, and $\rho^{\mathrm{s}}\,c_3=\mu/c_3$.

11.8.3 Impedance matrix: dry/drained medium

When the pore pressure vanishes over a finite time interval, the velocities are linked by the condition $\lambda^{\mathrm{sw}}\,\mathbf{v}_{\mathrm{s}}\cdot\mathbf{n}+\lambda^{\mathrm{ww}}\;\mathbf{v}_{\mathrm{w}}\cdot\mathbf{n}=0$. Substituting the normal fluid velocity in the partial solid stress yields,

$$\boldsymbol{\sigma}^{\mathrm{s}}\;=-\frac{1}{c}\left(\lambda\;\mathbf{v}_{\mathrm{s}}\cdot\mathbf{n}\,\mathbf{I}\;+\;\mu\,(\mathbf{v}_{\mathrm{s}}\otimes\mathbf{n}+\mathbf{n}\otimes\mathbf{v}_{\mathrm{s}})\right). \tag{11.8.12}$$

with $\lambda=\lambda^{\mathrm{ss}}-(\lambda^{\mathrm{sw}})^2/\lambda^{\mathrm{ww}}$ the drained Lamé modulus. According to Section 11.5.2.2, the drained medium is endowed with a longitudinal wave-speed c_{LD} and a shear wave-speed $c_{\mathrm{SD}}=c_3$ of double multiplicity. The viscous traction can then be cast in the format $\mathbf{h}^{\mathrm{s}}=\boldsymbol{\sigma}^{\mathrm{s}}\cdot\mathbf{n}=-\mathbf{A}^{\mathrm{ss}}\cdot\mathbf{v}_{\mathrm{s}}$ with

$$\mathbf{A}^{\mathrm{ss}}=\rho^{\mathrm{s}}\,c_{\mathrm{LD}}\;\mathbf{n}\otimes\mathbf{n}+\rho^{\mathrm{s}}\,c_{\mathrm{SD}}\;(\mathbf{I}-\mathbf{n}\otimes\mathbf{n}), \tag{11.8.13}$$

where $\rho^{\mathrm{s}}\,c_{\mathrm{LD}}=(\lambda+2\,\mu)/c_{\mathrm{LD}}$ and $\rho^{\mathrm{s}}\,c_{\mathrm{SD}}=\mu/c_{\mathrm{SD}}$.

11.8.4 Impedance matrix: undrained medium

When the permeability vanishes, the motions of the solid and fluid phases are identical, and the flow turns out undrained. The converse is not true, since the undrained property concerns only the volumes of the phases. In both cases, the velocities are linked by the condition $\mathbf{v}_{\mathrm{s}}\cdot\mathbf{n}=\mathbf{v}_{\mathrm{w}}\cdot\mathbf{n}$. Substituting the normal fluid velocity in the total stress yields,

$$\boldsymbol{\sigma}\;=-\frac{1}{c}\left(\lambda^{\mathrm{U}}\;\mathbf{v}_{\mathrm{s}}\cdot\mathbf{n}\,\mathbf{I}\;+\;\mu\,(\mathbf{v}_{\mathrm{s}}\otimes\mathbf{n}+\mathbf{n}\otimes\mathbf{v}_{\mathrm{s}})\right) \tag{11.8.14}$$

with λ^{U} the undrained Lamé modulus. According to Section 11.5.2.3, the undrained medium is endowed with a longitudinal wave-speed c_{LU} and a shear wave-speed c_{SU} of double multiplicity. The total viscous traction can then be cast in the format,

$$\mathbf{h}=\boldsymbol{\sigma}\cdot\mathbf{n}=-\mathbf{A}\cdot\mathbf{v}_{\mathrm{s}},\quad \mathbf{A}=\rho\,c_{\mathrm{LU}}\;\mathbf{n}\otimes\mathbf{n}+\rho\,c_{\mathrm{SU}}\;(\mathbf{I}-\mathbf{n}\otimes\mathbf{n}). \tag{11.8.15}$$

11.9 Surface waves in a saturated porous half-plane

The analyses of the preceding sections, except Section 11.8, have considered the propagation of waves in infinite media. The corresponding waves are termed *body waves*. When the waves encounter a boundary, the mechanical conditions at the boundary should be satisfied, Fig. 11.9.1. If the body is finite, e.g., a finite bar, the waves may travel back and fourth and the motion will be periodic if there is no energy dissipation, as in elastic solids. When the body is semi-infinite, e.g., a half-plane or half-space, the fact that the total energy that generates the motion is finite implies that the amplitude of the wave should decay away from the source. As an example, reflection of a plane shear wave impinging a free surface at large incident angles may imply the wave to be reflected, no longer as a plane wave, but as a wave with an amplitude decreasing with depth. Such waves are referred to as *surface waves*.

Surface waves in solids are covered in several treatises, and in particular in Achenbach [1975] or Graff [1991]. The analysis below addresses surface waves in a saturated porous half-plane endowed with isotropic properties in both its elastic and permeability properties. Biot [1956], Jones [1961], Deresiewicz [1962] and Staroszczyk [1992] inter alii have contributed to the subject matter. Beskos et al. [1989] consider a refined analysis where the saturated porous half-space involves two porosities.

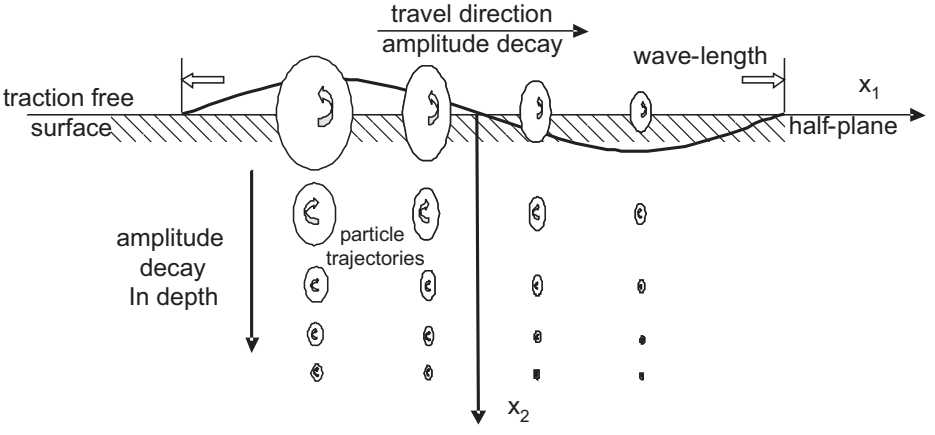

Fig. 11.9.1: Axes used for the analysis of surface waves in the poroelastic lower half-plane. The amplitude of the motion decays both in depth and in the travel direction. Actually, the latter decay is present for a poroelastic half-plane but absent for an elastic half-plane. Conversely, the particle elliptical trajectories as shown are typical of an elastic half-plane, being retrograde at distances smaller than 0.2 wave-length and clockwise deeper.

11.9.1 Time harmonic solutions decreasing with depth

The displacements are sought in the form of harmonic waves in the plane (x_1, x_2) traveling in the x_1-direction and decreasing in depth, i.e., for a generic function f that depends on space and time,

$$f(x_1, x_2, t) = \hat{f}(x_2)\, e^{i(\omega\, t - k\, x_1)} = \hat{f}(x_2)\, e^{i(\omega\, t - \mathrm{Re}\, k\, x_1) + \mathrm{Im}\, k\, x_1}\,. \tag{11.9.1}$$

The pulsation $\omega > 0$ [unit : Hz] is a real number, the wave-number k [unit : 1/m] may be complex. The direction of propagation of the Rayleigh wave, namely towards increasing or decreasing x_1, depends on the sign of the real part of k. Actually, one may choose the positive sign, since the secular equation is phrased in terms of the square of the wave-number. On the other hand, the ratio $-\mathrm{Im}\, k/\mathrm{Re}\, k$ should be positive in order the amplitude to remain bounded in the direction of propagation. In particular, the Helmholtz potentials ϕ_α and ψ_α in the two phases $\alpha = \mathrm{s}$, w, adopt the form (11.9.1),

$$\begin{bmatrix} \phi_\alpha(x_1, x_2, t) \\ \psi_\alpha(x_1, x_2, t) \end{bmatrix} = \begin{bmatrix} \hat{\phi}_\alpha(x_2) \\ \hat{\psi}_\alpha(x_2) \end{bmatrix} e^{i(\omega\, t - k\, x_1)}\,. \tag{11.9.2}$$

The Laplacian and time derivative operators transform to

$$\Delta = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} \to -k^2 + \frac{\partial^2}{\partial x_2^2}\,; \qquad \frac{\partial}{\partial t} \to i\,\omega\,; \qquad \frac{\partial^2}{\partial t^2} \to -\,\omega^2\,. \tag{11.9.3}$$

The field equations (11.7.11) and (11.7.12) become

$$\left(\begin{bmatrix} \lambda^{\rm ss}+2\,\mu & \lambda^{\rm sw} \\ \lambda^{\rm sw} & \lambda^{\rm ww} \end{bmatrix} \frac{\partial^2}{\partial x_2^2} + \begin{bmatrix} -k^2(\lambda^{\rm ss}+2\,\mu)+\rho^{\rm s}\omega^2-i\omega\,k_{\rm Sd} & -k^2\lambda^{\rm sw}+i\omega\,k_{\rm Sd} \\ -k^2\lambda^{\rm sw}+i\omega\,k_{\rm Sd} & -k^2\lambda^{\rm ww}+\rho^{\rm w}\omega^2-i\omega\,k_{\rm Sd} \end{bmatrix}\right)\begin{bmatrix}\hat\phi_{\rm s}\\ \hat\phi_{\rm w}\end{bmatrix}=\begin{bmatrix}0\\0\end{bmatrix}, \tag{11.9.4}$$

and

$$\left(\begin{bmatrix} \mu & 0 \\ 0 & 0 \end{bmatrix} \frac{\partial^2}{\partial x_2^2} + \begin{bmatrix} -k^2\mu+\rho^{\rm s}\omega^2-i\omega\,k_{\rm Sd} & i\omega\,k_{\rm Sd} \\ i\,\omega\,k_{\rm Sd} & \rho^{\rm w}\omega^2-i\,\omega\,k_{\rm Sd} \end{bmatrix}\right)\begin{bmatrix}\hat\psi_{\rm s}\\ \hat\psi_{\rm w}\end{bmatrix}=\begin{bmatrix}0\\0\end{bmatrix}. \tag{11.9.5}$$

11.9.2 The complete formal solution

The depth-decreasing dilatational potentials can be shown to be of the form,

$$\begin{bmatrix}\hat\phi_{\rm s}\\ \hat\phi_{\rm w}\end{bmatrix}=\begin{bmatrix}a_{\rm s1}\\ a_{\rm w1}\end{bmatrix}e^{-A_1\,x_2}+\begin{bmatrix}a_{\rm s2}\\ a_{\rm w2}\end{bmatrix}e^{-A_2\,x_2},\quad \mathrm{Re}\,A_j>0\,,\ j=1,2\,, \tag{11.9.6}$$

and, similarly for the shear potentials,

$$\begin{bmatrix}\hat\psi_{\rm s}\\ \hat\psi_{\rm w}\end{bmatrix}=\begin{bmatrix}a_{\rm s3}\\ a_{\rm w3}\end{bmatrix}e^{-A_3\,x_2},\quad \mathrm{Re}\,A_3>0\,. \tag{11.9.7}$$

Thus the displacements $\mathbf{u}_\alpha$, $\alpha=$ s, w, (11.7.4) become with help of (11.9.2), (11.9.6), and (11.9.7),

$$\begin{aligned} u_{\alpha1}(x_1,x_2,t)&=[-i\,k\,(a_{\alpha1}\,e^{-A_1\,x_2}\ +\ \ a_{\alpha2}\,e^{-A_2\,x_2})-A_3\,a_{\alpha3}\,e^{-A_3\,x_2}]\,e^{i(\omega\,t-k\,x_1)},\\ u_{\alpha2}(x_1,x_2,t)&=[\ -A_1\,a_{\alpha1}\,e^{-A_1\,x_2}-A_2\,a_{\alpha2}\,e^{-A_2\,x_2}+i\,k\,a_{\alpha3}\,e^{-A_3\,x_2}]\,e^{i(\omega\,t-k\,x_1)}\,. \end{aligned} \tag{11.9.8}$$

The coefficients of depth dependence A_j, $j\in[1,3]$, may be complex, but their real parts are required to be strictly positive, so as to ensure a vanishing displacement as $x_2\to\infty$. They are defined in Section 11.9.4.

The depth dependent part of the stresses can be calculated either via (11.7.6), (11.9.1), (11.9.6), and (11.9.7), or via (11.5.17), (11.7.5), and (11.9.8), as

$$\begin{bmatrix}\hat\sigma^{\rm s}_{22}(x_2)\\ \hat\sigma^{\rm s}_{12}(x_2)\\ -n^{\rm w}\hat p^{\rm w}(x_2)\end{bmatrix}=\mathcal{R}\begin{bmatrix}a_{\rm s1}\,e^{-A_1\,x_2}\\ a_{\rm s2}\,e^{-A_2\,x_2}\\ a_{\rm s3}\,e^{-A_3\,x_2}\end{bmatrix}, \tag{11.9.9}$$

with the Rayleigh matrix,

$$\mathcal{R}=\begin{bmatrix} 2\,\mu\,k^2+(\lambda^{\rm ss}+2\mu+\lambda^{\rm sw}\frac{a_{\rm w1}}{a_{\rm s1}})\,(A_1^2-k^2) & 2\,\mu\,k^2+(\lambda^{\rm ss}+2\mu+\lambda^{\rm sw}\frac{a_{\rm w2}}{a_{\rm s2}})\,(A_2^2-k^2) & -2\,\mu\,i\,k\,A_3\\ 2\,\mu\,i\,k\,A_1 & 2\,\mu\,i\,k\,A_2 & \mu\,(A_3^2+k^2)\\ (\lambda^{\rm sw}+\lambda^{\rm ww}\frac{a_{\rm w1}}{a_{\rm s1}})\,(A_1^2-k^2) & (\lambda^{\rm sw}+\lambda^{\rm ww}\frac{a_{\rm w2}}{a_{\rm s2}})\,(A_2^2-k^2) & 0 \end{bmatrix}. \tag{11.9.10}$$

11.9.3 Frequency dependent dissipation

Along the definitions of Section 7.3.2, the viscous coefficient $k_{\rm Sd}$ [unit : kg/m^3/s] is inversely proportional to the hydraulic conductivity $K_{\rm H}$ [unit : m/s],

$$k_{\rm Sd}=\frac{n^{\rm w}\rho^{\rm w}g}{K_{\rm H}}\,, \tag{11.9.11}$$

with g the acceleration of gravity. Biot [1956] has introduced a frequency dependent dissipation, through the function $F = F(\kappa)$, submitted to $F(0) = 1$ and increasing linearly for a large argument. The actual function $F(\kappa)$ used in the calculations is detailed in Section 11.9.7. Here κ is a dimensionless frequency,

$$\kappa = \delta \sqrt{\frac{\omega\, K_{\rm H}(\omega=0)}{n^{\rm w}\, g}}\,, \tag{11.9.12}$$

phrased in terms of actual properties, of the pulsation ω and of an arbitrary dimensionless frequency coefficient δ. Therefore

$$\frac{k_{\rm Sd}}{\rho^{\rm w}\,\omega} = G(\kappa) \quad \text{with} \quad G(\kappa) = \left(\frac{\delta}{\kappa}\right)^2 F(\kappa)\,, \tag{11.9.13}$$

and the hydraulic conductivity vanishes at large frequencies,

$$\frac{K_{\rm H}(\omega)}{K_{\rm H}(\omega=0)} = \frac{1}{F(\kappa)}\,. \tag{11.9.14}$$

The linear increase of the function $F(\kappa)$ at high dimensionless frequencies enlarges the set of frequencies for which Rayleigh waves exist. Indeed, for the material properties used, there exists, in a certain domain of porosity, a frequency cutoff above which Rayleigh waves are not available. The virtue of the function F is to increase this frequency cutoff. Thus the following equivalent interpretations hold,

$$\begin{array}{ccccccc} \text{large } k_{\rm Sd} & \rightleftharpoons & \text{small permeability} & \rightleftharpoons & \text{large frequency } \omega & \rightleftharpoons & \text{large } \kappa\,, \\ \text{small } k_{\rm Sd} & \rightleftharpoons & \text{large permeability} & \rightleftharpoons & \text{small frequency } \omega & \rightleftharpoons & \text{small } \kappa\,. \end{array} \tag{11.9.15}$$

Actually, the situation is somehow complex: in addition to frequency, the hydraulic conductivity depends on porosity, as detailed in Section 16.4.1,

$$\frac{K_{\rm H}(e,\omega)}{K_{\rm H}(e_0,0)} = \left(\frac{e}{e_0}\right)^3 \frac{1+e_0}{1+e}\,\frac{1}{F(\kappa)}\,. \tag{11.9.16}$$

where $e = n^{\rm w}/(1-n^{\rm w})$ is the void ratio and e_0 a reference value. Moreover, like the conductivity, the mechanical moduli depend on porosity, Section 7.3.6.6.

11.9.4 Determination of the coefficients of depth dependence A_j, $j \in [1,3]$

The unit of the depth dependence coefficients and of the wave-number k is m^{-1}. Next to a dimensionless wave-number,

$$\tilde{k} = \frac{k}{k_r} \quad \text{with} \quad k_r = \frac{\omega}{c_{\rm SU}}\,, \tag{11.9.17}$$

it is also instrumental to introduce dimensionless depth dependence coefficients $\tilde{A}$ and eigenvalues $\tilde{X}$,

$$\tilde{A}_j = \frac{A_j}{k_r}\,,\ j=1,3; \quad \tilde{X}_j^2 = \frac{H^{\rm U}}{\mu}\,(\tilde{A}_j^2 - \tilde{k}^2)\,, \quad j=1,2\,; \quad \tilde{X}_3^2 = \tilde{A}_3^2 - \tilde{k}^2\,, \tag{11.9.18}$$

in terms of the longitudinal undrained modulus $H^{\rm U} = \lambda^{\rm U} + 2\,\mu$ defined in Section 11.5.2.3.

The definitions and relative order of the wave-speeds and wave-speed like quantities discussed in Section 11.5.2.1 are used repeatedly.

11.9.4.1 Dilatation potentials

Insertion of the solution (11.9.6) in the two equations (11.9.4) yields an eigenvalue problem,

$$\begin{bmatrix} (\lambda^{\rm ss}+2\,\mu)\,(A^2-k^2) + \rho^{\rm s}\omega^2 - i\,\omega\,k_{\rm Sd} & \lambda^{\rm sw}\,(A^2-k^2) & +i\,\omega\,k_{\rm Sd} \\ \lambda^{\rm sw}\,(A^2-k^2) & +i\,\omega\,k_{\rm Sd} & \lambda^{\rm ww}\,(A^2-k^2) + \rho^{\rm w}\omega^2 - i\,\omega\,k_{\rm Sd} \end{bmatrix} \begin{bmatrix} a_{\rm s} \\ a_{\rm w} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}\,. \tag{11.9.19}$$

The characteristic equation associated with this eigenvalue problem is viewed as the equation that defines the coefficients A_1 and A_2 of depth dependence. Equivalently, with the normalization introduced by (11.9.17) and (11.9.18), this equation can be viewed as defining the two solutions $\tilde{X}_j = \tilde{X}_j(\kappa)$, $j \in [1,2]$,

$$(\tilde{X}^2)^2 \frac{c_1^2\, c_2^2}{c_{\rm LU}^4} + \tilde{X}^2 \left(\frac{c_1^2 + c_2^2}{c_{\rm LU}^2} - i\, G(\kappa) \frac{\rho}{\rho^{\rm s}} \right) + 1 - i\, G(\kappa) \frac{\rho}{\rho^{\rm s}} = 0\,. \tag{11.9.20}$$

The eigenvector associated with each of the two solutions of the above equation is defined as,

$$\frac{a_{{\rm w}j}}{a_{{\rm s}j}} = -\frac{\dfrac{c_{\rm mw}^2}{c_{\rm LU}^2}\, \tilde{X}_j^2 + i\, G(\kappa)}{\dfrac{c_{\rm w}^2}{c_{\rm LU}^2}\, \tilde{X}_j^2 + 1 - i\, G(\kappa)} = -\frac{\dfrac{c_{\rm s}^2}{c_{\rm LU}^2}\, \tilde{X}_j^2 + 1 - i\, \dfrac{\rho^{\rm w}}{\rho^{\rm s}}\, G(\kappa)}{\dfrac{c_{\rm ms}^2}{c_{\rm LU}^2}\, \tilde{X}_j^2 + i\, \dfrac{\rho^{\rm w}}{\rho^{\rm s}}\, G(\kappa)}\,, \quad j = 1, 2\,. \tag{11.9.21}$$

The wave-speeds c_1 and c_2 are defined by (11.5.22), the undrained longitudinal wave-speed $c_{\rm LU}$ by (11.5.35), and the wave-speed like quantities $c_{\rm s}$, $c_{\rm w}$, $c_{\rm ms}$ and $c_{\rm mw}$ by (11.5.20). Repeated use is made of the relations (11.5.25) and (11.5.26).

11.9.4.2 Shear potential

Insertion of the solution (11.9.7) in the two equations (11.9.5) yields an eigenvalue problem,

$$\begin{bmatrix} \mu\,(A^2 - k^2) & +\rho^{\rm s}\omega^2 - i\omega\, k_{\rm Sd} & i\omega\, k_{\rm Sd} \\ & i\,\omega\, k_{\rm Sd} & \rho^{\rm w}\omega^2 - i\,\omega\, k_{\rm Sd} \end{bmatrix} \begin{bmatrix} a_{\rm s} \\ a_{\rm w} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{11.9.22}$$

The characteristic equation associated with this eigenvalue problem is viewed as the equation that defines the coefficient A_3 of depth dependence. Equivalently, with the normalization introduced by (11.9.17) and (11.9.18), this equation can be viewed as defining the solution $\tilde{X}_3 = \tilde{X}_3(\kappa)$,

$$\tilde{X}_3^2 = -\frac{\rho^{\rm s}/\rho - i\, G(\kappa)}{1 - i\, G(\kappa)}\,, \tag{11.9.23}$$

with associated eigenmode,

$$\frac{a_{\rm w3}}{a_{\rm s3}} = -\frac{i\, G(\kappa)}{1 - i\, G(\kappa)}\,. \tag{11.9.24}$$

11.9.5 Permeable and traction free surface

Since the pore pressure vanishes on the boundary, the boundary conditions along the surface $x_2 = 0$ write equivalently in terms of the total stress $\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\rm s} - n^{\rm w} p_{\rm w}\, \mathbf{I}$,

$$\sigma_{22}(x_1, x_2 = 0, t) = 0, \quad \sigma_{12}(x_1, x_2 = 0, t) = 0, \quad -n^{\rm w} p_{\rm w}(x_1, x_2 = 0, t) = 0, \quad \forall x_1 \in]-\infty, \infty[\,, \tag{11.9.25}$$

or of the partial stresses $\boldsymbol{\sigma}^{\rm s}$,

$$\sigma_{22}^{\rm s}(x_1, x_2 = 0, t) = 0, \quad \sigma_{12}^{\rm s}(x_1, x_2 = 0, t) = 0, \quad -n^{\rm w} p_{\rm w}(x_1, x_2 = 0, t) = 0, \quad \forall x_1 \in]-\infty, \infty[\,. \tag{11.9.26}$$

11.9.5.1 The dispersion relation

With the normalization (11.9.17) and (11.9.18), and the tractions (11.9.9) and (11.9.10), the secular equations can be cast in the matrix form,

$$\begin{bmatrix} \hat{\sigma}_{22}^{\rm s}(x_2) \\ \hat{\sigma}_{12}^{\rm s}(x_2) \\ -n^{\rm w}\hat{p}^{\rm w}(x_2) \end{bmatrix} = \mu\, k_r^2\, \mathcal{R}_{\rm per} \begin{bmatrix} a_{\rm s1}\, e^{-A_1\, x_2} \\ a_{\rm s2}\, e^{-A_2\, x_2} \\ a_{\rm s3}\, e^{-A_3\, x_2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{11.9.27}$$

with the permeable Rayleigh matrix,

$$\mathcal{R}_{\rm per}=\begin{bmatrix} 2\,\tilde{k}^2+(\lambda^{\rm ss}+2\,\mu+\lambda^{\rm sw}\,\frac{a_{\rm w1}}{a_{\rm s1}})\,\frac{\tilde{X}_1^2}{H^{\rm U}} & 2\,\tilde{k}^2+(\lambda^{\rm ss}+2\,\mu+\lambda^{\rm sw}\,\frac{a_{\rm w2}}{a_{\rm s2}})\,\frac{\tilde{X}_2^2}{H^{\rm U}} & -2\,i\,\tilde{k}\,\tilde{A}_3 \\ 2\,i\,\tilde{k}\,\tilde{A}_1 & 2\,i\,\tilde{k}\,\tilde{A}_2 & 2\,\tilde{k}^2+\tilde{X}_3^2 \\ (\lambda^{\rm sw}+\lambda^{\rm ww}\,\frac{a_{\rm w1}}{a_{\rm s1}})\,\frac{\tilde{X}_1^2}{H^{\rm U}} & (\lambda^{\rm sw}+\lambda^{\rm ww}\,\frac{a_{\rm w2}}{a_{\rm s2}})\,\frac{\tilde{X}_2^2}{H^{\rm U}} & 0 \end{bmatrix}. \tag{11.9.28}$$

In view of comparison with an impermeable free surface, note that the determinant of this matrix is the same as the determinant of the following matrix obtained by summing the first and third lines,

$$\begin{bmatrix} 2\,\tilde{k}^2+\beta_1\,\tilde{X}_1^2 & 2\,\tilde{k}^2+\beta_2\,\tilde{X}_2^2 & -2\,i\,\tilde{k}\,\tilde{A}_3 \\ 2\,i\,\tilde{k}\,\tilde{A}_1 & 2\,i\,\tilde{k}\,\tilde{A}_2 & 2\,\tilde{k}^2+\tilde{X}_3^2 \\ \gamma_1\,\tilde{X}_1^2 & \gamma_2\,\tilde{X}_2^2 & 0 \end{bmatrix}, \tag{11.9.29}$$

where we have introduced some notations to compact the components,

$$\tau_j\equiv\frac{a_{{\rm w}j}}{a_{{\rm s}j}}-1\,,\quad j\in[1,3]\,;\quad \beta_j\equiv 1+\frac{\lambda^{\rm sw}+\lambda^{\rm ww}}{H^{\rm U}}\,\tau_j\,,\quad \gamma_j\equiv\frac{\lambda^{\rm sw}+\lambda^{\rm ww}}{H^{\rm U}}+\frac{\lambda^{\rm ww}}{H^{\rm U}}\,\tau_j,\quad j\in[1,2]\,. \tag{11.9.30}$$

All coefficients of the above matrix are functions of the dimensionless frequency κ, Eqn (11.9.12). The vanishing of the determinant of this matrix defines the **dispersion relation** that links the wave-number k to the pulsation ω,

$$\tilde{k}=\tilde{k}(\kappa)\quad\Leftrightarrow\quad k=k(\omega)\,, \tag{11.9.31}$$

and the **Rayleigh wave-speed**

$$c_R=c_R(\omega)=\frac{c_{\rm SU}}{{\rm Re}\,\tilde{k}}=\frac{\omega}{{\rm Re}\,k}\,. \tag{11.9.32}$$

If this ratio is independent of frequency, the wave is said to be non dispersive. Body waves and Rayleigh waves in elastic solids and body waves in saturated poroelastic media are non dispersive. At variance, Rayleigh waves in saturated poroelastic media will be observed to be dispersive.

11.9.5.2 Results in graphical form

The material data shown in Table 11.9.1 are representative of a compact bone (or of a rock). The hydraulic conductivity depends on porosity $n^{\rm w}$ and frequency ω as indicated by (11.9.16). The poroelastic moduli depend on porosity as defined in Section 7.3.6.6.

Table 11.9.1: Material parameters used in the graphical outputs.

Shear modulus of solid constituent	$\mu_{\rm s}=20\,{\rm GPa}$
Bulk modulus of solid constituent	$K_{\rm s}=36\,{\rm GPa}$
Mass density of solid constituent	$\rho_{\rm s}=2500\,{\rm kg/m^3}$
Reference void ratio (porosity)	$e_0=0.25$ $(n^{\rm w}_0=0.2)$
Hydraulic conductivity	$K_{\rm H}(e_0,0)=10^{-10}\,{\rm m/s}$
Bulk modulus of water	$K_{\rm w}=2.2\,{\rm GPa}$
Mass density of water	$\rho_{\rm w}=1000\,{\rm kg/m^3}$
Frequency coefficient	$\delta=3.0$
Acceleration of gravity	$g=9.81\,{\rm m/s^2}$

Given the intrinsic bulk moduli of water $K_{\rm w}$ and of the solid constituent $K_{\rm s}$, and the shear modulus of the solid constituent $\mu_{\rm s}$, the drained bulk modulus $K=\lambda+\frac{2}{3}\,\mu$, the shear modulus μ and the coefficient of Biot $\alpha_{\rm w}$ deduce as indicated by (7.3.48),

$$\frac{K}{K_{\rm s}}=\frac{\mu}{\mu_{\rm s}}=(1-\sqrt{n^{\rm w}})^2,\quad \alpha_{\rm w}=1-(1-\sqrt{n^{\rm w}})^2\,, \tag{11.9.33}$$

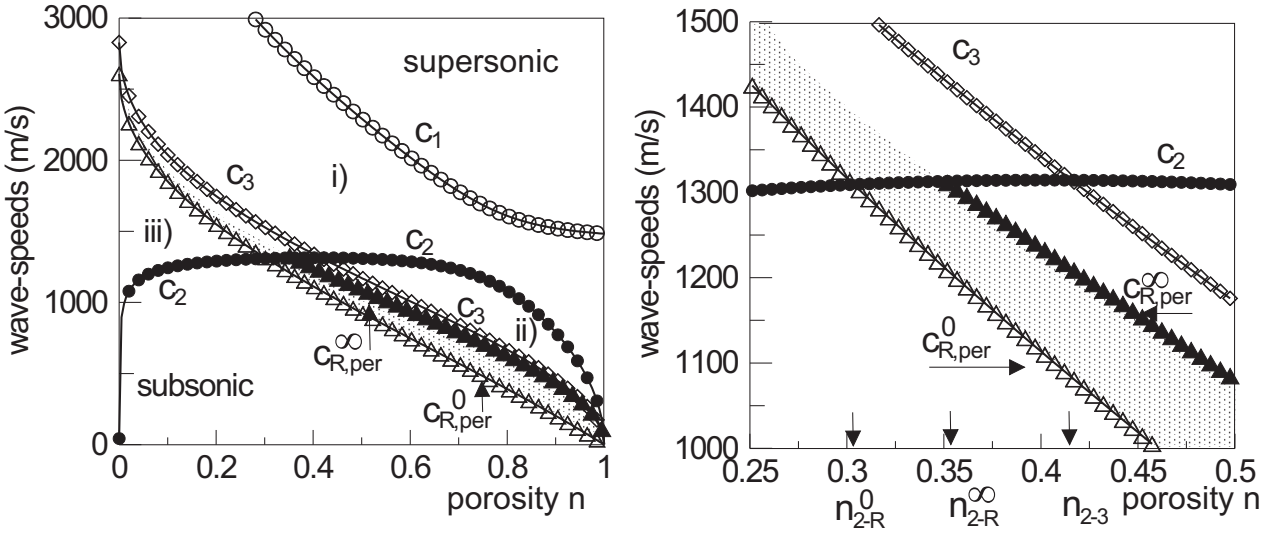

Fig. 11.9.2: Permeable free surface. Longitudinal body wave-speeds c_1, c_2, shear body wave-speed c_3, Rayleigh wave-speeds at vanishingly small and high frequencies, $c^0_{R\mathrm{per}}$ and $c^\infty_{R\mathrm{per}}$, respectively, and a close-up around the critical porosity range.

The relative order of the three body wave-speeds depends on the porosity as sketched in Fig. 11.5.2. For $n^{\mathrm{w}} < n_{2-3}$ (respectively, $n^{\mathrm{w}} > n_{2-3} \simeq 0.415$), the shear wave-speed c_3 is larger (respectively smaller) than the second longitudinal wave-speed c_2. Furthermore, as explained in Sections (11.9.5.4) and (11.9.5.3),

- there exists a porosity $n^0_{2-\mathrm{R}} \simeq 0.30$ at which the second longitudinal wave-speed c_2 and the Rayleigh wave-speed for low frequency $c^0_{R\mathrm{per}}$ are equal;
- there exists also a porosity $n^\infty_{2-\mathrm{R}} \simeq 0.35$, at which the second longitudinal wave-speed c_2 and the Rayleigh wave-speed for infinitely large frequencies $c^\infty_{R\mathrm{per}}$ are equal;
- above this porosity, the Rayleigh waves exist for all frequencies, and they are subsonic;
- below this porosity, there exists a frequency cutoff above which the Rayleigh waves do not exist. This cutoff depends on porosity, Fig. 11.9.3;
- below the porosity $n^0_{2-\mathrm{R}}$, the existing Rayleigh waves are intersonic;
- the range of variation of the Rayleigh wave-speeds with the frequency, at given porosity, is shown dotted: it is modest. For higher porosity $n^{\mathrm{w}} > n^\infty_{2-\mathrm{R}}$, this range is bounded below by the zero frequency speed $c^0_{R\mathrm{per}}$, and above by the infinite frequency speed $c^\infty_{R\mathrm{per}}$. For lower porosity $n^{\mathrm{w}} < n^\infty_{2-\mathrm{R}}$, it is bounded below by the zero frequency speed $c^0_{R\mathrm{per}}$, and above by the wave-speed associated with the frequency cutoff. Although the allowable frequency range becomes larger as the porosity tends to vanish, Fig. 11.9.3, the zero frequency and the cutoff frequency wave-speeds become closer. The latter collapse to the Rayleigh wave-speed for a solid which is indeed known to be frequency independent and slightly smaller than the shear wave-speed.

whence the mixture coefficients by (7.3.44),

$$\lambda^{\mathrm{ww}} = \frac{(n^{\mathrm{w}})^2\, K_{\mathrm{s}}^2}{\left(\dfrac{1-n^{\mathrm{w}}}{K_{\mathrm{s}}} + \dfrac{n^{\mathrm{w}}}{K_{\mathrm{w}}}\right) K_{\mathrm{s}}^2 - K} > 0, \quad \frac{\lambda^{\mathrm{sw}}}{\lambda^{\mathrm{ww}}} = \frac{\alpha_{\mathrm{w}}}{n^{\mathrm{w}}} - 1 \geq 0, \quad \lambda^{\mathrm{ss}} = K - \frac{2}{3}\,\mu + \frac{(\lambda^{\mathrm{sw}})^2}{\lambda^{\mathrm{ww}}}\,. \tag{11.9.34}$$

The calculations are performed according to the following scheme:

1. a porosity n^{w} is selected;
2. a range of frequencies of interest either in terms of ω or in terms of κ is defined;
3. given a frequency κ, the eigenvalues $\tilde{X}^2$'s are obtained first by solving (11.9.20) and (11.9.23);
4. the eigenmodes are then known by (11.9.21) and (11.9.24), and parts of the coefficients of the secular matrix by (11.9.28), except those that involve the $\tilde{A}$'s themselves, not their squares;
5. the determinant of the secular matrix is expanded in polynomial form, so as to eliminate the $\tilde{A}$'s by squaring, in order to make appear the $\tilde{A}^2$'s, and be able to use (11.9.18). The squarings induce spurious solutions that will be eliminated later. The dispersion relation appears as a polynomial of order 14 in $\tilde{k}$, actually of order 7 in $\tilde{k}^2$,

$$\sum_{j=1,7} s_j^{\mathrm{per}}\, \tilde{k}^{2j} = 0\,. \tag{11.9.35}$$

The coefficients of the polynomial are in general complex. The equation is solved using an algorithm that finds all solutions of such a polynomial. Out of the 14 complex solutions, only the ones with positive real part and negative imaginary part are retained, at maximum 7 $\tilde{k}$'s;
6. given the $\tilde{X}^2$'s and the set of $\tilde{k}$'s, the $\tilde{A}_j^2$, $j \in [1,3]$, are deduced by (11.9.18): the latter should not be real negative so as to satisfy the decay in depth. The real parts of the admissible $\tilde{A}$'s are chosen strictly positive;
7. an additional screening is required over the set of $\tilde{k}$'s to eliminate the spurious solutions induced by the algebraic manipulations (squaring) in step 5 above, that is, to eliminate the wave-numbers $\tilde{k}$'s that do not zero the secular determinant $\det \mathcal{R}_{\rm per}$.

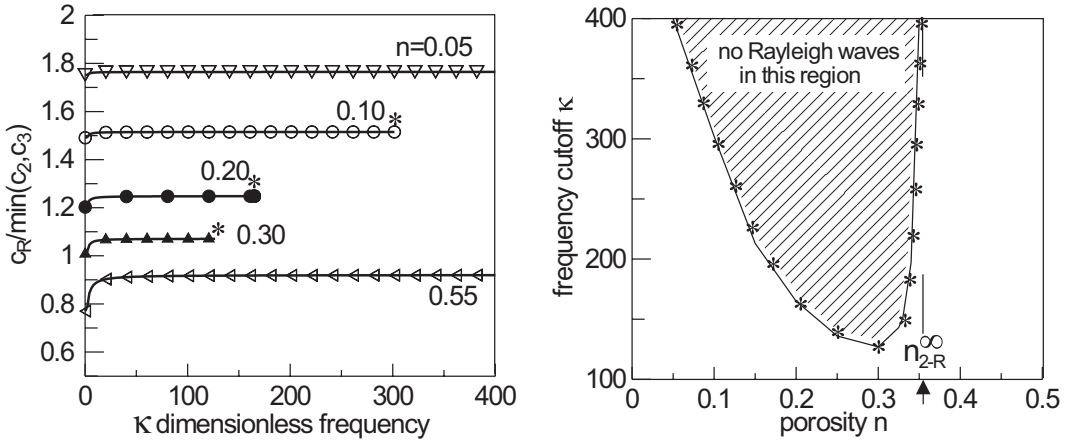

Fig. 11.9.3: Permeable free surface. (Left) Rayleigh wave-speeds as a function of frequency, for several porosities. (Right) Cutoff frequency, above which the Rayleigh waves do not exist, as a function of porosity, in the range $n^{\rm w} < n^{\infty}_{2-{\rm R}}$. In this range, the Rayleigh waves are intersonic. For larger porosities, the Rayleigh waves exist for all frequencies and are subsonic.

The results highlight the following features, which can be observed in Figs. 11.9.2 to 11.9.5:
1. the low frequency limit Rayleigh wave exists at all porosities. There exists a porosity $n^0_{2-{\rm R}}$ at which the low frequency Rayleigh wave-speed $c_R(0)$ is equal to the slow longitudinal wave-speed c_2. For a porosity smaller (respectively larger) than $n^0_{2-{\rm R}}$, the low frequency wave-speed is intersonic (respectively subsonic);
2. there exists a porosity for $n^{\infty}_{2-{\rm R}}$ at which the Rayleigh wave-speed $c_R(\infty)$ at large frequencies is equal to the second longitudinal wave-speed c_2;
3. for a porosity $n^{\rm w} \geq n^{\infty}_{2-{\rm R}}$, the Rayleigh waves exist at all frequencies, and they are subsonic;
4. for a porosity $n^{\rm w} < n^{\infty}_{2-{\rm R}}$, there exists a frequency cutoff above which the Rayleigh wave does not exist, Fig. 11.9.3. Below the frequency cutoff, the Rayleigh waves are intersonic for $n^{\rm w} < n^0_{2-{\rm R}}$, and, in the range $n^0_{2-{\rm R}} < n^{\rm w} < n^{\infty}_{2-{\rm R}}$, they are subsonic at the lowest frequencies and intersonic at the largest available frequencies;
5. the frequency cutoff is correlative with the vanishing of the real part of the coefficient of depth dependence A_1, Figs. 11.9.4 and 11.9.5.

For any porosity and any frequency, there exists at maximum a single Rayleigh wave associated with the permeable surface. The existence is guaranteed at any frequency for a porosity larger than $n^{\infty}_{2-{\rm R}}$.

11.9.5.3 Low frequency limit, $\kappa \to 0$

Since $F(0) = 1$, it follows from (11.9.13) that, at low frequency, namely for small κ,

$$\frac{k_{\rm Sd}}{\rho^{\rm w}\,\omega} = G(\kappa) = \left(\frac{\delta}{\kappa}\right)^2 = O(\kappa^{-2}) \to \infty\,. \tag{11.9.36}$$

Solving (11.9.20) and (11.9.23) leads to

$$\tilde{X}_1^2 = -1 + O(\kappa^2)\,, \quad \tilde{X}_2^2 = i\,G(\kappa)\frac{c_3^2}{c_{\rm SU}^2}\,\frac{c_{\rm LU}^4}{c_1^2\,c_2^2} + 1 - c_{\rm LU}^2\,\frac{c_1^2+c_2^2}{c_1^2\,c_2^2} = O(\kappa^{-2})\,, \quad \tilde{X}_3^2 = -1 + O(\kappa^2)\,, \tag{11.9.37}$$

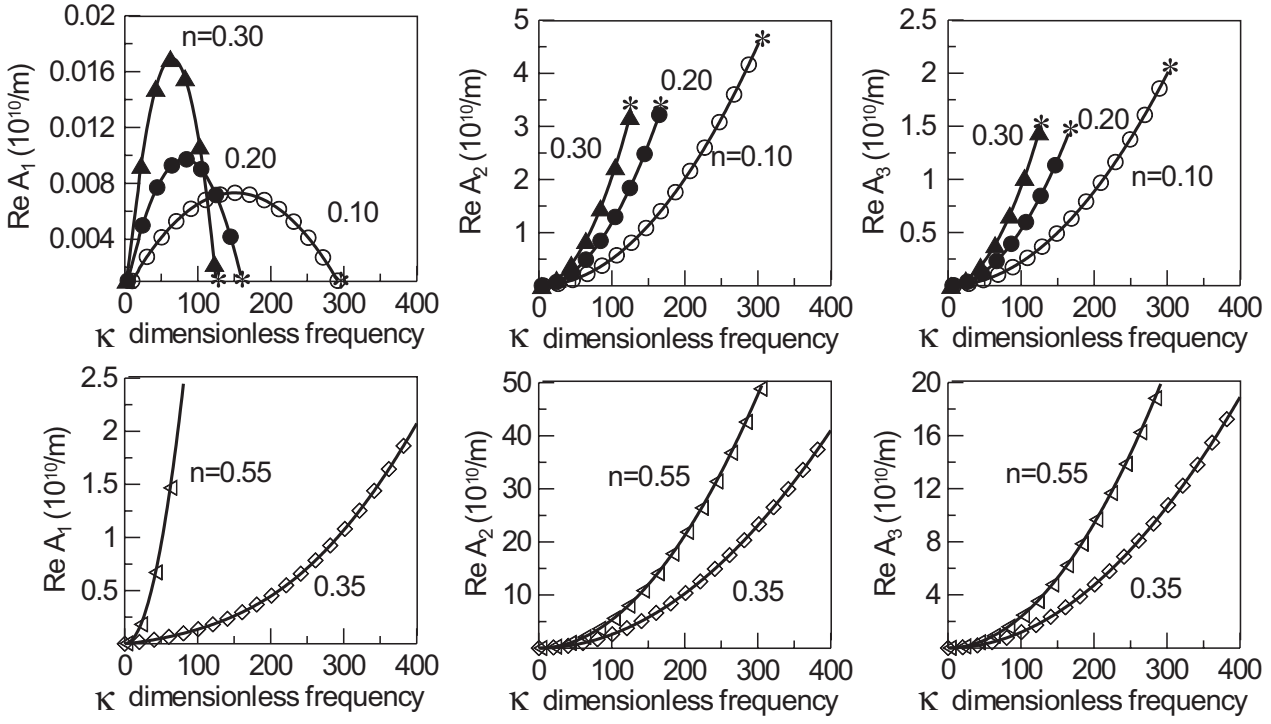

Fig. 11.9.4: Permeable free surface. Real parts of the coefficients of depth dependence as a function of frequency, for several porosities. According to (11.9.12) and (11.9.18), the depth dependence coefficients scale inversely with the hydraulic conductivity. These coefficients tend to vanish at low frequencies, see Section 11.9.5.3. Conversely, they are large at high frequencies, especially in the zone $n^{\mathrm{w}} > n^{\infty}_{2-\mathrm{R}}$. Rayleigh waves cease to exist at high frequencies in the range $n^{\mathrm{w}} < n^{\infty}_{2-\mathrm{R}}$ when one depth dependence coefficient vanishes.

$$\tilde{A}_1^2 = \tilde{k}^2 - \frac{\mu}{H^{\mathrm{U}}} + O(\kappa^2)\,,\ \ \tilde{A}_2^2 = \tilde{k}^2 + i\,G(\kappa)\,\frac{c_{\mathrm{LU}}^2\,c_3^2}{c_1^2\,c_2^2} + (1 - c_{\mathrm{LU}}^2\,\frac{c_1^2 + c_2^2}{c_1^2\,c_2^2})\,\frac{c_{\mathrm{SU}}^2}{c_{\mathrm{LU}}^2}\,,\ \ \tilde{A}_3^2 = \tilde{k}^2 - 1 + O(\kappa^2)\,, \tag{11.9.38}$$

and

$$\tau_j \equiv \frac{a_{\mathrm{w}j}}{a_{\mathrm{s}j}} - 1 = O(\kappa^2), \quad j \in [1,3]\,. \tag{11.9.39}$$

The determinant of the secular matrix (11.9.29) can be shown to be proportional to main order to

$$\Phi_0(\tilde{k}^2) = (2\,\tilde{k}^2 - 1)^2 - 4\,\tilde{k}^2\,\tilde{A}_1\,\tilde{A}_3\,, \tag{11.9.40}$$

which can be transformed by squaring to a cubic polynomial in $\tilde{k}^2$,

$$P_0(\tilde{k}^2) = 16\,(1 - \frac{\mu}{H^{\mathrm{U}}})\,(\tilde{k}^2)^3 - 8\,(3 - 2\,\frac{\mu}{H^{\mathrm{U}}})\,(\tilde{k}^2)^2 + 8\;\tilde{k}^2 - 1 = 0\,. \tag{11.9.41}$$

The secular matrix and the cubic polynomial are identical to their counterparts for an elastic solid, to within the fact the undrained modulus H^{U}, associated with the undrained Poisson's ratio ν^{U}, takes the place of the longitudinal modulus H, associated with the drained Poisson's ratio ν. Since the undrained Poisson's ratio is bounded by -1 and $1/2$, Eqn (7.4.43), the ratio $\mu/H^{\mathrm{U}} = (1-2\,\nu^{\mathrm{U}})/(2\,(1-\nu^{\mathrm{U}}))$ varies between the same bounds as for a solid. Therefore the analysis pertaining to the elastic solid of Section 11.9.8 applies to a saturated porous medium in the limit case of low frequency. In essence, the single admissible dimensionless wave-number $\tilde{k}$ defined by (11.9.31) and (11.9.32) is larger than 1, so that the real wave-speed is smaller than $c_{\mathrm{SU}} = \sqrt{\mu/\rho}$, and hence smaller than the shear wave-speed $c_3 = \sqrt{\mu/\rho^{\mathrm{s}}}$, but it can be larger than c_2, Fig. 11.9.2. Since $\tilde{k}$ is finite, it follows from (11.9.38) that the coefficients of depth decay tend to vanish as the frequency goes to 0, and, in fact, $A_1 = O(\kappa^2)$, $A_2 = O(\kappa)$, $A_3 = O(\kappa^2)$.

11.9.5.4 High frequency limit, $\kappa \to \infty$

The comments below assume the wave-number k to be real at large frequency,

$$\mathrm{Im}\,k(\kappa \to \infty) = 0\,, \tag{11.9.42}$$

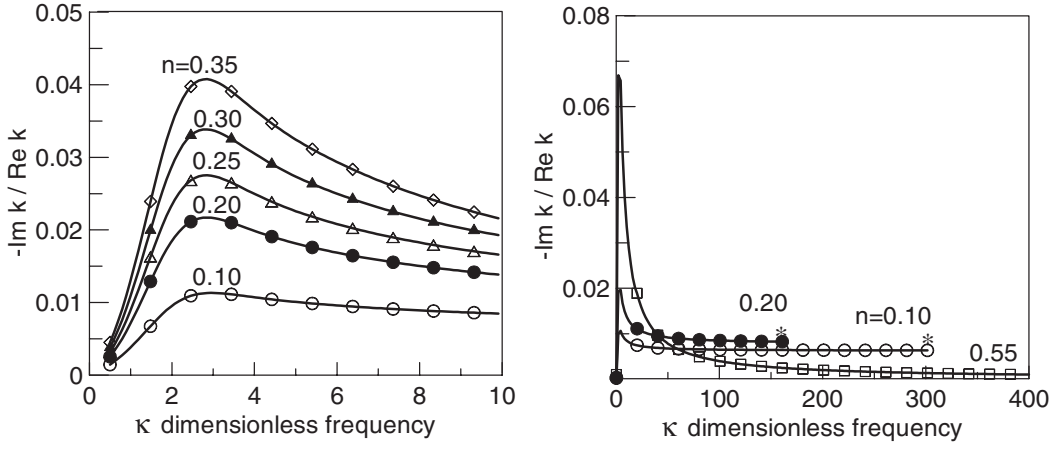

Fig. 11.9.5: Permeable free surface. Wave-number as a function of frequency, for several porosities. The ratio $-\mathrm{Im}\,k/\mathrm{Re}\,k$ should remain negative for the amplitude of the wave to remain bounded in the direction of propagation. The wave-number is real at the low and high frequency limits.

so that Eqn (11.9.32) yields $c_R(\infty) = \omega/k$.

From (11.9.13) and the fact that $F(\kappa \gg 1) = O(\kappa)$,

$$\frac{k_{\mathrm{Sd}}}{\rho^{\mathrm{w}}\,\omega} = G(\kappa) = O(\kappa^{-1})\,. \tag{11.9.43}$$

Solving (11.9.20) and (11.9.23) provides (recall that $c_{\mathrm{LU}} = \sqrt{H^{\mathrm{U}}/\rho}$),

$$\tilde{X}_1^2 = -\frac{c_{\mathrm{LU}}^2}{c_1^2}\,, \quad \tilde{X}_2^2 = -\frac{c_{\mathrm{LU}}^2}{c_2^2}\,, \quad \tilde{X}_3^2 = -\frac{\rho^{\mathrm{s}}}{\rho}\,, \tag{11.9.44}$$

and the eigenmodes (11.9.21) and (11.9.24) simplify somehow,

$$\frac{a_{\mathrm{w}j}}{a_{\mathrm{s}j}} = \frac{c_j^2 - c_{\mathrm{s}}^2}{c_{\mathrm{ms}}^2},\ j = 1, 2; \quad \frac{a_{\mathrm{w}3}}{a_{\mathrm{s}3}} = 0\,. \tag{11.9.45}$$

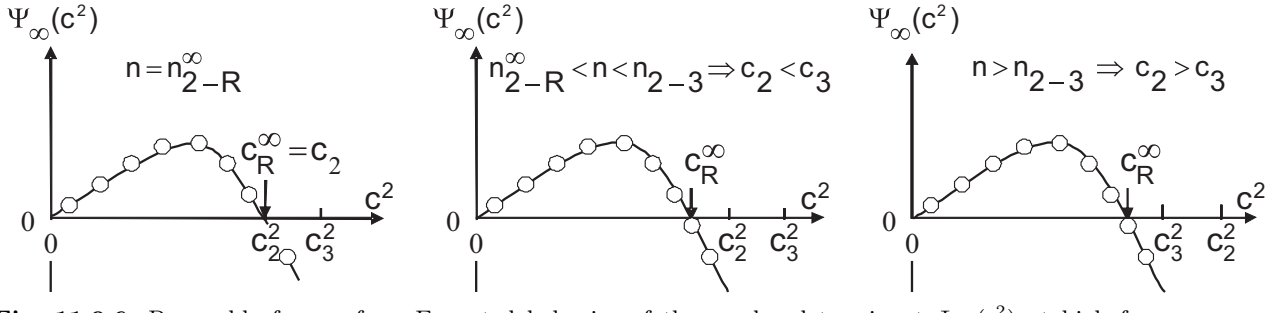

Fig. 11.9.6: Permeable free surface. Expected behavior of the secular determinant $\Psi_\infty(c^2)$ at high frequency as a function of the square of the wave-speed. The critical porosity n^∞_{2-R} is associated with the Rayleigh wave-speed c_R^∞ being equal to the second longitudinal wave speed c_2. Intersonic wave-speeds, potentially associated with porosities smaller than the critical porosity, are ruled out because they do not satisfy the decay conditions.

These results can be checked to hold as well in the case of a vanishingly small dissipation coefficient k_{Sd}, i.e., of a large permeability. The coefficients of depth dependence A's result from (11.9.17) and (11.9.18), and, as another consequence of (11.9.42), they are either real positive, or imaginary. A decay of the wave in depth excludes the latter possibility and, in fact, *constraints the Rayleigh wave to be subsonic,*

$$c_R(\infty) < c_j\,, \quad j \in [1, 3]\,. \tag{11.9.46}$$

Then the three coefficients α's, defined by their squares,

$$\alpha_j^2(c^2) \equiv \frac{A_j^2}{k^2} = 1 - \frac{c^2}{c_j^2}\,, \quad j \in [1,3]\,, \tag{11.9.47}$$

with $c = c_R(\infty)$, are real. The determinant of the secular matrix (11.9.28) becomes,

$$\Psi_\infty(c^2) \simeq \det \begin{bmatrix} 1+\alpha_3^2 & 1+\alpha_3^2 & -2\,\alpha_3\,i \\ 2\,\alpha_1\,i & 2\,\alpha_2\,i & 1+\alpha_3^2 \\ c_2^2 - c_{\rm w}^2 & c_1^2 - c_{\rm w}^2 & 0 \end{bmatrix}\,, \tag{11.9.48}$$

or

$$\Psi_\infty(c^2) \simeq 4\,\alpha_1\,\alpha_3\,(c_1^2 - c_{\rm w}^2) + 4\,\alpha_2\,\alpha_3\,(c_{\rm w}^2 - c_2^2) - (1+\alpha_3^2)^2\,(c_1^2 - c_2^2)\,, \tag{11.9.49}$$

and

$$\Psi_\infty(0) = 0\,, \quad \frac{d\,\Psi_\infty}{dc^2}(0) > 0\,, \quad \Psi_\infty(c_3^2) < 0\,. \tag{11.9.50}$$

Consequently, as sketched in Fig. 11.9.6,

1. if $c_3 = \min\{c_2\,, c_3\}$, that is for $n^{\rm w} > n_{2-3}$, then there exists at least one real (subsonic) Rayleigh speed $c_R(\infty) < \min\{c_2\,, c_3\}$;
2. if $c_2 = \min\{c_2\,, c_3\}$, then, for $n_{2-{\rm R}}^\infty < n^{\rm w} < n_{2-3}$, there exists at least one real (subsonic) Rayleigh speed $c_R(\infty) < c_2$ if $\Psi(c_2^2) < 0$. Otherwise, that is for $n^{\rm w} < n_{2-{\rm R}}^\infty$, a Rayleigh wave associated with strictly decaying amplitude down the half-space might not exist, and indeed, this hypothesis is confirmed by the numerical results (but we have not proved it).

The equation that defines the porosity $n_{2-{\rm R}}^\infty$ at which $c_R(\infty) = c_2$ is thus

$$4\,\alpha_1\,\alpha_3\,(c_1^2 - c_{\rm w}^2) - (1+\alpha_3^2)^2\,(c_1^2 - c_2^2) = 0\,, \tag{11.9.51}$$

with α_1 and α_3 defined by (11.9.47) with $c = c_R(\infty) = c_2$.

11.9.6 Impermeable free surface

The boundary conditions along the surface $x_2 = 0$ now involve the total traction and the normal velocity, or displacement, of the fluid relative to the solid,

$$\sigma_{22}(x_1, x_2 = 0) = 0, \quad \sigma_{12}(x_1, x_2 = 0) = 0, \quad (u_{\rm s2} - u_{\rm w2})(x_1, x_2 = 0) = 0, \quad \forall x_1 \in]-\infty, \infty[\,. \tag{11.9.52}$$

11.9.6.1 The dispersion relation

With the normalization (11.9.17), (11.9.18), since $\sigma_{22} = \sigma_{22}^{\rm s} - n^{\rm w} p_{\rm w}$ and $\sigma_{12} = \sigma_{12}^{\rm s}$, the stresses (11.9.10) and displacements (11.9.8) combine to yield the secular equation in matrix form as,

$$\begin{bmatrix} \hat\sigma_{22}(x_2) \\ \hat\sigma_{12}(x_2) \\ \mu\,k_r\,(u_{\rm s2} - u_{\rm w2})(x_2) \end{bmatrix} = \mu\,k_r^2\;\mathcal{R}_{\rm imp} \begin{bmatrix} a_{\rm s1}\,e^{-A_1\,x_2} \\ a_{\rm s2}\,e^{-A_2\,x_2} \\ a_{\rm s3}\,e^{-A_3\,x_2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}\,, \tag{11.9.53}$$

with the secular Rayleigh matrix,

$$\mathcal{R}_{\rm imp} = \begin{bmatrix} 2\,\tilde k^2 + \beta_1\,\tilde X_1^2 & 2\,\tilde k^2 + \beta_2\,\tilde X_2^2 & -2\,i\,\tilde k\,\tilde A_3 \\ 2\,i\,\tilde k\,\tilde A_1 & 2\,i\,\tilde k\,\tilde A_2 & 2\,\tilde k^2 + \tilde X_3^2 \\ \tau_1\,\tilde A_1 & \tau_2\,\tilde A_2 & -i\,\tilde k\,\tau_3 \end{bmatrix}\,, \tag{11.9.54}$$

the β's and τ's being defined by (11.9.30). The procedure to solve the secular equation in terms of the dimensionless frequency κ is identical to the permeable case. The dispersion relation appears as a polynomial of order 18 in $\tilde k$, actually of order 9 in $\tilde k^2$,

$$\sum_{j=1,9} s_j^{\rm imp}\;\tilde k^{2j} = 0\,. \tag{11.9.55}$$

The use of a symbolic software is required to obtain the complex coefficients $s^{\rm imp}$ which are *very* lengthy.

The results are shown in Figs. 11.9.7 to 11.9.9. In essence

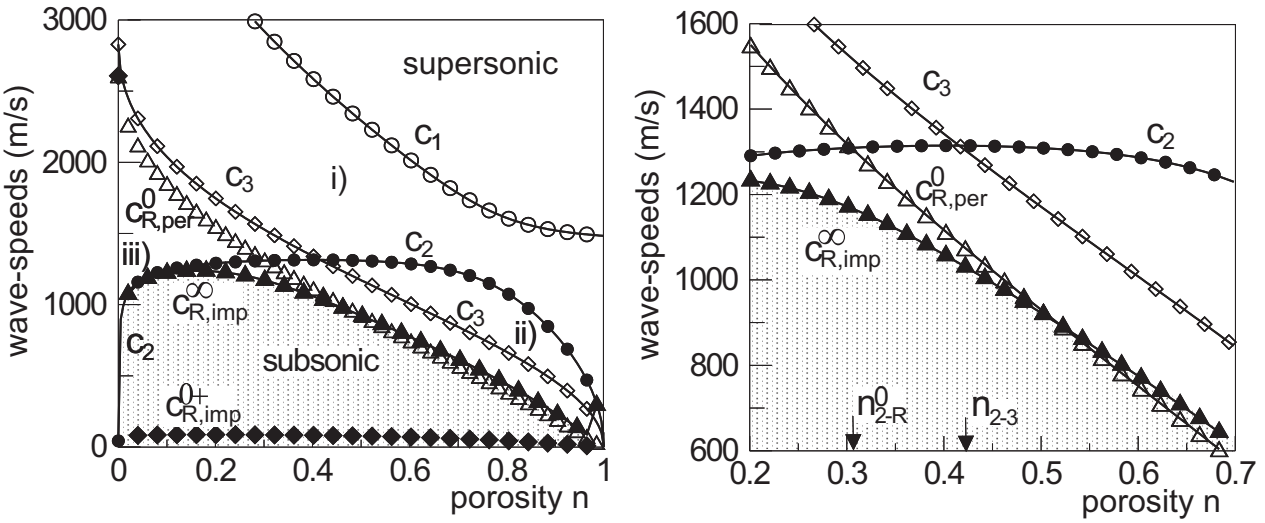

Fig. 11.9.7: Impermeable free surface. Body wave-speeds c_1, c_2 and c_3 and Rayleigh wave-speeds at zero, small and infinite frequencies, and a close-up around the critical porosity.

There exists a single Rayleigh wave at any frequency and any porosity. The Rayleigh wave-speed at zero frequency is equal to its counterpart for the permeable free surface, $c^0_{R\mathrm{imp}} = c^0_{R\mathrm{per}}$, while the Rayleigh wave-speed at small but non zero frequency is vanishingly small. As the frequency increases, the Rayleigh wave-speed increases but it remains subsonic, even if, at small porosity, it tends to the second longitudinal body wave-speed c_2.

The dependence on frequency, at given porosity, is displayed in Fig. 11.9.8. The range of variation, shown dotted here, is large, but the actual variations take place mainly at small frequencies.

1. there always exists a single Rayleigh wave which, except at zero frequency, is subsonic;
2. at zero frequency, the Rayleigh wave-speed is equal to its permeable counterpart;
3. at small, but non zero, frequency, the wave-speed is vanishingly small and it increases monotonically with frequency.

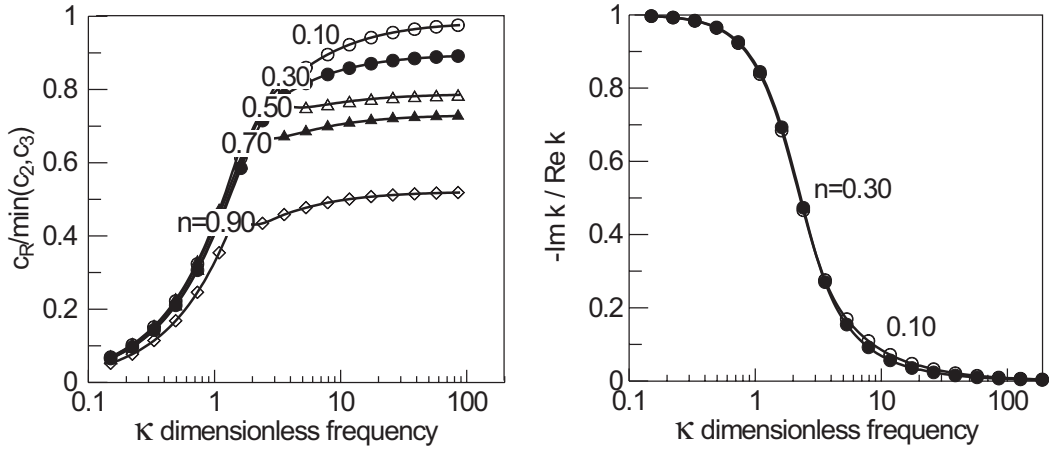

Fig. 11.9.8: Impermeable free surface. (Left) Rayleigh wave-speeds as a function of frequency, for several porosities. The wave-speeds increase from zero towards a subsonic asymptotic speed, which is close to the 2nd longitudinal wave-speed c_2 for small porosities.

(Right) Ratio of the imaginary and real parts of the wave-number as a function of frequency, for several porosities. This ratio should be negative for the amplitude of the wave to remain bounded. The wave-number is real at high frequencies, like for a permeable free surface. On the other hand, at low frequencies, as indicated by (11.9.56) and (11.9.57), the ratio $-\mathrm{Im}\, k/\mathrm{Re}\, k \simeq 1 + Y\,(\kappa/\delta)^2$ is equal to 1 at $\kappa = 0^+$ and it decreases as the frequency increases, the coefficient Y being negative.

Some qualitative explanations of the existence, number, and dependence of the solution in terms of frequency and porosity may be provided at low and high frequencies.

11.9.6.2 Low frequency limit, $\kappa \to 0$

The relations (11.9.36)-(11.9.39) pertaining to the eigenvalues $\tilde{X}$'s and eigenmodes τ's hold irrespective of the boundary conditions. The three τ's almost vanish according to (11.9.39), but $\tau_2 = O(\kappa^2)$ while $\tilde{A}_2 = O(\kappa^{-1})$ is large. Thus the secular determinant is the product of two factors. One factor is exactly as for a permeable free surface, namely Eqn (11.9.40): the vanishing of this factor implies that the zero frequency solution of the permeable case is also a solution of the impermeable case. The second factor is equal to $\tau_2\,\tilde{A}_2$. It may be of interest to study the solution of $\tilde{A}_2 = 0$ for small frequencies, even if it does not furnish an appropriate decay. Eqns (11.9.37) and (11.9.38) provide the eigenvalue,

$$\tilde{X}_2^2 = i\,(\frac{\delta}{\kappa})^2\,\frac{\rho}{\rho^{\rm s}}\,\frac{c_{\rm LU}^4}{c_1^2\,c_2^2}\left(1 - i\,Y\,(\frac{\kappa}{\delta})^2\right), \quad Y \equiv \left(1 - c_{\rm LU}^2\,\frac{c_1^2 + c_2^2}{c_1^2\,c_2^2}\right)\frac{c_1^2\,c_2^2}{c_{\rm LU}^4}\,\frac{\rho^{\rm s}}{\rho} < 0\,. \tag{11.9.56}$$

The resulting admissible dimensionless wave-number with ($\mathrm{Re}\,\tilde{k} > 0$, $\mathrm{Im}\,\tilde{k} < 0$),

$$\tilde{k} = \frac{1}{\sqrt{2}}\,\frac{\delta}{\kappa}\,\frac{c_{\rm LU}\,c_3}{c_1\,c_2}\left(1 - \frac{Y}{2}\,(\frac{\kappa}{\delta})^2 - i\,(1 + \frac{Y}{2}\,(\frac{\kappa}{\delta})^2)\right), \tag{11.9.57}$$

is large, actually of the order of δ/κ, while the Rayleigh wave-speed,

$$c_R(0) = \frac{c_{\rm SU}}{\mathrm{Re}\,\tilde{k}} \simeq \sqrt{2}\,c_{\rm SU}\,\frac{c_1\,c_2}{c_{\rm LU}\,c_3}\,\frac{\kappa}{\delta}\left(1 + \frac{Y}{2}\,(\frac{\kappa}{\delta})^2\right), \tag{11.9.58}$$

is small, of the order κ/δ. The depth dependence coefficients (11.9.38),

$$A_1 = k_r\tilde{A}_1 = \frac{\kappa}{\delta}\,\frac{c_{\rm LU}\,c_3}{c_1\,c_2}\,\frac{n^{\rm w}\,g}{c_{\rm SU}K_{\rm H}(\omega = 0)}\,e^{-i\pi/4}\left(1 + O(\kappa^2)\right) \simeq A_3\,, \tag{11.9.59}$$

are seen to vanish with the frequency, like for the permeable free surface, Fig. 11.9.9.

Thus at zero frequency, the Rayleigh wave-speed $c_{R\rm imp}(0)$ is identical to the wave-speed associated with the permeable free surface $c_{R\rm per}(0)$. At small but not zero frequency, the Rayleigh wave-speed is close to 0 and it increases with frequency, as confirmed by the numerical results displayed in Fig. 11.9.8.

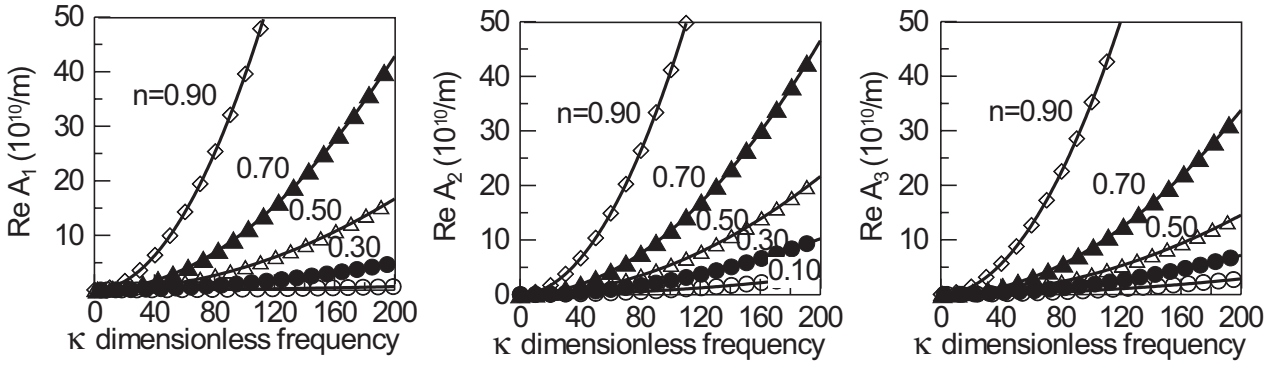

Fig. 11.9.9: Impermeable free surface. Real parts of the coefficients of depth dependence as a function of frequency, for several porosities. These coefficients tend to vanish at low frequencies, and increase with frequency.

11.9.6.3 High frequency limit, $\kappa \to \infty$

The relations (11.9.42)-(11.9.46) pertaining to the eigensolutions still hold. The secular determinant can be shown to be proportional to

$$\Psi_\infty(c^2) = \det\begin{bmatrix} 2 + \chi_1\,(-1 + \alpha_3^2) & 2 + \chi_2\,(-1 + \alpha_3^2) & -2\,\alpha_3\,i \\ 2\,\alpha_1\,i & 2\,\alpha_2\,i & 1 + \alpha_3^2 \\ -\tau_1\,\alpha_1 & -\tau_2\,\alpha_2 & -i \end{bmatrix}. \tag{11.9.60}$$

The α's involved in this subsection are in fact real positive, since it will be shown that the Rayleigh wave is subsonic. The χ's and τ's are defined as follows,

$$\chi_j = \frac{c_j^2 - c_{\rm s}^2}{c_{\rm mw}^2} + 1\,, \quad \tau_j = \frac{c_j^2 - c_{\rm s}^2}{c_{\rm ms}^2} - 1\,, \quad j = 1, 2\,. \tag{11.9.61}$$

Therefore

$$\begin{aligned} \Psi_\infty(c^2) &= 4\,\alpha_1\,\alpha_2\,\alpha_3\,(\tau_1 - \tau_2) \\ &- \alpha_1\left(2 + \chi_2\,(-1 + \alpha_3^2)\right)\left(2 + \tau_1\,(1 + \alpha_3^2)\right) \\ &+ \alpha_2\left(2 + \chi_1\,(-1 + \alpha_3^2)\right)\left(2 + \tau_2\,(1 + \alpha_3^2)\right). \end{aligned} \tag{11.9.62}$$

The following relations,

$$\Psi_\infty(0) = 0\,; \quad \frac{d\,\Psi_\infty}{dc^2}(0) > 0\,; \quad \Psi_\infty(c_3^2) < 0 \text{ for } c_3 \le c_2; \quad \Psi_\infty(c_2^2) < 0 \text{ for } c_2 \le c_3\,, \tag{11.9.63}$$

may be established with the proviso that the mechanical coupling coefficient $\lambda^{\rm sw}$ is positive, Eqn (11.9.34). The proof of the relation $\Phi(c_3^2) < 0$ for $c_3 \le c_2$ goes as follows. First $\Psi_\infty(c_3^2)$ simplifies to,

$$\Psi_\infty(c_3^2) = -\alpha_1\,(2 - \chi_2)\,(2 + \tau_1) + \alpha_2\,(2 - \chi_1)\,(2 + \tau_2)\,, \tag{11.9.64}$$

and $2 - \chi_2$ and $2 + \tau_1$ are easily shown to be positive. Furthermore, use of the relation $(c_j^2 - c_{\rm w}^2)\,(c_j^2 - c_{\rm s}^2) = c_{\rm ms}^2\,c_{\rm mw}^2$, for $j = 1, 2$, yields $2 - \chi_1 = 1 - 1/X$ and $2 + \tau_2 = 1 - X$, with $X = (c_1^2 - c_{\rm w}^2)/c_{\rm ms}^2 > 0$, so that $(2 - \chi_1)\,(2 + \tau_2) < 0$.

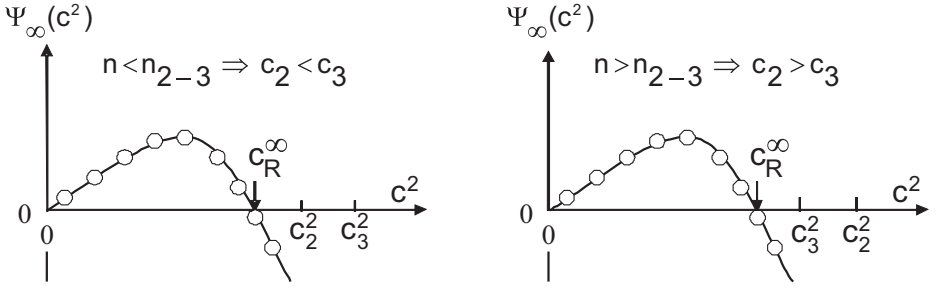

Fig. 11.9.10: Impermeable free surface. Expected shape of the secular determinant Ψ_∞ as a function of the wave-speed, leading to the existence of a single subsonic Rayleigh wave-speed.

As a consequence of (11.9.63), the variation of the secular determinant (11.9.60) as a function of the wave-speed is expected as sketched in Fig. 11.9.10, indicating that there exists at least one Rayleigh wave which is subsonic. Note that we have not proved uniqueness.

11.9.7 The Kelvin functions ber and bei

Biot [1956] makes use of the frequency function $F(\kappa)$,

$$F(\kappa) = \frac{\kappa^2}{4}\,\frac{d{\rm be}(\kappa)/d\kappa}{\kappa\,{\rm be}(\kappa) + 2\,i\,d{\rm be}(\kappa)/d\kappa}\,, \tag{11.9.65}$$

with

$${\rm be}(\kappa) = {\rm ber}(\kappa) + i\,{\rm bei}(\kappa) = I_0(i^{\frac{1}{2}}\kappa) = J_0(i^{\frac{3}{2}}\kappa), \tag{11.9.66}$$

where I_0 is the modified Bessel function of zeroth order, and ber and bei are referred to as Kelvin functions. The actual series definitions follow from (7.5.66),

$${\rm ber}(\kappa) = \sum_{n=0}^{\infty} \frac{(-1)^n}{((2n)!)^2}\left(\frac{\kappa^2}{4}\right)^{2n}, \quad {\rm bei}(\kappa) = \sum_{n=0}^{\infty} \frac{(-1)^n}{((2n+1)!)^2}\left(\frac{\kappa^2}{4}\right)^{2n+1}. \tag{11.9.67}$$

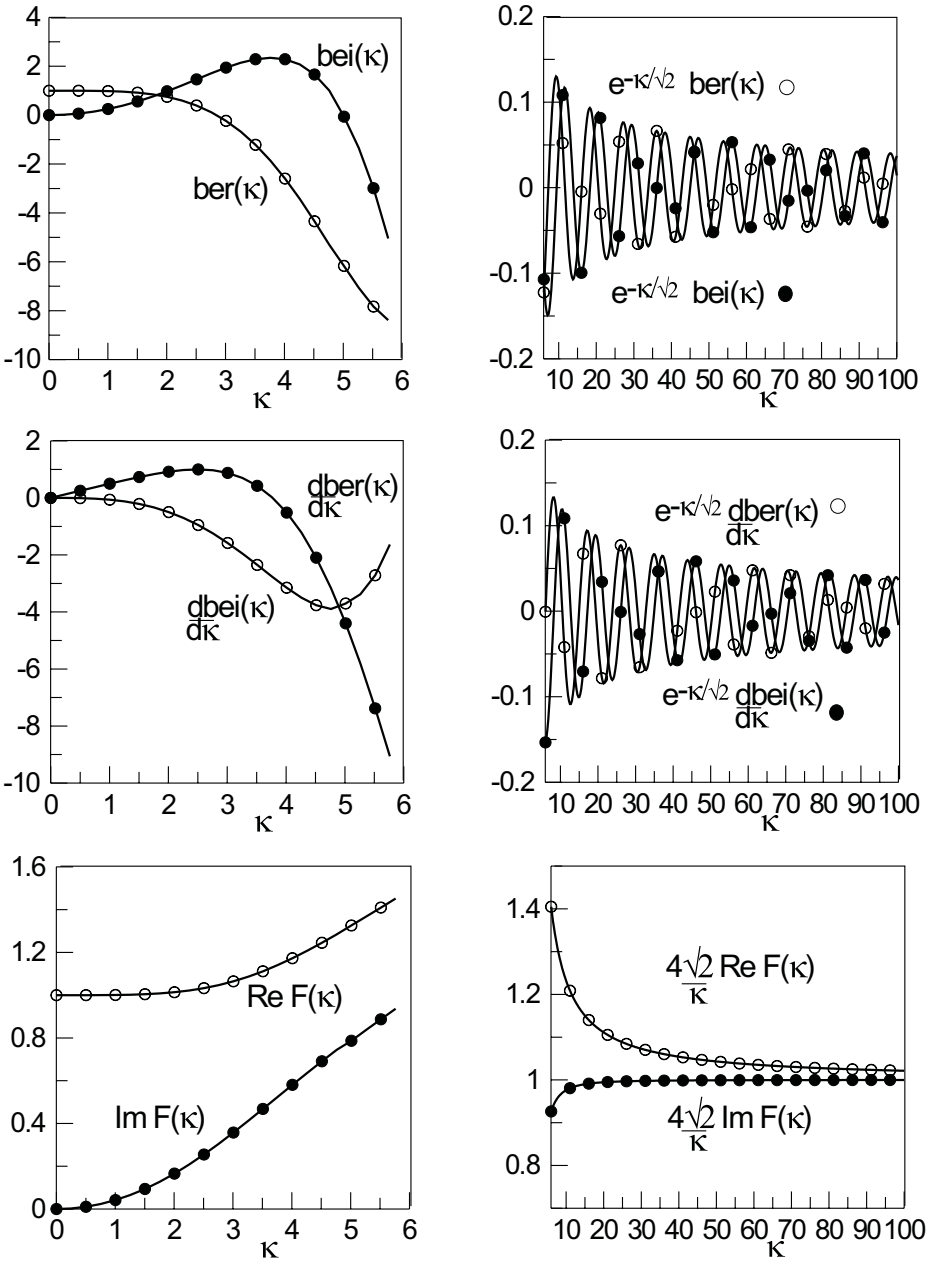

Fig. 11.9.11: The Kelvin functions ber(κ) and bei(κ), their derivatives, and the function $F(\kappa)$ used to introduce a frequency dependent hydraulic conductivity.

These functions are plotted in Fig. 11.9.11. In actual computations, the series are defined recursively, with about 50 terms. For $\kappa > 5$, based on (7.5.77), the following asymptotic expression may be used:

$$\mathrm{be}(\kappa) = \frac{1}{\sqrt{2\,\pi\kappa}}\,\exp\Big(\frac{1+i}{\sqrt{2}}\,\kappa - i\,\frac{\pi}{8}\Big)\,. \tag{11.9.68}$$

More generally, the Kelvin functions of order $m \geq 0$,

$$\mathrm{be}_m(\kappa) = \mathrm{ber}_m(\kappa) + i\,\mathrm{bei}_m(\kappa) = I_m(i^{\frac{1}{2}}\kappa) = i^{-m}\,J_m(i^{\frac{3}{2}}\kappa)\,, \tag{11.9.69}$$

are solutions bounded at $\kappa = 0$ of the homogeneous differential equation $\kappa^2\,d^2y/d\kappa^2 + \kappa\,dy/d\kappa - (i\kappa^2 + m^2)\,y = 0$.

With help of the relation $(7.5.70)_2$ with $m = 1$, and (7.5.72) with $m = 0$, the function $F(\kappa)$ may be rephrased directly in terms of the modified Bessel functions of the first kind I_1 and I_2,

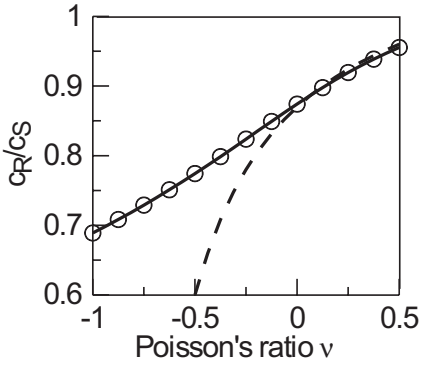
$$F(\kappa) = \frac{i^{\frac{1}{2}}\kappa}{4}\,\frac{I_1(i^{\frac{1}{2}}\kappa)}{I_2(i^{\frac{1}{2}}\kappa)}\,. \tag{11.9.70}$$

Therefore, with further use of the asymptotic expressions (7.5.77) and (7.5.78) for large and small arguments, respectively,

$$\lim_{\kappa\to 0}\; F(\kappa) = 1, \quad \lim_{\kappa\to\infty}\; F(\kappa) = \frac{1}{4}\,i^{\frac{1}{2}}\kappa\,. \tag{11.9.71}$$

11.9.8 Surface waves in an elastic half-plane

Instead of a complete derivation, the analysis for an elastic solid may be obtained from the analysis for a poroelastic medium performed in the previous sections, simply by setting the fluid volume fraction to 0 and disregarding Darcy's law, and the associated balance of momentum and boundary condition. A key difference emerges, namely that the Rayleigh waves are *not dispersive* in an elastic solid unlike in the poroelastic medium, that is, the wave-speed $c_R = \omega/\mathrm{Re}\,k$ which is the ratio between the pulsation ω and the wave-number k is independent of ω. The Rayleigh wave-speed which turns out to be smaller than the shear wave-speed and a standard approximation are plotted in Fig. 11.9.12.



ν	cR/cS
-1	0.689
-0.5	0.774
0	0.874
0.25	0.919
0.333	0.932
0.5	0.955

Fig. 11.9.12: Rayleigh wave-speed in an elastic solid as a function of Poisson's ratio. The dotted standard approximation $c_R/c_S = (0.874 + 1.117\,\nu)/(1+\nu)$ holds for $\nu \geq 0$ only.

The relations for the solid deduce from the analysis of the poroelastic medium by changing the indices 1 and 3 pertaining to the largest longitudinal wave and shear wave, respectively, to L and S. The eigenvalue problems (11.9.19) and (11.9.22) yield

$$X_L^2 = \frac{H}{\mu}\,(A_L^2 - k^2) = -\frac{\omega^2}{c_S^2}, \quad X_S^2 = A_S^2 - k^2 = -\frac{\omega^2}{c_S^2}\,, \tag{11.9.72}$$

with $H = \lambda + 2\,\mu$ the longitudinal modulus. The Rayleigh matrix (11.9.10) simplifies to,

$$\mathcal{R} = \begin{bmatrix} \mu\,(2\,k^2 + X_L^2) & -2\,\mu\,i\,k\,A_S \\ 2\,\mu\,i\,k\,A_L & \mu\,(2\,k^2 + X_S^2) \end{bmatrix}. \tag{11.9.73}$$

Dimensionless entities denoted by a superimposed tilde result via scaling by the wave-number $k_r = \omega/c_S$ yielding the secular Rayleigh matrix,

$$\mathcal{R} = \mu\,k_r^2 \begin{bmatrix} 2\,\tilde{k}^2 - 1 & -2\,i\,\tilde{k}\,\tilde{A}_S \\ 2\,i\,\tilde{k}\,\tilde{A}_L & 2\,\tilde{k}^2 - 1 \end{bmatrix}. \tag{11.9.74}$$

The determinant of the secular matrix is viewed as an equation for the dimensionless wave-number $\tilde{k} = c_S/c_R$,

$$\Phi(\tilde{k}^2) = (2\,\tilde{k}^2 - 1)^2 - 4\tilde{k}^2\,\tilde{A}_L\,\tilde{A}_S\,, \tag{11.9.75}$$

which can be transformed, by squaring, to a cubic polynomial in $\tilde{k}^2$,

$$P(\tilde{k}^2) = 16\,(1 - \frac{\mu}{H})\,(\tilde{k}^2)^3 - 8\,(3 - 2\,\frac{\mu}{H})\,(\tilde{k}^2)^2 + 8\;\tilde{k}^2 - 1 = 0\,. \tag{11.9.76}$$

The ratio μ/H can be expressed in terms of the Poisson's ratio ν, namely $\mu/H = (1-2\,\nu)/(2\,(1-\nu))$. Since Poisson's ratio is bounded by -1 and $1/2$, the ratio μ/H decreases from $3/4$ to 0. Therefore, by Descartes's rule of signs, Section 11.9.10, the polynomial has one or three positive roots and no negative root.

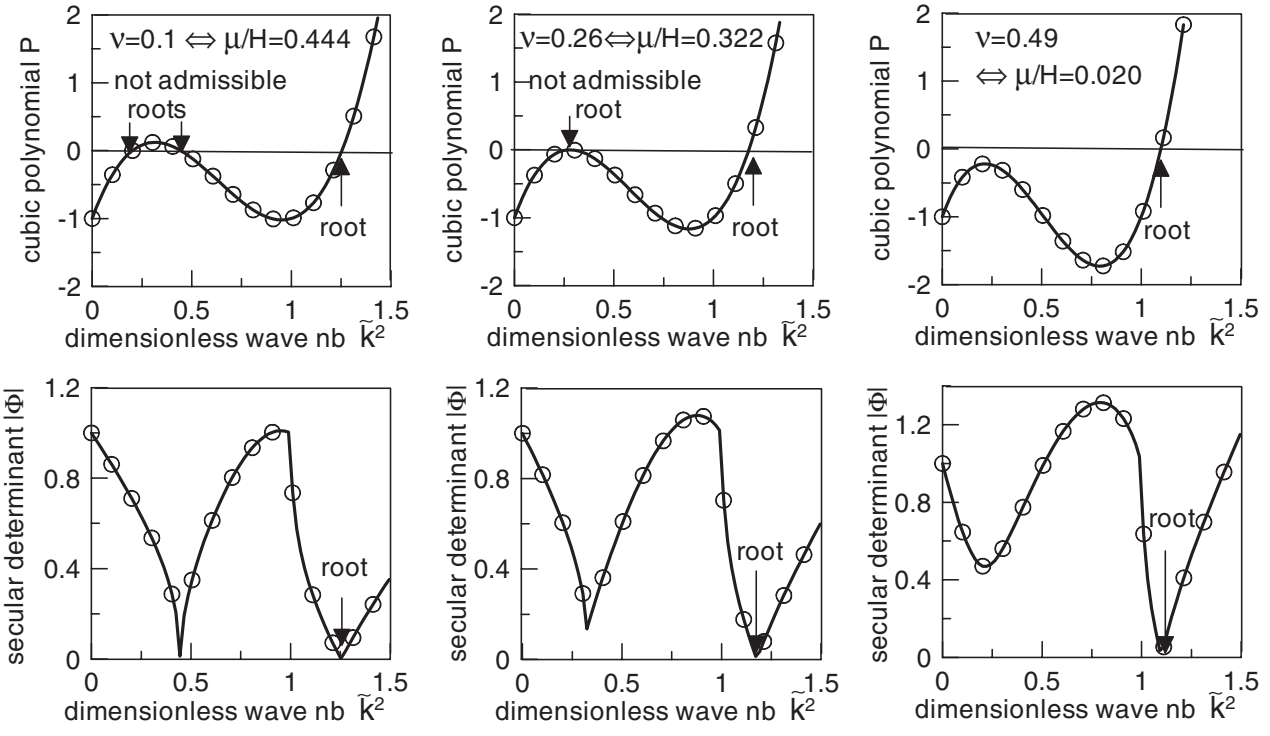


Fig. 11.9.13: Rayleigh waves in an elastic solid. Cubic polynomial P and secular determinant Φ as a function of the square of the dimensionless wave-number $\tilde{k} = c_S/c_R$.

Since $P(0) = P(1) = -1$ and $P(\infty) = \infty$, there exists a real root to $P = 0$ that is larger than 1. This root satisfies the decay conditions and is also a root of the original secular determinant Φ. Therefore, it represents an admissible solution, actually the sole solution, and the associated Rayleigh wave-speed c_R is smaller than the shear wave-speed c_S.

Two other real roots of P exist for $\mu/H \geq 0.322$ but they are smaller than 1 and do not satisfy the decay conditions. Note that the largest of these roots $\tilde{k}'$ is not a root of the secular determinant Φ even if $\Phi(\tilde{k}')$ is quite small for $\nu > 0$. The sole exception is for $\nu = 0$, and then $\tilde{k}' = 1/2$. The two complex conjugate roots of $P = 0$ for $\mu/H < 0.322$ are not roots of the secular determinant either.

While it is easier to obtain the roots of the polynomial equation, the squaring process introduces solutions of the polynomial that are not solutions of the original secular determinant. To help the understanding, the polynomial $P(\tilde{k}^2)$ and the original secular determinant $\Phi(\tilde{k}^2)$ have been plotted in Fig. 11.9.13 for three values of Poisson's ratio.

There are special cases for which the roots can be obtained easily. First, for $\mu/H = 1/2$, i.e. $\nu = 0$, the roots $\tilde{k}^2$ are $1/2$ and $(3 \pm \sqrt{5})/4$, yielding the sole admissible solution $c_R/c_S = \sqrt{3 - \sqrt{5}} \simeq 0.874$. For $\nu = 1/4$, the roots $\tilde{k}^2$ are $1/4$ and $3/4\,(1 \pm 1/\sqrt{3})$, yielding the sole solution $c_R/c_S = \sqrt{2 - 2/\sqrt{3}} \simeq 0.919$.

Since $P(0) = P(1) = -1$ and $P(\infty) \to +\infty$, there always exists a real and positive root $\tilde{k}^2$ of the cubic polynomial (11.9.41), which is larger than 1. This root satisfies the decay conditions in depth (11.9.38), and it is also a root of the original secular equation (11.9.40). Since $\tilde{k} = c_S/c_R$, it follows that the associated Rayleigh wave-speed c_R is smaller than the shear wave-speed c_S.

The discriminant of the cubic polynomial can be shown to be positive if $\mu/H < 0.322$, equivalent to $\nu > 0.263$. Then the above root is the single real root[11.5].

If $\mu/H \geq 0.322$, the two other real roots of the cubic polynomial are both either smaller or larger than 1 because $P(1) = -1$ and $P(\infty) \to +\infty$. The product of the roots is equal to $1/16\,(1-\mu/H)$, which is bounded above by $1/4$. Therefore, the two additional roots fall in the interval $]0,1[$, that is, the decay condition $\tilde{k}^2 - 1 > 0$ is not satisfied.

It remains to consider the two complex roots for $\mu/H < 0.322$. In fact, they are not roots of the secular determinant as indicated in Section 11.9.9 below.

The motion of particles near the surface and the strains and stresses are described in textbooks. The horizontal and vertical displacements are 90° out of phase. Close to the surface, the motion is retrograde, counterclockwise for a wave traveling to the right, and the vertical displacement is about 1.5 larger than the horizontal displacement. The horizontal displacement changes sign at a depth about 0.2 wave-length c_R/ω. The motion penetrates slightly more than one wave-length below the surface.

11.9.9 The principle of the argument

The principle of the argument gives the number of roots minus the number of poles (multiplicity included) of a function of the complex variable over a domain defined by a closed contour and inside which it is single-valued. It has been used to determine the number of roots of the Rayleigh secular determinant by, e.g., Achenbach [1975] and Freund [1990], accounting of the fact that the latter has no pole.

The wave-number $\tilde{k} = c_S/c$ may also be viewed as a scaled slowness s/s_S, the slowness s being the reciprocal of wave-speed c. The secular determinant (11.9.75) may be recast in the explicit format,

$$R(\tilde{k}) = (2\,\tilde{k}^2 - 1)^2 - 4\,\tilde{k}^2\,\sqrt{\tilde{k}^2 - 1}\sqrt{\tilde{k}^2 - \tilde{k}_L^2}\,, \tag{11.9.77}$$

or equivalently

$$R(\tilde{k}) = (2\,\tilde{k}^2 - 1)^2 + 4\,\tilde{k}^2\,\sqrt{1 - \tilde{k}^2}\,\sqrt{\tilde{k}_L^2 - \tilde{k}^2}\,, \tag{11.9.78}$$

with $\tilde{k}_L = c_S/c_L = s_L/s_S = \sqrt{1-2\,\nu}/\sqrt{2-2\,\nu}$. The square-roots involve four branch points $\pm\tilde{k}_L$ and $\pm\tilde{k}_S$. The branch cuts may in a first step be chosen to run on the real axis from the branch points to $\pm\infty$, say $]\tilde{k}_S, +\infty[$ and $]-\infty, -\tilde{k}_S[$ on one hand and $]\tilde{k}_L, +\infty[$ and $]-\infty, -\tilde{k}_L[$ on the other hand. However, since these two branch cuts overlap, the branch cuts of the secular determinant may be restricted to contours around the pairs $(\tilde{k}_L, 1)$ and $(-1, -\tilde{k}_L)$.

The square-root,

$$\sqrt{1-\tilde{k}^2} = \sqrt{|\tilde{k} - (-1)|}\,\sqrt{|\tilde{k} - 1|}\;\exp\big(\frac{i}{2}\,(\theta_a + \theta_b) - i\,\frac{\pi}{2}\big)\,, \tag{11.9.79}$$

is defined in terms of the angles $\theta_a = \text{angle}(\text{real axis}, \tilde{k} - 1)$ and $\theta_b = \text{angle}\big(\text{real axis}, \tilde{k} - (-1)\big)$. Therefore the square-root has positive real parts for points on the real segment from -1 to $+1$ where the angles θ_a and θ_b are equal to π and 0 respectively. A similar determination is used for the second square-root involved in the Rayleigh determinant (11.9.78). Therefore there are no roots of (11.9.78) between $\tilde{k}_L$ and 1 nor between -1 and $-\tilde{k}_L$. The number of roots in the remaining of the complex plane is obtained by using the principle of the argument on a closed contour C that respects the cuts and that includes an outer circle whose radius may be made arbitrary large, Fig. 11.9.14. Fig. 11.9.15 displays the evolution of the integral $(2\,i\,\pi)^{-1}\int_C dR(\tilde{k})/R$ along this contour. The end value is 2, indicating two roots. The latter are real and belong to the interval $]1,\infty$ and $]-\infty,-1[$ since $R(1) > 0$ and $R(\pm\infty) < 0$: indeed, at large $|\tilde{k}|$,

$$R(\tilde{k}) \simeq -2\,\tilde{k}^2\,(1 - \tilde{k}_L^2)\,. \tag{11.9.80}$$

11.9.10 Descartes's rule of signs

Descartes's rule of signs is a useful tool that provides information on the number of real roots of a real polynomial which is arranged in increasing, or decreasing, power. It states that the number p of positive roots is less than or equal to the number v of sign changes in the coefficients, ignoring the powers that do not appear. Moreover, the

[11.5] The discriminant of the cubic equation $x^3 + a\,x^2 + b\,x + c = 0$ with real coefficients is equal to $R^2 - Q^3$ with $Q = (a^2 - 3\,b)/9$ and $R = (2\,a^3 - 9\,a\,b + 27\,c)/54$. The equation has three real roots if the discriminant is negative.

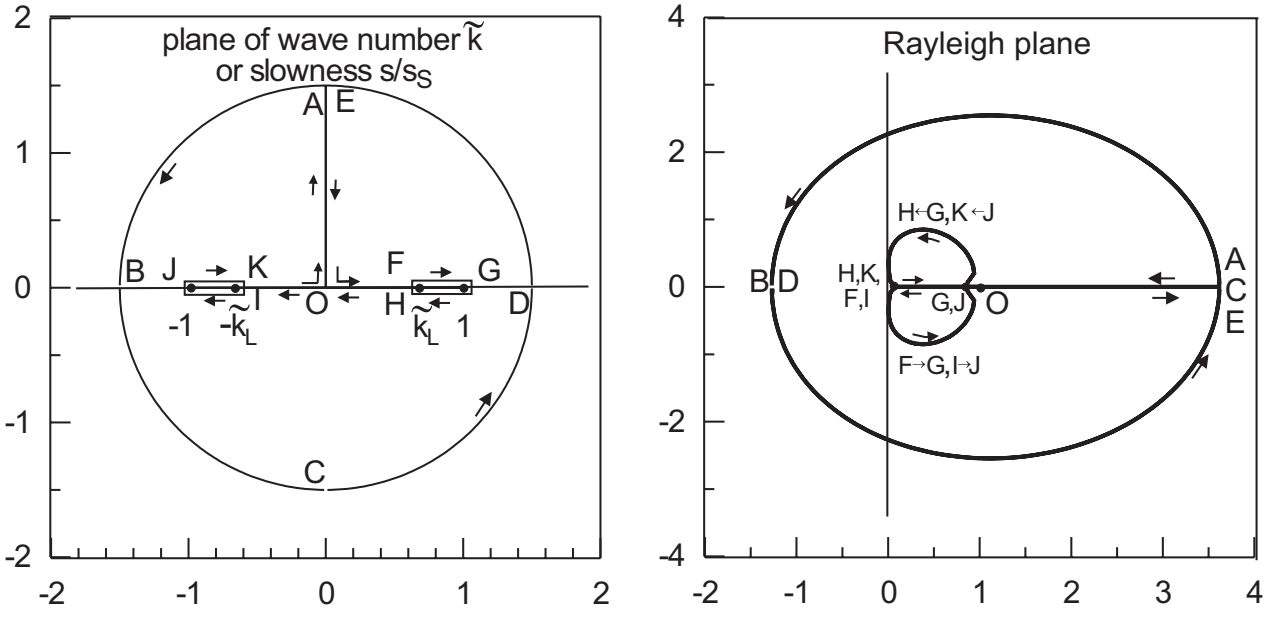

Fig. 11.9.14: The number of roots of the Rayleigh secular determinant in the complex plane is obtained through the principle of the argument by counting the number of tours (here equal to 2) about the origin of the Rayleigh plane associated with a closed path in the slowness plane that respects the branch cuts. Isotropic elastic solid with Poisson's ratio $\nu = 0.1$. A small ν implies a smaller outer contour in the R-plane, and therefore lends itself more easily to scrutinize the details of the path.

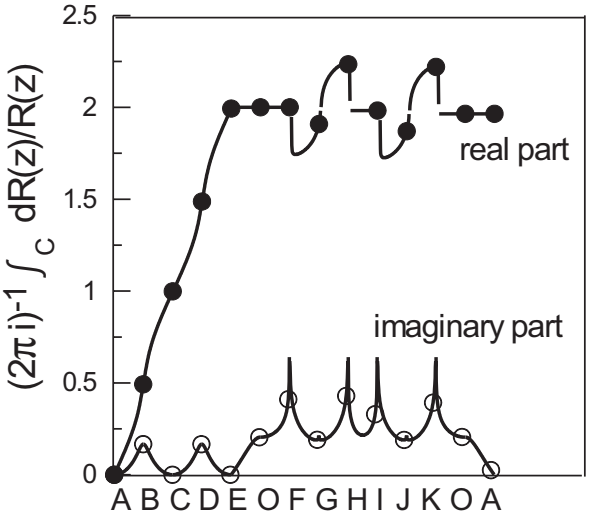

Fig. 11.9.15: Evolution along the closed path in the complex slowness plane displayed in Fig. 11.9.14 of the integral associated with the principle of the argument that yields the number of roots of the Rayleigh determinant, equal to 2 here.

difference $v - p$ is a non negative even integer, namely $v - p = 0, 2, 4 \cdots$. The multiplicity of the root is included: $f(x) = x^2 - 2\,x + 1 = 0$ has $v = 2$, hence p equal 0 or 2. The rule can be applied to the polynomial $P(x)$ to get information on the positive roots of $P(x)$, and to the polynomial $P(-x)$ to get information on the negative roots of $P(x)$.

11.10 First order waves in saturated porous media

Key features of first order waves in saturated porous media are illustrated via the propagation, at constant speed $c > 0$, of a plane crack along a rectilinear path in an infinite medium. Besides a fixed cartesian system $(0, X_1, X_2, X_3)$, a second cartesian coordinate system $(0, x_1, x_2, x_3)$ centered at the crack tip and moving with it in the X_1 direction is used, with the out-of-plane x_3-axis along the straight crack front. Under steady state crack propagation, an arbitrary scalar field $\varphi = \varphi(X_1, X_2, t)$ depends on time t through the x-coordinates, and, although an abuse of notation, it will be denoted by $\varphi = \varphi(x_1 = X_1 - c\,t, x_2 = X_2)$. Its first and second material time derivatives are defined by the relations $d\varphi/dt = -c\,\partial\varphi/\partial x_1$, and $d^2\varphi/dt^2 = c^2\,\partial^2\varphi/\partial^2 x_1$.

The regime of the flow equations is governed by the relative position of the crack tip speed c with respect to the three body wave-speeds of the porous medium c_1, c_2 and c_3 based on the classification shown in Table 11.5.1. Given that the motion considered here is a steady state motion, the issue deserves to be considered in this context.

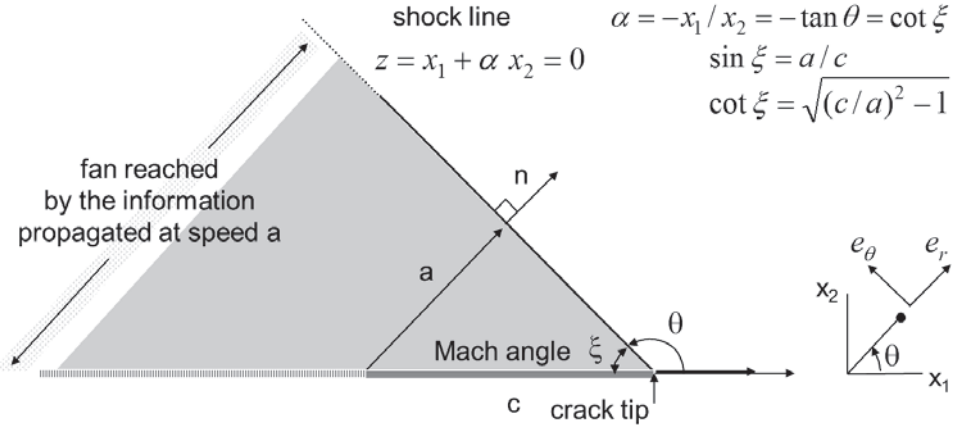

Fig. 11.10.1: A crack tip propagates in the saturated porous medium at speed c to the right along the axis x_1, while the mechanical information propagates at speed a. The problem being symmetric with respect to the crack line, only the upper half-plane is displayed. A first order discontinuity exists if $c > a$. It is referred to as shock line (curve) or Mach line. The direction of the discontinuity is defined by the Mach angle ξ such that $\sin\xi = a/c$. The first order discontinuity is characterized by the fact that only a fan in the wake of the crack tip, between the crack line and the Mach line, is reached by the shear, or longitudinal, information propagated by the moving crack tip.

In the intersonic range, the material wave-speed a can be the second longitudinal wave-speed c_2 or the shear wave-speed c_3. Thus there may be two discontinuity lines, as indeed displayed in the region i) in Fig. 11.10.4.

Emphasis is on intersonic propagation of the crack tip, and on the type and on the properties of the first order discontinuities that may propagate through the medium across the characteristic lines, as sketched in Fig. 11.10.1. The derivations of the elements reported below are detailed in Radi and Loret [2007], [2008].

11.10.1 Regime of the field equations

Along a standard terminology, a partial differential equation, involving second order derivatives in both time and space, e.g., $\partial^2\phi/\partial x_1^2 + \partial^2\phi/\partial x_2^2 - a^{-2}\,\partial^2\phi/\partial t^2 = 0$, is said to be hyperbolic if there exist real characteristics which allow for the mechanical information to propagate at finite speed, e.g., for non zero real a. Otherwise, for a purely imaginary, it is said elliptic. Here, the partial time derivative is given by $\partial\phi/\partial t = -c\,\partial\phi/\partial x_1$, so that the above equation becomes $(1 - c^2/a^2)\,\partial^2\phi/\partial x_1^2 + \partial^2\phi/\partial x_2^2 = 0$.

Thus according to the above terminology, the subsonic propagation of the crack tip $c < a$ corresponds to an elliptic equation. In the intersonic regions, the material wave-speed a can be either the second longitudinal wave-speed c_2 or the shear wave-speed c_3. A first order discontinuity exists if $c > a$. Its trace is referred to as shock line (curve) or Mach line. Its direction is defined by the Mach angle ξ or by the polar angle θ,

$$\sin\xi_j = \frac{c_j}{c}, \quad \cot\xi_j = \sqrt{\Big(\frac{c}{c_j}\Big)^2 - 1}, \quad \theta_j = \pi - \xi_i, \quad j \in [1,3]\,. \tag{11.10.1}$$

The displacement field derives from the potentials ϕ which obey second order partial differential equations: a real characteristic for ϕ in the hyperbolic regime bears a first order discontinuity, i.e. a discontinuity of the displacement gradient, and an accompanying velocity discontinuity. According to Hadamard's compatibility relations, there exists a vector $\boldsymbol{\eta}$ such that $[\![\nabla \mathbf{u}]\!] = \boldsymbol{\eta} \otimes \mathbf{n}$, $[\![\mathbf{v}]\!] = -a\,\boldsymbol{\eta}$, with $\mathbf{n}$ the unit normal to the wave front. The displacement gradient being discontinuous, the poroelastic strain and stress result discontinuous as well.

For poroelastic media under plane deformation, there are four equations of balance of momentum, namely two for each phase, as described in Section 11.7. Equivalently, the field equations involve four equations for four potentials. There exist four body wave-speeds, accounting for the multiplicity of degree two of the shear wave. The solution will be expressed in terms of the three complex variables $z_j = x_1 + \Omega_j\, x_2$, $j \in [1,3]$. The Ω's, with moduli α, can be real or imaginary numbers. They are (not unambiguously) defined by their squares,

$$\Omega_j^2 = \left(\frac{c}{c_j}\right)^2 - 1, \quad \alpha_j = |\Omega_j|, \quad j \in [1,3]\,. \tag{11.10.2}$$

The regime of the field equations thus depends on the region of the plane (porosity n^{w}, crack tip speed c), as shown in Fig. 11.5.2.

- region (i): the equation associated with the fastest longitudinal wave is elliptic, while the three others are hyperbolic, and $z_1 = x_1 + i\,\alpha_1\, x_2$, $z_2 = x_1 \pm \alpha_2\, x_2$, $z_3 = x_1 \pm \alpha_3\, x_2$;
- region (ii): the two equations associated with the longitudinal waves are elliptic while those two associated with the shear waves are hyperbolic and $z_1 = x_1 + i\,\alpha_1\, x_2$, $z_2 = x_1 + i\,\alpha_2\, x_2$, $z_3 = x_1 \pm \alpha_3\, x_2$;
- region (iii): the equation associated with the second longitudinal wave is hyperbolic while the three others are elliptic and $z_1 = x_1 \pm i\,\alpha_1\, x_2$, $z_2 = x_1 \pm \alpha_2\, x_2$, $z_3 = x_1 + i\,\alpha_3\, x_2$;
- subsonic region: the four equations are elliptic, and $z_j = x_1 + i\,\alpha_j\, x_2$, $j \in [1,3]$.

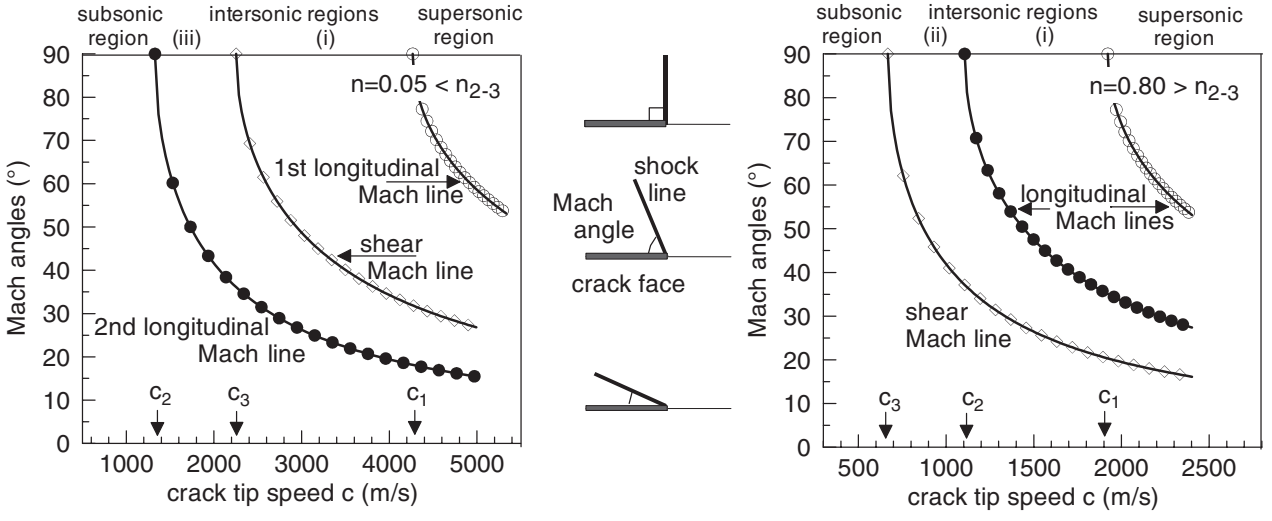

Fig. 11.10.2: Variations of Mach angles with the crack tip speed for two porosities. In region (i), the Mach angle defining the first order shear discontinuity is smaller or larger than the Mach angle of the first order longitudinal discontinuity depending on the position of the porosity with respect to $n_{2-3} \simeq 0.415$, indicated in Fig. 11.5.2, where the second longitudinal wave-speed and the shear wave-speed are equal. Reprinted with permission from Radi and Loret [2007].

In the present context, a first order discontinuity corresponds to the existence of a ray emanating from the crack tip that limits the zone of extension of the mechanical information propagated by the wave, as sketched in Fig. 11.10.1. Fig. 11.10.2 displays the variations of Mach angles with the crack tip speed for two porosities. The closer the crack tip speed to the critical wave-speed, i.e., c_3 for the shear Mach line, c_2 for the longitudinal Mach line, the closer the Mach angle is to 90°. Conversely, the farther the crack tip speed from the critical wave-speed, the more oblique is the Mach line.

11.10.2 Form of the solution

The analysis follows the initial steps adopted in Section 11.9.1 for surface waves. The displacements in the solid and fluid phases are sought in terms of potentials which are obtained as functions of the three complex variables

$z_j = x_1 + \Omega_j\, x_2,\ j \in [1,3]$. Satisfaction of the field equations gives rise to eigenvalue problems similar to those described in Section 11.9.4 that delivers the Ω's shown in (11.10.2). The counterpart of the complete formal solution of Section 11.9.2 may be expressed in terms of three complex functions $F_j(z_j)$ of the complex variables z_j,

$$\begin{aligned}
&\phi_{\rm s}(x_1,x_2) = \mathrm{Re}\, F_1(z_1) + \mathrm{Re}\, F_2(z_2),\\
&\phi_{\rm w}(x_1,x_2) = c_{\rm ms}^{-2}\left((c_1^2-c_{\rm s}^2)\,\mathrm{Re}\, F_1(z_1) - (c_{\rm s}^2-c_2^2)\,\mathrm{Re}\, F_2(z_2)\right),\\
&\psi_{\rm s}(x_1,x_2) = \mathrm{Im}\, F_3(z_3), \quad \psi_{\rm w}(x_1,x_2) = 0\,.
\end{aligned} \tag{11.10.3}$$

For example, in the intersonic region (i), z_1 is complex while z_2 and z_3 are real, so that the functions $\mathrm{Re}\, F_2(z_2)$ and $\mathrm{Im}\, F_3(z_3)$ may be substituted by the respective real functions $f(z_2)$ and $g(z_3)$. The components of the displacements in the solid and fluid phases result from (11.7.4),

$$\begin{aligned}
u_{\rm s1} &= \mathrm{Re}\, F_1'(z_1) + f'(z_2) + \alpha_3\, g'(z_3),\\
u_{\rm s2} &= -\alpha_1\, \mathrm{Im}\, F_1'(z_1) + \alpha_2\, f'(z_2) - g'(z_3)\,,
\end{aligned} \tag{11.10.4}$$

and

$$\begin{aligned}
u_{\rm w1} &= c_{\rm ms}^{-2}\left((c_1^2-c_{\rm s}^2)\,\mathrm{Re}\, F_1'(z_1) - (c_{\rm s}^2-c_2^2)\, f'(z_2)\right),\\
u_{\rm w2} &= -c_{\rm ms}^{-2}\big(\alpha_1\,(c_1^2-c_{\rm s}^2)\,\mathrm{Im}\, F_1'(z_1) + \alpha_2\,(c_{\rm s}^2-c_2^2) f'(z_2)\big)\,,
\end{aligned} \tag{11.10.5}$$

and similarly for the apparent solid stresses and pore pressure using (11.7.6),

$$\begin{aligned}
\mu^{-1}\,\sigma_{11}^{\rm s} &= (1+\alpha_3^2+2\,\alpha_1^2)\,\mathrm{Re}\, F_1''(z_1) + (1+\alpha_3^2-2\,\alpha_2^2)\, f''(z_2) + 2\,\alpha_3\, g''(z_3),\\
\mu^{-1}\,\sigma_{22}^{\rm s} &= (\alpha_3^2-1)\,(\mathrm{Re}\, F_1''(z_1) + f''(z_2)) - 2\,\alpha_3\, g''(z_3),\\
\mu^{-1}\,\sigma_{12}^{\rm s} &= -2\,\alpha_1\,\mathrm{Im}\, F_1''(z_1) + 2\,\alpha_2\, f''(z_2) + (\alpha_3^2-1)\, g''(z_3),\\
-\mu^{-1}\, n^{\rm w}\, p_{\rm w} &= (1+\alpha_3^2)\, c_{\rm mw}^{-2}\left((c_1^2-c_{\rm s}^2)\,\mathrm{Re}\, F_1''(z_1) - (c_{\rm s}^2-c_2^2)\, f''(z_2)\right).
\end{aligned} \tag{11.10.6}$$

The calculations of the strains and velocities are facilitated by the formulas below that express the spatial derivatives of the real and imaginary parts of a complex function $F(z)$ of the complex variable $z = x_1 + i\,\alpha\, x_2$ in terms of its derivative $F' \equiv dF/dz$, namely

$$\begin{aligned}
&\frac{\partial\,\mathrm{Re}\, F}{\partial x_1} = \mathrm{Re}\, F'; \quad \frac{\partial\,\mathrm{Re}\, F}{\partial x_2} = -\alpha\,\mathrm{Im}\, F';\\
&\frac{\partial^2 \mathrm{Re}\, F}{\partial x_1^2} = \mathrm{Re}\, F''; \quad \frac{\partial^2 \mathrm{Re}\, F}{\partial x_1 \partial x_2} = -\alpha\,\mathrm{Im}\, F''; \quad \frac{\partial^2 \mathrm{Re}\, F}{\partial x_2^2} = -\alpha^2\,\mathrm{Re}\, F'',
\end{aligned} \tag{11.10.7}$$

and

$$\begin{aligned}
&\frac{\partial\,\mathrm{Im}\, F}{\partial x_1} = \mathrm{Im}\, F'; \quad \frac{\partial\,\mathrm{Im}\, F}{\partial x_2} = \alpha\,\mathrm{Re}\, F';\\
&\frac{\partial^2 \mathrm{Im}\, F}{\partial x_1^2} = \mathrm{Im}\, F''; \quad \frac{\partial^2 \mathrm{Im}\, F}{\partial x_1 \partial x_2} = \alpha\,\mathrm{Re}\, F''; \quad \frac{\partial^2 \mathrm{Im}\, F}{\partial x_2^2} = -\alpha^2\,\mathrm{Im}\, F''.
\end{aligned} \tag{11.10.8}$$

The actual expressions of the three primary unknown functions deduce from the boundary conditions on the crack line. The latter naturally delineate points ahead of the crack and points behind the crack tip. These conditions involve the gradient along the propagation direction of some displacement components, the total normal stress, the shear stress and either the pore pressure for a permeable crack surface or the fluid flux for an impervious crack surface. In addition, Mode I and Mode II crack propagations are distinguished by distinct symmetry conditions with respect to the crack line. In the context of the functions of a complex variable, these mixed boundary conditions give rise to inhomogeneous Riemann-Hilbert problems, whose solutions express as integrals over the cohesive zone of singular functions with a characteristic singularity exponent γ. The existence of a cohesive zone in the vicinity of the crack tip allows the energy release to be positive, an energetic requirement.

While the intersonic propagation of a non cohesive crack is energetically admissible only for some special speeds of the crack tip, much like for linear elastic solids, it is still worth interest, as it is likely to display limit features

of a cohesive crack as the cohesive length tends to zero, Radi and Loret [2007] [2008]. Then, in the vicinity of the crack tip, the dissipative terms associated with seepage provide higher order contributions with respect to the stress divergence and acceleration. The basic primary functions are found to be singular, with a singularity exponent $\gamma \in [0, 1/2]$ that depends on the body wave-speeds and crack tip speed, namely

$$F_1''(z_1) \simeq \frac{1}{i\, z_1^{\gamma}}, \quad f''(z_2) \simeq \frac{\mathcal{H}(-z_2)}{|z_2|^{\gamma}}, \quad g''(z_3) \simeq \frac{\mathcal{H}(-z_3)}{|z_3|^{\gamma}}\,, \tag{11.10.9}$$

where $\mathcal{H}$ denotes the unit step function. Due to symmetry, it will be sufficient to consider only the upper half-plane $x_2 > 0$. Given that the Ω's are defined by their squares, there are a priori two variables $z_j = x_1 \pm \Omega_j\, x_2$ for each of the three Ω_j's. However, in the upper complex plane $x_2 > 0$, the complex variable is definitely $z_1 = x_1 + i\,\alpha_1\, x_2$. On the other hand, the segments $z_2 = x_1 + \alpha_1\, x_2 = 0$ and $z_2 = x_1 - \alpha_1\, x_2 = 0$ both involve points of the upper half-plane. The lines $z_2 = x_1 + \alpha_2\, x_2 = 0$ and $z_3 = x_1 + \alpha_3\, x_2 = 0$ define two waves that propagate to the left of the crack tip in the upper half-plane, as sketched in Fig. 11.10.1. The lines $z_2 = x_1 - \alpha_2\, x_2$ and $z_3 = x_1 - \alpha_3\, x_2$, which correspond to two waves travelling to the right of the crack tip in the upper half-plane, are excluded because the material particles ahead of the crack tip have not yet felt the disturbance caused by the crack propagation.

11.10.3 Discontinuities across the shear Mach line in regions (i) and (ii)

A priori both a shear and a longitudinal, or dilatational, Mach lines may exist in the region (i), while the sole shear Mach line may take place in region (ii), and the sole longitudinal Mach line in region (iii).

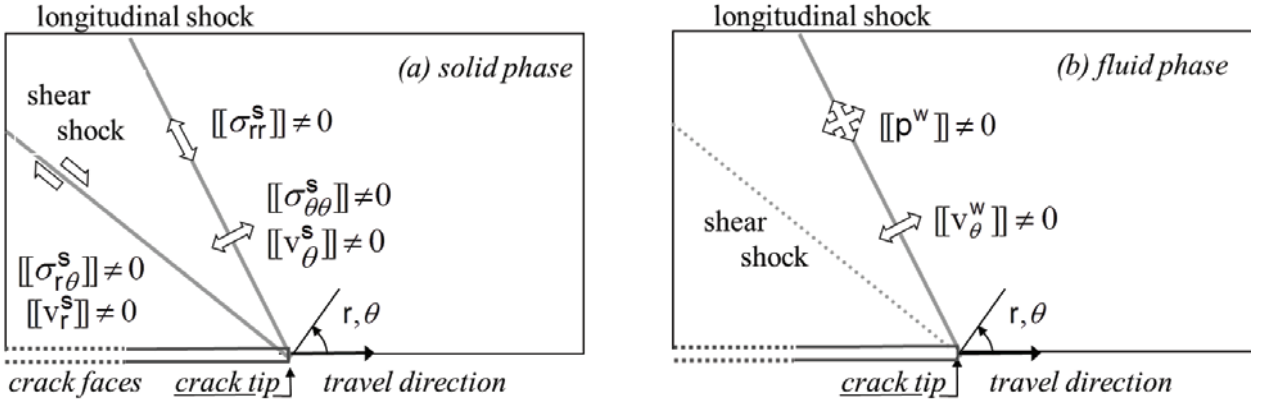

Fig. 11.10.3: Components of the stress and velocity which undergo a discontinuity across the Mach lines for a non cohesive crack. The Mach rays emanating from the crack tip are directed towards the rear, with respect to the direction of propagation of the crack. The entities which undergo a non zero first order discontinuity across the Mach lines depend on the nature, shear or longitudinal, of the discontinuity. A first order shear discontinuity affects only the solid phase, while a first order longitudinal discontinuity affects both the solid and fluid phases. The sketch indicates a longitudinal Mach angle larger than the shear Mach angle, and thus corresponds to a porosity larger than n_{2-3} in region (i), as shown in Fig. 11.10.2(b). Reprinted with permission from Radi and Loret [2007].

In these regions, the issue concerns the continuity of the real function $g''(z_3)$ across the ray $z_3 = x_1 + \alpha_3\, x_2 = 0$, with $z_3 = |z_3|$ ahead of the Mach line and $z_3 = |z_3|\, e^{i\pi}$ behind the Mach line. It is instrumental to introduce polar coordinates (r, θ) centered at the crack tip, and to express the stress and velocity in these coordinates. The ray $z_3 = 0$ is defined by the polar angle $\theta_3 = \pi/2 + \arctan \alpha_3$, Figs. 11.10.1 and 11.10.2. Let $[\![g'']\!]$ be the discontinuity of g'' across the Mach line at a current point (r, θ_3) of the Mach line. The contributions of $[\![g'']\!]$ to the stress components, and to the velocity components, e.g., Eqns (11.10.4), (11.10.5) and (11.10.6) in region i), are collected. As expected, the sole shear stress is observed to undergo a discontinuity,

$$[\![\sigma^{\rm s}_{rr}]\!] = 0, \quad [\![\sigma^{\rm s}_{\theta\theta}]\!] = 0, \quad [\![\sigma^{\rm s}_{r\theta}]\!] = \mu\, \frac{c^2}{c_3^2}\, [\![g'']\!], \quad [\![n^{\rm w}\, p_{\rm w}]\!] = 0\,, \tag{11.10.10}$$

and, similarly the sole discontinuous velocity component is the solid radial velocity,

$$[\![v^{\rm s}_r]\!] = \frac{c^2}{c_3}\, [\![g'']\!], \quad [\![v^{\rm s}_\theta]\!] = 0, \qquad [\![v^{\rm w}_r]\!] = 0, \quad [\![v^{\rm w}_\theta]\!] = 0\,. \tag{11.10.11}$$

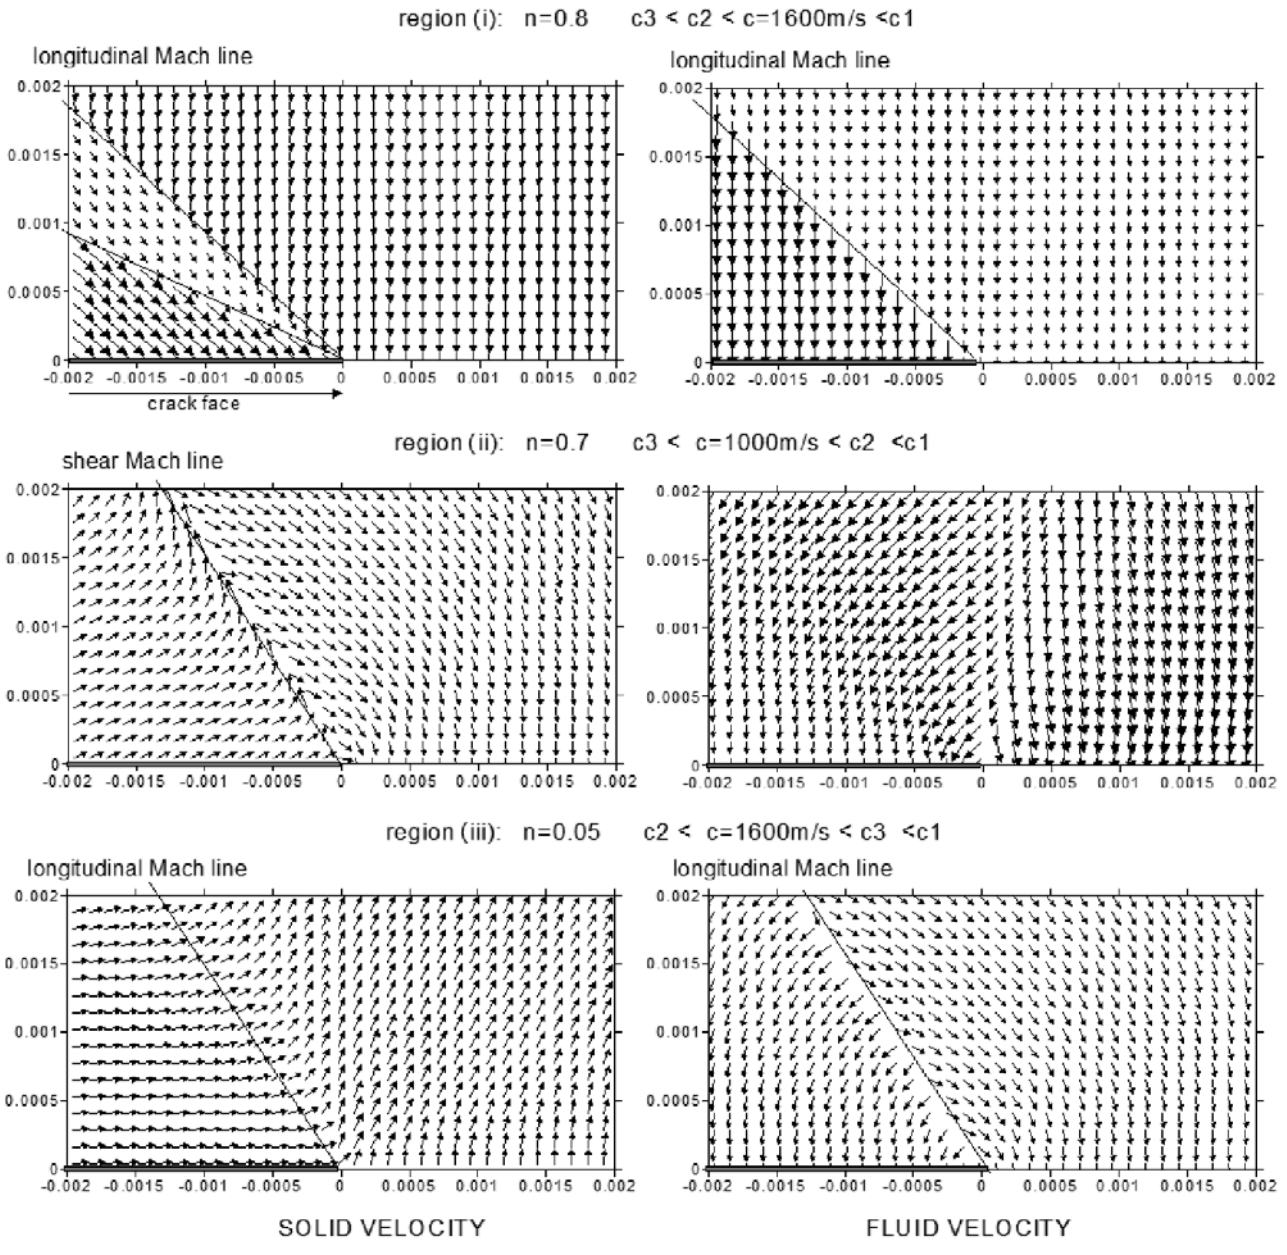

Fig. 11.10.4: Velocity fields for the non cohesive crack under Mode II loading conditions, from Radi and Loret [2007]. The velocity fields have been obtained by analytical integration of singular integrals in the complex plane. For graphical purpose, the velocity is scaled by r^{γ}, with r distance to the crack tip and γ singularity exponent. The size of the arrows pertains to each plot. A first order shear discontinuity gives rise to velocity discontinuities in the solid phase only, while a first order longitudinal discontinuity affects both phases, as indicated in Fig. 11.10.3. In region (i), the crack tip speed is larger than both the shear wave-speed and the 2nd longitudinal wave-speed, so that there are two shock lines. In region (ii), there is only a shear shock and, in region (iii), a longitudinal shock. Reprinted with permission from Radi and Loret [2007].

Since $z_3 = 0$ on the Mach line, the function g'' undergoes an infinite jump for the noncohesive crack according to (11.10.9). Consequently, the stress and velocity fields undergo, across the shear Mach line, an infinite jump that is *parallel* to, and extends all along the Mach line, Fig. 11.10.3. The presence of cohesion in the vicinity of the crack removes the jump, which is in fact smoothed out. The actual smoothing is obviously expected to depend on the properties of the cohesion. Still, it has been observed in Radi and Loret [2007], [2008] to deteriorate considerably for large singularity exponents.

11.10.4 Discontinuities across the longitudinal Mach line in regions (i) and (iii)

In these regions, the concern is the continuity of the real function $f''(z_2)$ across the ray $z_2 = x_1 + \alpha_2\, x_2 = 0$, defined by the polar angle $\theta_2 = \pi/2 + \arctan\alpha_2$. Collecting the contributions of the discontinuity of f'' in the expressions of stress and pore pressure, e.g., Eqn (11.10.6) for region (i), results in

$$[\![\sigma^{\rm s}_{rr}]\!] = (-2\,\frac{c^2}{c_2^2} + \frac{c^2}{c_3^2})\,\mu\,[\![f'']\!], \quad [\![\sigma^{\rm s}_{\theta\theta}]\!] = \mu\,\frac{c^2}{c_3^2}\,[\![f'']\!], \quad [\![\sigma^{\rm s}_{r\theta}]\!] = 0, \quad [\![n^{\rm w}\,p_{\rm w}]\!] = \frac{c_{\rm s}^2 - c_2^2}{c_{\rm mw}^2}\,\frac{c^2}{c_3^2}\,\mu\,[\![f'']\!]\,. \tag{11.10.12}$$

Similarly, the discontinuity of f'', in, e.g., Eqns (11.10.4), (11.10.5) for region (i), yields discontinuities of the solid and fluid velocities, namely

$$[\![v^{\rm s}_r]\!] = 0, \quad [\![v^{\rm s}_\theta]\!] = \frac{c^2}{c_2}\,[\![f'']\!], \qquad [\![v^{\rm w}_r]\!] = 0, \quad [\![v^{\rm w}_\theta]\!] = -\frac{c_{\rm s}^2 - c_2^2}{c_{\rm ms}^2}\,\frac{c^2}{c_2}\,[\![f'']\!]\,. \tag{11.10.13}$$

The function f'' undergoes an infinite jump across the longitudinal Mach line according to (11.10.9), and so do the stress and velocity. The velocity jump is *normal* to the Mach line.

11.10.5 Jumps of strains across first order waves

Consider a first order wave that propagates at speed a relative to the phase $\alpha = {\rm s}, {\rm w}$. The displacement being continuous, the strain jump across the wave front is obtained from the compatibility relation (11.1.9), namely $[\![\nabla \mathbf{u}_\alpha]\!] = -a^{-1}\,[\![\mathbf{v}_\alpha]\!] \otimes \mathbf{n}$. Therefore, in the local polar axes where $\mathbf{n} = -\mathbf{e}_\theta$, $\mathbf{e}_\theta(\theta)$ being the orthoradial vector $(-\sin\theta, \cos\theta)$, as indicated in Fig. 11.10.1, the sole non zero discontinuous components of the strain in phase α write,

$$[\![\epsilon^\alpha_{r\theta}]\!] = \frac{[\![v^\alpha_r]\!]}{2\,a}, \quad [\![\epsilon^\alpha_{\theta\theta}]\!] = \frac{[\![v^\alpha_\theta]\!]}{a}, \quad \alpha = {\rm s},\, {\rm w}\,. \tag{11.10.14}$$

The first order shear discontinuity is thus clearly isochoric. Across the first order longitudinal discontinuity on the other hand, the solid and fluid phases undergo volume changes that are of opposite signs, but do not compensate.

In fact, if the solid and fluid constituents were incompressible, the volume changes in the body would satisfy the constraint $n^{\rm s}\,{\rm tr}\,\boldsymbol{\epsilon}^{\rm s} + n^{\rm w}\,{\rm tr}\,\boldsymbol{\epsilon}^{\rm w} = 0$, and thus the jumps of the normal velocities across the discontinuity would be such that $n^{\rm s}\,[\![v^{\rm s}_\theta]\!] + n^{\rm w}\,[\![v^{\rm w}_\theta]\!] = 0$. That this relation is indeed satisfied by the jumps (11.10.13) may easily be checked. Indeed, as detailed in Sections (7.3.6.5) and (7.3.6.7), incompressibility of the two constituents implies the two moduli $\lambda^{\rm sw}$ and $\lambda^{\rm ww}$ to become infinite but their ratio $\lambda^{\rm sw}/\lambda^{\rm ww}$ tends to $n^{\rm s}/n^{\rm w}$ and the drained Lamé modulus $\lambda = \lambda^{\rm ss} - (\lambda^{\rm sw})^2/\lambda^{\rm ww}$ remains finite. Thus, the ratio $c_{\rm s}^2/c_{\rm ms}^2$ tends to $n^{\rm s}/n^{\rm w}$, as expected.

11.10.6 Balances of momentum across first order waves

For the first order shear discontinuity that propagates at speed c_3, the stress and velocity discontinuities (11.10.10) and (11.10.11) can be checked to satisfy the generic balance of momentum (11.1.56) that applies across a first order wave, namely $[\![\boldsymbol{\sigma}^\alpha]\!]\cdot\mathbf{n} + (\rho^\alpha\,a)\,[\![\mathbf{v}_\alpha]\!] = \mathbf{0}$, for $\alpha = {\rm s}, {\rm w}$, and with $a = c_3$ and $\mathbf{n}$ equal to $-\mathbf{e}_\theta(\theta_3)$.

For the first order longitudinal discontinuity that propagates at speed c_2, the relation (11.1.56) is satisfied as well by the stress and velocity discontinuities (11.10.12) and (11.10.13), with $a = c_2$ and $\mathbf{n} = -\mathbf{e}_\theta(\theta_2)$.

Section 7.3.2 indicates the general form of the momentum supplies. The momentum supply $\hat{\boldsymbol{\pi}}^\alpha$ to phase α does not contribute to the jump of the balance of momentum as long as it is finite. Still, such is not the case here, but the field analysis reported by Radi and Loret [2007], [2008] applies close to the crack tip and the dissipative terms can be neglected from the outset, Loret and Radi [2001].

Velocity fields, associated with a crack steadily propagating at speed c, are displayed in Figs. 11.10.4, at a certain point $(n^{\rm w}, c)$ of the plane (porosity, propagation speed) of each of the three intersonic regions.

Exercises on Chapter 11

Exercise 11.1 LU factorization

1. Consider the symmetric block matrix,

$$\begin{bmatrix} \mathbf{A} & \mathbf{a} \\ \mathbf{a}^{\mathrm{T}} & a \end{bmatrix}, \tag{11.E.1}$$

where the individual components have the following respective sizes, namely, matrix $\mathbf{A}:\ n\times n$, vector $\mathbf{a}:\ n$ and $a\neq 0$ a scalar. Let

$$\mathbf{A}^{*} = \mathbf{A} - \frac{1}{a}\,\mathbf{a}\,\mathbf{a}^{\mathrm{T}}. \tag{11.E.2}$$

be the Schur complement of a. Check that the block matrix admits the LU factorization,

$$\begin{bmatrix} \mathbf{A}_{[n,n]} & \mathbf{a}_{[n,1]} \\ \mathbf{a}^{\mathrm{T}}_{[1,n]} & a \end{bmatrix} = \begin{bmatrix} \mathbf{I}_{[n,n]} & \dfrac{\mathbf{a}}{a} \\ \mathbf{0} & 1 \end{bmatrix} \begin{bmatrix} \mathbf{A}^{*}_{[n,n]} & \mathbf{0}_{[n,1]} \\ \mathbf{a}^{\mathrm{T}} & a \end{bmatrix}. \tag{11.E.3}$$

The sizes of some elements are displayed to ease the reading.

2. Consider the symmetric block matrix,

$$\begin{bmatrix} \mathbf{A} & \mathbf{a} & \mathbf{b} \\ \mathbf{a}^{\mathrm{T}} & a & b \\ \mathbf{b}^{\mathrm{T}} & b & c \end{bmatrix}, \tag{11.E.4}$$

where the individual components have the following respective sizes, namely, matrix $\mathbf{A}:\ n\times n$, vector $\mathbf{a}:\ n$, vector $\mathbf{b}:\ n$, and a, b and c are scalars. Let

$$\Delta = a\,c - b^{2}, \quad \mathbf{A}^{*} = \mathbf{A} - \frac{1}{\Delta}\left(c\,\mathbf{a}\,\mathbf{a}^{\mathrm{T}} + a\,\mathbf{b}\,\mathbf{b}^{\mathrm{T}} - b\,(\mathbf{a}\,\mathbf{b}^{\mathrm{T}} + \mathbf{b}\,\mathbf{a}^{\mathrm{T}})\right), \tag{11.E.5}$$

If $c\neq 0$ and $\Delta\neq 0$, then check that the block matrix admits the LU factorization,

$$\begin{bmatrix} \mathbf{A}_{[n,n]} & \mathbf{a}_{[n,1]} & \mathbf{b}_{[n,1]} \\ \mathbf{a}^{\mathrm{T}}_{[1,n]} & a & b \\ \mathbf{b}^{\mathrm{T}}_{[1,n]} & b & c \end{bmatrix} = \begin{bmatrix} \mathbf{I}_{[n,n]} & \dfrac{c}{\Delta}\mathbf{a} - \dfrac{b}{\Delta}\mathbf{b} & \dfrac{\mathbf{b}}{c} \\ \mathbf{0} & 1 & \dfrac{b}{c} \\ \mathbf{0} & 0 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{A}^{*}_{[n,n]} & \mathbf{0}_{[n,1]} & \mathbf{0}_{[n,1]} \\ \mathbf{a}^{\mathrm{T}} - \dfrac{b}{c}\mathbf{b}^{\mathrm{T}} & \dfrac{\Delta}{c} & 0 \\ \mathbf{b}^{\mathrm{T}} & b & c \end{bmatrix}. \tag{11.E.6}$$

Exercise 11.2 Strong ellipticity of the linear elastic *transverse isotropic* matrix

Using the elastic matrix (5.2.51), show that the condition for strong ellipticity (6.2.16) is equivalent to, Payton [1983],

$$c_{11}>0, \quad c_{11}>c_{12}, \quad c_{33}>0, \quad c_{44}>0, \quad \sqrt{c_{11}\,c_{33}}+c_{44}>|c_{13}+c_{44}|\,. \tag{11.E.7}$$

Exercise 11.3 Spectral analysis of the material defined by a fabric anisotropy in Section 5.2.11

Calculate the wave-speeds c and associated propagation modes $\boldsymbol{\eta}$ of the material defined by a fabric anisotropy.

Hint: use Eqns (11.2.25) or (11.2.31).

Exercise 11.4 Extended generalized eigenvalue problem

Consider the generalized eigenvalue problem $(\mathbf{A}-\lambda\,\mathbf{B})\cdot\mathbf{e}^{R}=\mathbf{0}$ where $\mathbf{A}$ and $\mathbf{B}$ are 3×3 matrices, and $\mathbf{e}^{R}$ is the single right eigenvector associated with the eigenvalue λ. The associated left eigenvector, assumed to be unique, is denoted by $\mathbf{e}^{L}$. Now let $\mathbf{C}$ be another arbitrary 3×3 matrix. Find a way to estimate the ratio $(\mathbf{e}^{L}\cdot\mathbf{C}\cdot\mathbf{e}^{R})/(\mathbf{e}^{L}\cdot\mathbf{B}\cdot\mathbf{e}^{R})$.

Answer: the following procedure has been introduced by Stoer and Bulirsch [1980]. Consider the *extended* generalized eigenvalue problem:

$$\big(\mathbf{A}+\varphi\,\mathbf{C}-\lambda(\varphi)\,\mathbf{B}\big)\cdot\mathbf{e}^{R}(\varphi)=\mathbf{0}\,. \tag{11.E.8}$$

For φ a sufficiently small real number, the eigenvalue $\lambda(\varphi)$ is an analytic function of φ, Stoer and Bulirsch [1980], p. 389. Scalar multiplication of (11.E.8) by the left eigenvector $\mathbf{e}^{L}(0)=\mathbf{e}^{L}$, differentiation with respect to φ of the resulting product and estimation of the derivative at $\varphi=0$ lead to

$$\frac{d\lambda}{d\varphi}(\varphi=0)=\frac{\mathbf{e}^{L}\cdot\mathbf{C}\cdot\mathbf{e}^{R}}{\mathbf{e}^{L}\cdot\mathbf{B}\cdot\mathbf{e}^{R}}\,. \tag{11.E.9}$$

The procedure breaks down if the right and left eigenvectors associated with the same eigenvalue λ are orthogonal with respect to the matrix $\mathbf{B}$. See Section 11.6.2.2 for more details.

Part II

Electro-chemomechanical couplings in tissues with a fixed electrical charge

Taylor & Francis
Taylor & Francis Group
http://taylorandfrancis.com

Chapter 12

Fiber-reinforced tissues: directional averaging

This chapter is essentially concerned with the presence in tissues of collagen fibers which endow their mechanical and transport properties with a directional dependence. Indeed, while the collagen fibers in the middle zone of articular cartilages may be considered to develop in a three-dimensional isotropic network, they tend to be aligned tangentially to the synovial joint in the upper zone and orthogonally to the subchondral bone in the lower zone. They constitute planar lamellae with alternate directions in the corneal stroma and annulus fibrosus and form one-dimensional structures in ligaments and tendons.

Here focus is on directional averaging over fibers. Still, the mechanical properties of individual fibers present issues of their own. Under an extension the fibers progressively uncrimp. They can be considered fully activated if their extension is larger than some characteristic value. Fibers aligned with a tensile load are certainly in extension, slightly inclined fibers may uncrimp later as the load intensity increases while fibers along orthogonal directions are likely to undergo contraction and to be mechanically inactive.

At physiological pH the compressive stiffness of articular cartilages is contributed mostly by the ground substance via the electrical repulsion between charged GAGs. The collagen network contributes as well at non physiological pHs where collagen molecules become charged. The tensile stiffness is provided mostly by collagen fibers even if the ground substance may not be negligible.

12.1 Directional analysis

12.1.1 Spatial and directional averaging

When defining the properties of material, reference is made to a representative elementary volume, which becomes a material point at the scale at which the constitutive equations are built. This scale is referred to as macroscopic level.

In general, it is not possible to keep track at this macroscopic level of all details of the representative element, which involve both geometry and physical properties. The characteristic features which survive in the upscaling procedure are smoothed images of the fine scale structure.

A purely macroscopic model has tools on its own that do not necessarily emanate from an upscaling procedure. For example, consider a network of collagen fibers. One issue is to describe the properties of individual fibers. Another issue is to consider the assembly of the fibers. Each fiber is endowed with a direction. A set of fibers may be assembled together in such a way that the network of fibers may also be endowed with an *orientation*. There are indications that the lamellar structure of the corneal stroma may be endowed with interlacing features that are displayed by woven fabrics, Sections 19.1.2.4 and 19.19.2.5. Of course, a macroscopic model may not be able to keep track of the details of the weave fabric. Still, the fact that the fibers are oriented may be made effective by devising a theory that respects the basic principles of material modeling listed in Section 4.9 and that allows the unit vector $\mathbf{m}$ indicating the direction and *sense* of the fiber to enter the constitutive equations. By contrast, the sense is elusive in the dyadic product $\mathbf{m} \otimes \mathbf{m}$.

Typically, a macroscopic property is obtained by averaging over the points $\mathbf{X}$ of the REV of volume V, and at each point, over the directions $\mathbf{m}$ of the unit sphere $\mathbb{S}^2$,

$$\int_V \int_{\mathbb{S}^2} f(\mathcal{V}, \mathbf{m}, \mathbf{X}) \, \frac{dS}{4\,\pi} \, \frac{dV(\mathbf{X})}{V} \,, \tag{12.1.1}$$

where the property f depends, next to the fiber directions $\mathbf{m}$ at $\mathbf{X}$, on the set of variables $\mathcal{V} = \mathcal{V}(\mathbf{X})$. In a mixture theory, the property to be integrated would express as the product of this property $f_k(\mathcal{V}, \mathbf{m}, \mathbf{X})$ of the species k by the characteristic function $\chi_k(\mathbf{X})$ associated with this species,

$$f(\mathcal{V}, \mathbf{m}, \mathbf{X}) = f_k(\mathcal{V}, \mathbf{m}, \mathbf{X}) \; \chi_k(\mathbf{X}) \,. \tag{12.1.2}$$

The latter is equal to one at a point $\mathbf{X}$ belonging to the species k, and zero at points that belong to other species. In the simplest case where the property $f_k(\mathcal{V}, \mathbf{m})$ does not depend on the point $\mathbf{X}$, the spatial integration displays the volume fraction $n^k = V_k/V$. Then, we are left with a directional integration,

$$\int_V \int_{\mathbb{S}^2} f_k(\mathcal{V}, \mathbf{m}, \cancel{\mathbf{X}}) \; \chi_k(\mathbf{X}) \, \frac{dS}{4\,\pi} \, \frac{dV(\mathbf{X})}{V} = n^k \int_{\mathbb{S}^2} f_k(\mathcal{V}, \mathbf{m}) \, \frac{dS}{4\,\pi} \,. \tag{12.1.3}$$

As a particular case, consider $f_k(\mathcal{V}, \mathbf{m}) = \mathbf{m} \otimes \mathbf{m}$. Then the directional integration may be performed analytically to yield,

$$\int_V \int_{\mathbb{S}^2} \mathbf{m} \otimes \mathbf{m} \; \chi_k(\mathbf{X}) \, \frac{dS}{4\,\pi} \, \frac{dV(\mathbf{X})}{V} = n^k \int_{\mathbb{S}^2} \mathbf{m} \otimes \mathbf{m} \, \frac{dS}{4\,\pi} = n^k \, \frac{\mathbf{I}}{3} \,. \tag{12.1.4}$$

Scaling coefficients have been introduced in the averaging operator so that

$$\int_V \int_{\mathbb{S}^2} \frac{dS}{4\,\pi} \, \frac{dV(\mathbf{X})}{V} = 1 \,. \tag{12.1.5}$$

12.1.2 Directional integration

The issue is the integration of a function $f = f(\mathbf{m})$ over the directions $\mathbf{m}$ of two- and three-dimensional domains, typically the unit disc $\mathbb{S}^1$ and the unit sphere $\mathbb{S}^2$, or parts of these domains.

Integration over the unit disc:

The unit vector $\mathbf{m}$ is defined by the angle θ, namely componentwise in cartesian axes,

$$\underbrace{\mathbf{m} = \begin{bmatrix} \cos\,\theta \\ \sin\,\theta \end{bmatrix}}_{\text{unit direction}}, \quad \underbrace{dl = dS = |\frac{\partial \mathbf{m}}{\partial \theta}| \, d\theta = d\theta}_{\text{differential length}} \,, \tag{12.1.6}$$

where dl is the incremental integration length, Fig. 12.1.1. The integration over all directions of the plane is then cast in the format[12.1],

$$\int_{\mathbb{S}^1} f(\mathbf{m}) \, dS = \int_0^{2\pi} f(\theta) \, d\theta \,. \tag{12.1.7}$$

If the vector $\mathbf{m}$ is defined by the angle $\theta \in [0,\, 2\pi[$, the vector $-\mathbf{m}$ is defined by the angle $\theta + \pi$ modulo $2\,\pi$. The actual range of integration might take advantage of the possible symmetries of the integrand, e.g., if $f(\pi - \theta) = f(\theta)$, and the integration may be performed over a half disc only.

If $f(\mathbf{m})$ is a distribution density, say $\mathcal{D}$, then it satisfies the constraint

$$\int_{\mathbb{S}^1} \mathcal{D}(\mathbf{m}) \, dS = 1, \quad \int_{\mathbb{S}^1} dS = 2\,\pi \,. \tag{12.1.8}$$

[12.1] As an abuse of notation $f(\theta)$ stands for $f(\mathbf{m}(\theta))$.

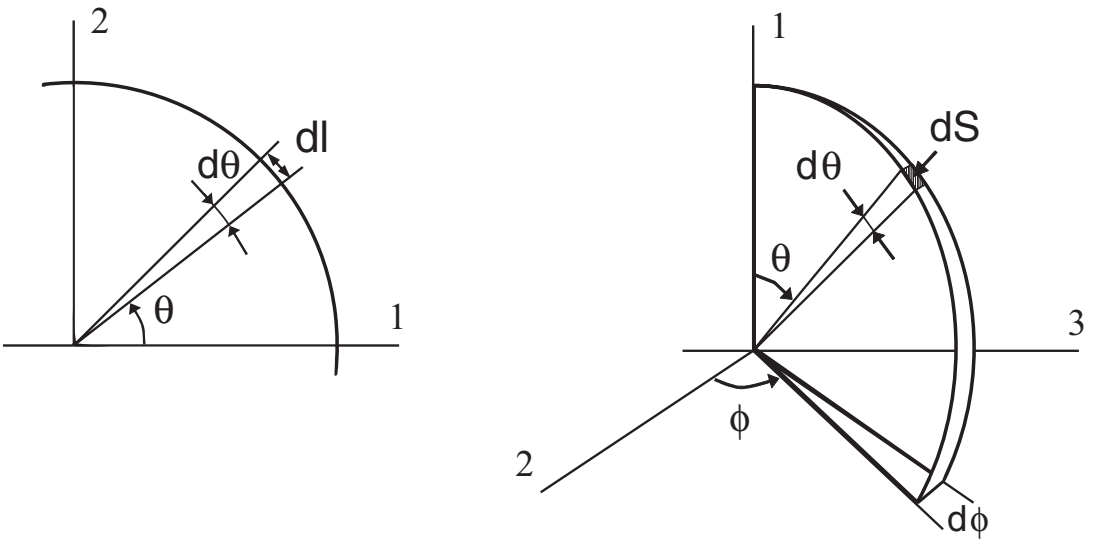

Fig. 12.1.1: Angular parametrization of the unit disc $\mathbb{S}^1 = \mathbb{S}^1(\theta \in [0, 2\pi[)$ and of the unit sphere $\mathbb{S}^2 = \mathbb{S}^2(\theta \in [0, \pi[, \phi \in [0, 2\pi[)$.

Integration over the unit sphere:

The unit vector $\mathbf{m}$ expresses componentwise in cartesian axes in terms of the angles (θ, ϕ), Fig. 12.1.1,

$$\mathbf{m} = \begin{bmatrix} \cos\theta \\ \sin\theta \;\; \cos\phi \\ \sin\theta \;\; \sin\phi \end{bmatrix} . \tag{12.1.9}$$

The differential vector area and differential area result as,

$$d\vec{\mathbf{S}} = \frac{\partial \mathbf{m}}{\partial \theta} \wedge \frac{\partial \mathbf{m}}{\partial \phi} \; d\theta \; d\phi = \mathbf{m} \; \sin\theta \; d\theta \; d\phi \,, \quad dS \equiv |d\vec{\mathbf{S}}| = \sin\theta \; d\theta \; d\phi \,, \tag{12.1.10}$$

and the integration over the unit sphere is cast in the form,

$$\int_{\mathbb{S}^2} f(\mathbf{m}) \, dS = \int_0^{2\,\pi} d\phi \int_0^{\pi} f(\theta, \phi) \, \sin\theta \; d\theta \,. \tag{12.1.11}$$

If $f(\mathbf{m})$ is a distribution density, say $\mathcal{D}$, then it satisfies the constraint

$$\int_{\mathbb{S}^2} \mathcal{D}(\mathbf{m}) \, dS = 1, \quad \int_{\mathbb{S}^2} dS = 4\,\pi \,. \tag{12.1.12}$$

While the vector $\mathbf{m}$ is defined by the angles $\theta \in [0, \pi[$ and $\phi \in [0, 2\pi[$, the vector $-\mathbf{m}$ is defined by the angle $\pi - \theta$ and $\pi + \phi$ modulo $2\,\pi$.

Cubature over the unit sphere:

The previous integration methods were scanning over directions $\mathbf{m}$. Alternatively, and equivalently, the methods below scan on points $\mathbf{M}$ on the unit sphere. The cubature, i.e., approximative integration over the unit sphere, of $\int_{\mathbb{S}^2} f(\mathbf{M}) \, dS$ may be defined through various ways:

- *The latitude-longitude rule.* Instead of integration with respect to the angles $\theta \in [0, \pi]$ and $\phi \in [0, 2\pi]$, use the latitude $x_1 = \cos\theta \in [-1, 1]$ and longitude $\phi \in [0, 2\pi]$. Integrate the latitude with a Gauss-Legendre rule with m points x_1^i and weights w_i which is exact for polynomials up to degree $2\,m - 1$. Integrate the longitude with the generalized mid-point rule with $L + 1$ points $\phi_j = 2\,\pi\, j/(L + 1)$ which is exact for trigonometric polynomials up to degree L, namely $1, \cos\phi, \sin\phi \, cdots, \cos(L\phi), \sin(L\phi)$. The cubature over the unit sphere is finally obtained by tensor product of these two one-dimensional rules,

$$\int_{\mathbb{S}^2} f(\mathbf{M}) \; dS = \frac{2\,\pi}{L+1} \sum_{j=0}^{L} \sum_{i=1}^{m} w_i \, f(\mathbf{M}(x_1^i, \phi_j)) \,. \tag{12.1.13}$$

- *Spherical designs.* Spherical t-designs, which consist in carefully selected P sampling points on the unit sphere and use of a uniform weight $4\,\pi/P$,

$$\int_{\mathbb{S}^2} f(\mathbf{M})\; dS = \frac{4\,\pi}{P} \sum_{i=1}^{P} f(\mathbf{M}^{(i)})\,, \tag{12.1.14}$$

achieve exact integration of spherical polynomials of degree t or less. The number P of points should be larger than $(t+2)^2/4$ if t is even, and $(t+1)\,(t+3)/4$ if t is odd. The points in spherical designs are more evenly distributed than with the Gauss-Legendre rule which involves a number of points near the poles with small weights. Tabulated designs with limited P may be found in Hardin and Sloane [1996].
- *Voronoi tessellation.* Hesse et al. [2010] provide a review of methods of cubature over the unit sphere, including integration of scattered data, namely when the integrand $f(\mathbf{M})$ is known only at certain points $\mathbf{M}^{(i)}$, $i \in [1, P]$. Then a Voronoi tessellation partitions the unit sphere over sets T_i of area $|T_i|$, and

$$\int_{\mathbb{S}^2} f(\mathbf{M})\; dS = \sum_{i=1}^{P} f(\mathbf{M}^{(i)})\,|T_i|\,. \tag{12.1.15}$$

- *Delaunay triangulation.* An alternative method is to use the Delaunay triangulation $\mathcal{T}$, associated with the scattered data points. The generic spherical triangles T_{ijk} with apices $(\mathbf{m}_i, \mathbf{m}_j, \mathbf{m}_k)$ are formed by three intersecting circular arcs. They have area $|T_{ijk}| = \alpha_i + \alpha_j + \alpha_k - \pi$, where the α's are the angles at the apices (for a planar triangle, the above sum vanishes). Then

$$\int_{\mathbb{S}^2} f(\mathbf{M})\; dS = \sum_{T_{ijk}\in\mathcal{T}} \frac{1}{3}\left(f(\mathbf{M}^{(i)}) + f(\mathbf{M}^{(j)}) + f(\mathbf{M}^{(k)})\right)|T_{ijk}|\,. \tag{12.1.16}$$

Differential operators over the unit sphere:

The definitions expressed in the spherical axes $\hat{\mathbf{e}}_r$, $\hat{\mathbf{e}}_\theta$ and $\hat{\mathbf{e}}_\phi$ of a few differential operators over the unit sphere are recorded as particular cases of the general definitions provided in Section 2.4.3.1.

$\boldsymbol{\nabla}_{\mathbb{S}}\, u$ denotes the left or right gradient of a scalar u, namely Eqn (2.4.57),

$$\boldsymbol{\nabla}_{\mathbb{S}}\, u = \overrightarrow{\boldsymbol{\nabla}}_{\mathbb{S}}\; u = u\; \overleftarrow{\boldsymbol{\nabla}}_{\mathbb{S}} = \frac{\partial u}{\partial \theta}\,\hat{\mathbf{e}}_\theta + \frac{1}{\sin\theta}\,\frac{\partial u}{\partial \phi}\,\hat{\mathbf{e}}_\phi\,, \tag{12.1.17}$$

while the Laplacian of a scalar follows from (2.4.66),

$$\Delta_{\mathbb{S}} u = \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}(\sin\theta\;\frac{\partial u}{\partial\theta}) + \frac{1}{\sin^2\theta}\frac{\partial^2 u}{\partial\phi^2}\,. \tag{12.1.18}$$

The (left) gradient $\boldsymbol{\nabla}_{\mathbb{S}}\mathbf{u} = \overrightarrow{\boldsymbol{\nabla}}_{\mathbb{S}}\;\mathbf{u}$ and divergence $\mathrm{div}_{\mathbb{S}}\mathbf{u} = \mathrm{tr}\,(\boldsymbol{\nabla}_{\mathbb{S}}\mathbf{u})$ of the vector $\mathbf{u}$ simplify to,

$$\boldsymbol{\nabla}_{\mathbb{S}}\mathbf{u} = \begin{bmatrix} 0 & 0 & 0 \\ \dfrac{\partial u_r}{\partial\theta} - u_\theta & \dfrac{\partial u_\theta}{\partial\theta} + u_r & \dfrac{\partial u_\phi}{\partial\theta} \\ \dfrac{1}{\sin\theta}\dfrac{\partial u_r}{\partial\phi} - u_\phi & \dfrac{1}{\sin\theta}\dfrac{\partial u_\theta}{\partial\phi} - u_\phi\,\cot\theta & \dfrac{1}{\sin\theta}\dfrac{\partial u_\phi}{\partial\phi} + u_r + u_\theta\,\cot\theta \end{bmatrix}, \tag{12.1.19}$$

and

$$\mathrm{div}_{\mathbb{S}}\mathbf{u} = 2\,u_r + \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}(u_\theta\,\sin\theta) + \frac{1}{\sin\theta}\frac{\partial u_\phi}{\partial\phi}\,. \tag{12.1.20}$$

For the record, let us note also

$$\boldsymbol{\nabla}_{\mathbb{S}}\hat{\mathbf{e}}_r = \mathbf{I} - \hat{\mathbf{e}}_r \otimes \hat{\mathbf{e}}_r\,, \tag{12.1.21}$$

and, using the rates (2.4.48) and gradients (12.1.19),

$$\frac{d\hat{\mathbf{e}}_r}{dt}\cdot\boldsymbol{\nabla}_{\mathbb{S}}\hat{\mathbf{e}}_r = \frac{d\hat{\mathbf{e}}_r}{dt}, \quad \frac{d\hat{\mathbf{e}}_r}{dt}\cdot\boldsymbol{\nabla}_{\mathbb{S}}\hat{\mathbf{e}}_\theta = \frac{d\hat{\mathbf{e}}_\theta}{dt}, \quad \frac{d\hat{\mathbf{e}}_r}{dt}\cdot\boldsymbol{\nabla}_{\mathbb{S}}\hat{\mathbf{e}}_\phi = \frac{d\hat{\mathbf{e}}_\phi}{dt}\,. \tag{12.1.22}$$

The component form of the unit vector $\mathbf{m}$ in the principal axes of the Cauchy stress tensor $\boldsymbol{\sigma}$ being given by (12.1.9), the normal stress $\mathbf{m}\cdot\boldsymbol{\sigma}\cdot\mathbf{m}$ is equal to $\sigma_1\,\cos^2\theta+\sin^2\theta\,(\sigma_2\,\cos^2\phi+\sigma_3\,\sin^2\phi)$, and its Laplacian,

$$\Delta_{\mathbb{S}}\,(\mathbf{m}\cdot\boldsymbol{\sigma}\cdot\mathbf{m})=2\,(1-3\,\cos^2\theta)\,(\sigma_1-\frac{\sigma_2+\sigma_3}{2})+3\,\cos(2\,\phi)\,\sin^2\theta\,(\sigma_3-\sigma_2)\,, \tag{12.1.23}$$

vanishes for all directions $\mathbf{m}$ only if the stress is isotropic.

The eigenfunctions $Y_{l,m}$ with eigenvalues $\lambda_{l,m}$ of the Laplacian, that satisfy the relation $\Delta_{\mathbb{S}}Y=\lambda\,Y$, namely

$$\lambda_{l,m}=-l\,(l+1),\quad Y_{l,m}(\theta,\phi)=\sqrt{\frac{2\,l+1}{4\,\pi}\frac{(l-m)!}{(l+m)!}}\,P_{l,m}(\cos\theta)\,e^{i\,m\,\phi},\quad -l\le m\le l,\quad l=0,1,\cdots, \tag{12.1.24}$$

are termed *spherical harmonics* and they constitute an orthonormal basis of functions on the unit sphere,

$$\int_{\mathbb{S}^2}Y_{l,m}(\theta,\phi)\,\overline{Y}_{l',m'}(\theta,\phi)\;dS=I_{ll'}\,I_{mm'}\,, \tag{12.1.25}$$

$\overline{Y}$ denoting the complex conjugate of Y. The associated Legendre polynomials $P_{l,m}(x)$, $x\in[0,1]$,

$$P_{l,m}(x)=(-1)^m\,(1-x^2)^{m/2}\,\frac{d^m}{dx^m}P_l(x),\quad m\ge 0,\quad P_{l,m}(x)=(-1)^m\,\frac{(l+m)!}{(l-m)!}\,P_{l,-m}(x),\quad m<0\,, \tag{12.1.26}$$

derive from the ordinary Legendre polynomials $P_l(x)=1/(2^l\,l!)\,d^l/dx^l(x^2-1)^l$. Note the addition theorem for $\mathbf{m}\equiv(\theta,\phi)$ and $\mathbf{n}\equiv(\theta',\phi')$ two unit vectors,

$$P_l(\mathbf{m}\cdot\mathbf{n})=\frac{4\,\pi}{2\,l+1}\sum_{m=-l}^{l}Y_{l,m}(\mathbf{m})\,\overline{Y}_{l,m}(\mathbf{n})\,. \tag{12.1.27}$$

For efficient and accurate numerical evaluation of the associated Legendre polynomials, refer to Press et al. [1992].

12.2 A simple fiber model for the collagen network

Emphasis is laid below on the interactions between the directional properties of the fiber network and chemomechanical couplings. Indeed, chemomechanical couplings, namely swelling and shrinking, modify the sets of directions in which the fibers are mechanically active.

To simplify the analysis, full activation of individual fibers is considered to take place as soon as they undergo extension. Progressive uncrimping is introduced through a nonlinear stress-strain relation. However the model, and some interesting properties, are first introduced in a conewise linear context.

12.2.1 A single family of collagen fibers

Let $\underline{\mathbf{m}}_{\mathrm{c}}$ be a unit vector indicating the direction of a collagen fiber in a reference configuration where the deformation gradient is equal to the identity, $\mathbf{F}=\mathbf{I}$. Let $\mathbf{C}=\mathbf{F}^{\mathrm{T}}\cdot\mathbf{F}$ be the right stretch associated with the deformation gradient $\mathbf{F}$. It is instrumental to introduce the operator $\langle\cdot\rangle$ which denotes the positive part of its argument. The collagen fibers are mechanically active only in extension, namely when $\langle\underline{\mathbf{m}}_{\mathrm{c}}\cdot\mathbf{C}\cdot\underline{\mathbf{m}}_{\mathrm{c}}-1\rangle$ is non zero. Then the strain energy of a collagen fiber per unit volume of collagen expresses in terms of the right stretch $\mathbf{C}=2\,\mathbf{E}_{\mathrm{G}}+\mathbf{I}$ or Green strain $\mathbf{E}_{\mathrm{G}}$ in the format,

$$w_{\mathrm{c}}=w_{\mathrm{c}}(L^2)\,, \tag{12.2.1}$$

where

$$L=\tfrac{1}{2}\,\langle\mathbf{C}:\underline{\mathbf{M}}_{\mathrm{c}}-1\rangle=\langle\underbrace{\mathbf{E}_{\mathrm{G}}:\underline{\mathbf{M}}_{\mathrm{c}}}_{x}\rangle\,, \tag{12.2.2}$$

and $\underline{\mathbf{M}}_{\mathrm{c}}=\underline{\mathbf{m}}_{\mathrm{c}}\otimes\underline{\mathbf{m}}_{\mathrm{c}}$. In (12.2.1), the square, actually any exponent strictly greater than 1, is required to ensure continuity of the stress at the extension-contraction transition $L=0$ where, in contrast, the stiffness may or may not be discontinuous.

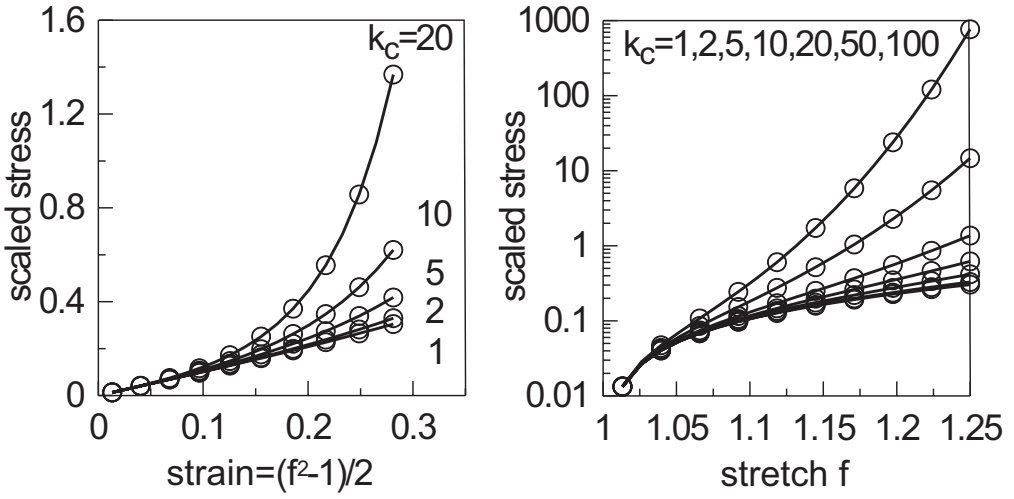

Fig. 12.2.1: The exponential law with a power 2 ensures continuity of the stress at the balance point where the strain becomes contractive. Effect of the exponent k_c on the scaled stress $\exp(k_c\,\epsilon^2)\;\epsilon$ as a function of the strain $\epsilon = (f^2-1)/2$ or stretch f.

Note that use of the deviatoric deformation in the above energy would lead isotropic extension, like swelling, to leave collagen fibers unactivated. We adopt the exponential form of energy, defined by the modulus K_c [unit : MPa] of the collagen fibers and the dimensionless exponent k_c,

$$\begin{aligned} w_c &= \frac{K_c}{2\,k_c}\Big(\exp(k_c\,L^2)-1\Big)\,, \\ \frac{\partial w_c}{\partial \mathbf{E}_G} &= K_c\,\exp(k_c\,L^2)\,L\,\underline{\mathbf{M}}_c\,, \\ \frac{\partial^2 w_c}{\partial \mathbf{E}_G \partial \mathbf{E}_G} &= K_c\,\exp(k_c\,L^2)\,\big(2\,k_c\,\underbrace{L^2}_{\text{continuous}} + \underbrace{\mathcal{H}(x)}_{\text{discontinuous}}\big)\,\underline{\mathbf{M}}_c\otimes\underline{\mathbf{M}}_c\,. \end{aligned} \tag{12.2.3}$$

Fig. 12.2.1 displays the quantitative influence of the exponent k_c.

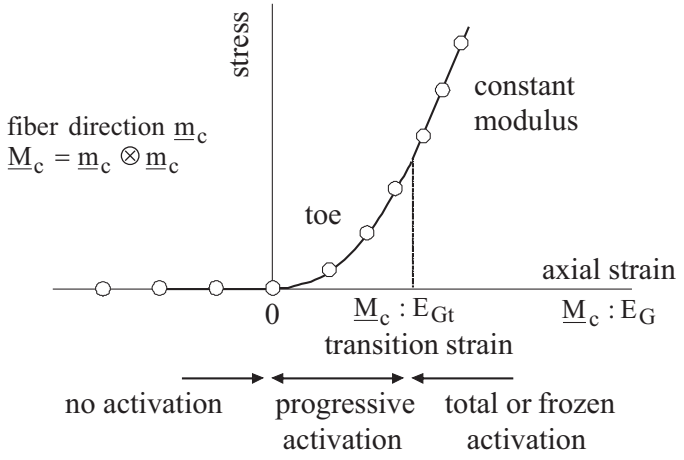

Fig. 12.2.2: One-dimensional sketch showing a progressive increase of the elastic modulus (toe region) followed by a region of constant modulus that avoids locking at large strains.

The above expression gives rise to infinite stiffness at large extension. In order to keep a constant stiffness for a strain larger than $\mathbf{E}_{Gt} : \underline{\mathbf{M}}_c$ as sketched in Fig. 12.2.2, consider the following strain energy density,

$$\begin{aligned} w_c &= \big(1-\mathcal{H}(x_2)\big)\,w_{cf1} + \mathcal{H}(x_2)\,w_{cf2}\,, \\ \underline{\boldsymbol{\tau}} &= \big(1-\mathcal{H}(x_2)\big)\,\underline{\boldsymbol{\tau}}_1 + \mathcal{H}(x_2)\,\underline{\boldsymbol{\tau}}_2\,, \\ \mathbb{E} &= \big(1-\mathcal{H}(x_2)\big)\,\mathbb{E}_1 + \mathcal{H}(x_2)\,\mathbb{E}_2\,, \end{aligned} \tag{12.2.4}$$

$$
\begin{aligned}
w_{\rm cf1} &= \frac{K_{\rm c}}{2\,k_{\rm c}}\left(\exp(k_{\rm c}\,L_1^2)-1\right),\\
\underline{\underline{\boldsymbol{\tau}}}_1 = \frac{\partial w_{\rm cf1}}{\partial \mathbf{E}_{\rm G}} &= K_{\rm c}\,\exp(k_{\rm c}\,L_1^2)\,L_1\,\underline{\mathbf{M}}_{\rm c}\,, \qquad (12.2.5)\\
\mathbb{E}_1 = \frac{\partial^2 w_{\rm cf1}}{\partial \mathbf{E}_{\rm G}\partial \mathbf{E}_{\rm G}} &= K_{\rm c}\,\exp(k_{\rm c}\,L_1^2)\left(2\,k_{\rm c}\,L_1^2+\mathcal{H}(x_1)\right)\underline{\mathbf{M}}_{\rm c}\otimes\underline{\mathbf{M}}_{\rm c}\,,\\
w_{\rm cf2} &= \underline{\underline{\boldsymbol{\tau}}}_t : \mathbf{E}_{\rm G} + \frac{1}{2}\,(\mathbf{E}_{\rm G}-\mathbf{E}_{{\rm G}t}) : \mathbb{E}_t : (\mathbf{E}_{\rm G}-\mathbf{E}_{{\rm G}t})\,,\\
\underline{\underline{\boldsymbol{\tau}}}_2 = \frac{\partial w_{\rm cf2}}{\partial \mathbf{E}_{\rm G}} &= \underline{\underline{\boldsymbol{\tau}}}_t + \mathbb{E}_t : (\mathbf{E}_{\rm G}-\mathbf{E}_{{\rm G}t})\,, \qquad (12.2.6)\\
\mathbb{E}_2 = \frac{\partial^2 w_{\rm cf2}}{\partial \mathbf{E}_{\rm G}\partial \mathbf{E}_{\rm G}} &= \mathbb{E}_t\,,
\end{aligned}
$$

where

$$
L_1 = \langle \underbrace{\mathbf{E}_{\rm G} : \underline{\mathbf{M}}_{\rm c}}_{x_1} \rangle, \quad L_2 = \langle \underbrace{(\mathbf{E}_{\rm G}-\mathbf{E}_{{\rm G}t}) : \underline{\mathbf{M}}_{\rm c}}_{x_2} \rangle\,, \qquad (12.2.7)
$$

and $\underline{\underline{\boldsymbol{\tau}}}_t = \underline{\underline{\boldsymbol{\tau}}}_1(\mathbf{E}_{{\rm G}t})$ and $\mathbb{E}_t = \mathbb{E}_1(\mathbf{E}_{{\rm G}t})$.

An even more drastic departure from locking is exposed in Section 6.5.2.

12.2.2 Random directional distribution of collagen fibers

Henceforth we have in mind a tissue that can be assumed to be isotropic. For example, we may think of a specimen taken in the middle zone of articular cartilages. Otherwise, the directional distribution of fibers should be specified. The fibers are assumed to be independent: there are no crosslinks between fibers nor direct interactions with the matrix.

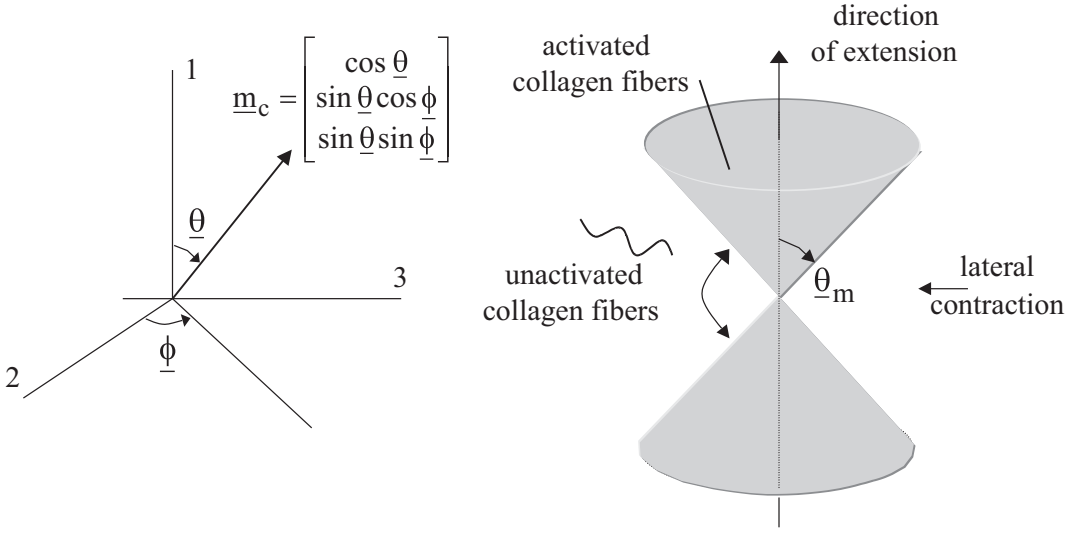

Fig. 12.2.3: Cones of activation of collagen fibers under axial extension and lateral contraction.

The unit vector $\underline{\mathbf{m}}_{\rm c}$ indicating the direction of a collagen fiber is expressed in terms of the angles $\underline{\phi} \in [0,\, 2\,\pi[$ and $\underline{\theta} \in [0,\, \pi[$, Fig. 12.2.3,

$$
\underline{\mathbf{m}}_{\rm c} = \begin{bmatrix} \cos\underline{\theta} \\ \sin\underline{\theta}\,\cos\,\underline{\phi} \\ \sin\underline{\theta}\,\sin\,\underline{\phi} \end{bmatrix}\,. \qquad (12.2.8)
$$

Let us record the directional integrations over space directions of the second order tensor $\underline{\mathbf{M}}_{\mathrm{c}}$,

$$\int_{\mathbb{S}^2} \underline{\mathbf{m}}_{\mathrm{c}} \otimes \underline{\mathbf{m}}_{\mathrm{c}} \, \frac{d\underline{S}}{4\,\pi} = \frac{1}{4\,\pi} \int_0^{2\pi} d\underline{\phi} \int_0^{\pi} \underline{\mathbf{m}}_{\mathrm{c}} \otimes \underline{\mathbf{m}}_{\mathrm{c}} \, \sin\underline{\theta} \, d\underline{\theta} = \frac{\mathbf{I}}{3}\,, \tag{12.2.9}$$

and of the fourth order tensor $\underline{\mathbf{M}}_{\mathrm{c}} \otimes \underline{\mathbf{M}}_{\mathrm{c}}$,

$$\int_{\mathbb{S}^2} \underline{\mathbf{M}}_{\mathrm{c}} \otimes \underline{\mathbf{M}}_{\mathrm{c}} \, \frac{d\underline{S}}{4\,\pi} = \frac{1}{15} \left(\mathbf{I} \otimes \mathbf{I} + 2\,\mathbf{I} \,\overline{\underline{\otimes}}\, \mathbf{I}\right). \tag{12.2.10}$$

The tensor product $\overline{\underline{\otimes}}$ is defined componentwise as $(\mathbf{A}\,\overline{\underline{\otimes}}\,\mathbf{B})_{ijkl} = (A_{ik}\,B_{jl} + A_{il}\,B_{jk})/2$. The expression (12.2.10) results from the component relations,

$$\frac{1}{4\pi} \int_0^{2\pi} d\underline{\phi} \int_0^{\pi} \underline{m}_{ci}\,\underline{m}_{cj}\,\underline{m}_{ck}\,\underline{m}_{cl} \, \sin\underline{\theta} \, d\underline{\theta} = \begin{cases} 1/5, & i=j=k=l, \\ 1/15, & i=j\neq k=l, \\ 0, & \text{otherwise}\,. \end{cases} \tag{12.2.11}$$

Note the useful closed form integral for $m \geq 0$ and $n \geq 0$ integers,

$$\frac{1}{2\pi} \int_0^{2\pi} (\cos\underline{\phi})^{2m} \, (\sin\underline{\phi})^{2n} \, d\underline{\phi} = \frac{(2\,m-1)!!\,(2\,n-1)!!}{2^{m+n}\,(m+n)!}\,, \tag{12.2.12}$$

where $n! = (n)\,(n-1)\cdots(2)\,(1)$ denotes the factorial of n and $(2\,n-1)!!$ is the double factorial,

$$(2\,n-1)!! = (2\,n-1)\,(2\,n-3)\,\cdots\,(3)\,(1)\,. \tag{12.2.13}$$

Note also the generalization for even n, Kanatani [1984],

$$\frac{1}{4\pi} \int_0^{2\pi} d\underline{\phi} \int_0^{\pi} \underline{m}_{ci_1}\,\underline{m}_{ci_2}\,\cdots\underline{m}_{ci_n} \, \sin\underline{\theta} \, d\underline{\theta} = \frac{1}{n+1}\, I_{(i_1 i_2}\, I_{i_3 i_4} \cdots I_{i_{n-1} i_n)}\,, \tag{12.2.14}$$

where $\mathbf{I}$ is the second order identity tensor and the parentheses imply symmetrization of the indices, involving $(n-1)!!$ independent terms, namely 1 for $n=2$, 3 for $n=4$, 15 for $n=6$, 105 for $n=8\,\cdots$, e.g.,

$$\begin{aligned} &\frac{1}{4\pi} \int_0^{2\pi} d\underline{\phi} \int_0^{\pi} \underline{m}_{ci_1}\,\underline{m}_{ci_2}\,\cdots\underline{m}_{ci_n} \, \sin\underline{\theta} \, d\underline{\theta} = \\ &= \begin{cases} \dfrac{1}{3}\, I_{i_1 i_2}, & n=2; \\ \dfrac{1}{15}\,(I_{i_1 i_2}\, I_{i_3 i_4} + I_{i_1 i_3}\, I_{i_2 i_4} + I_{i_1 i_4}\, I_{i_2 i_3}), & n=4; \\ \dfrac{1}{105}\,(\, I_{i_1 i_2}\, I_{i_3 i_4}\, I_{i_5 i_6} + I_{i_1 i_3}\, I_{i_2 i_4}\, I_{i_5 i_6} + I_{i_1 i_4}\, I_{i_2 i_3}\, I_{i_5 i_6} & n=6 \\ \quad + I_{i_1 i_2}\, I_{i_3 i_5}\, I_{i_4 i_6} + I_{i_1 i_2}\, I_{i_3 i_6}\, I_{i_4 i_5} + I_{i_1 i_5}\, I_{i_3 i_4}\, I_{i_2 i_6} \\ \quad + I_{i_1 i_6}\, I_{i_3 i_4}\, I_{i_2 i_5} + I_{i_1 i_5}\, I_{i_2 i_3}\, I_{i_4 i_6} + I_{i_1 i_6}\, I_{i_2 i_3}\, I_{i_4 i_5} \\ \quad + I_{i_1 i_4}\, I_{i_3 i_5}\, I_{i_2 i_6} + I_{i_1 i_4}\, I_{i_3 i_6}\, I_{i_2 i_5} + I_{i_1 i_5}\, I_{i_2 i_4}\, I_{i_3 i_6} \\ \quad + I_{i_1 i_3}\, I_{i_4 i_6}\, I_{i_2 i_5} + I_{i_1 i_6}\, I_{i_2 i_4}\, I_{i_3 i_5} + I_{i_1 i_3}\, I_{i_4 i_5}\, I_{i_2 i_6})\,. \end{cases} \end{aligned} \tag{12.2.15}$$

12.2.3 Conewise linear stress-strain response of collagen fibers

In the limit of a small strain $\mathbf{C} = \mathbf{I} + 2\,\boldsymbol{\epsilon} + \cdots$, the effective elongation L writes $\langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\mathrm{c}} \rangle$, and the energy of a single collagen fiber and its first and second derivatives may be linearized to

$$\begin{aligned} w_{\mathrm{c}} &= \frac{K_{\mathrm{c}}}{2} \, \langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\mathrm{c}} \rangle^2\,, \\ \frac{\partial w_{\mathrm{c}}}{\partial \boldsymbol{\epsilon}} &= K_{\mathrm{c}} \, \langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\mathrm{c}} \rangle \, \underline{\mathbf{M}}_{\mathrm{c}}\,, \\ \frac{\partial^2 w_{\mathrm{c}}}{\partial \boldsymbol{\epsilon} \, \partial \boldsymbol{\epsilon}} &= K_{\mathrm{c}} \, \underbrace{\mathcal{H}(\boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\mathrm{c}})}_{\text{discontinuous}} \, \underline{\mathbf{M}}_{\mathrm{c}} \otimes \underline{\mathbf{M}}_{\mathrm{c}}\,. \end{aligned} \tag{12.2.16}$$

12.2.3.1 All fibers in extension

If *all* fibers are in extension, then integrations over space and directions of the apparent strain energy and of its first and second derivatives,

$$\left\{\begin{array}{c} n^{\rm c}\displaystyle\int_{\mathbb{S}^2} w_{\rm c}\,\frac{d\underline{S}}{4\pi} \\ n^{\rm c}\displaystyle\int_{\mathbb{S}^2} \frac{\partial w_{\rm c}}{\partial \boldsymbol{\epsilon}}\,\frac{d\underline{S}}{4\pi} \\ n^{\rm c}\displaystyle\int_{\mathbb{S}^2} \frac{\partial^2 w_{\rm c}}{\partial \boldsymbol{\epsilon}\,\partial \boldsymbol{\epsilon}}\,\frac{d\underline{S}}{4\pi} \end{array}\right. = \frac{K^{\rm c}}{15}\left\{\begin{array}{l} \frac{1}{2}\,(\mathbf{I}:\boldsymbol{\epsilon})^2+\boldsymbol{\epsilon}:\boldsymbol{\epsilon}\,, \\ (\boldsymbol{\epsilon}:\mathbf{I})\,\mathbf{I}+2\,\boldsymbol{\epsilon}\,, \\ \mathbf{I}\otimes\mathbf{I}+2\,\mathbf{I}\,\overline{\underline{\otimes}}\,\mathbf{I}\,, \end{array}\right. \tag{12.2.17}$$

yield an isotropic apparent stiffness with equal apparent Lamé moduli,

$$\lambda^{\rm c}=\mu^{\rm c}=\frac{K^{\rm c}}{15}\quad\text{with}\quad K^{\rm c}=n^{\rm c}\,K_{\rm c}\,, \tag{12.2.18}$$

that is, with a Poisson's ratio equal to 0.25.

12.2.3.2 Rotational symmetry about the traction direction

However, in general, the directions for which extension takes place are not known beforehand and the integration can not be performed analytically, except in particular cases.

For example, let us consider extension along the direction 1 with symmetry about this axis. Of course if the transverse directions undergo extension, we recover the isotropic case. However the fibers in the transverse directions may undergo contraction. Then the fibers which undergo extension,

$$\boldsymbol{\epsilon}:\underline{\mathbf{M}}_{\rm c}\;\geq 0\quad\Rightarrow\quad \cot^2\underline{\theta}=\frac{\underline{m}_{c1}^2}{\underline{m}_{c2}^2+\underline{m}_{c3}^2}\geq\cot^2\underline{\theta}_m\equiv\frac{-\epsilon_{22}}{\epsilon_{11}}\,, \tag{12.2.19}$$

form two symmetric cones of half angle $\underline{\theta}_m$ about the extension direction,

$$\underline{\theta}\in[0,\underline{\theta}_m]\cup[\pi-\underline{\theta}_m,\pi]\,. \tag{12.2.20}$$

In the principal axes of strain, we just need to calculate four components of the stiffness in view of the symmetry about the axis 1. Therefore the contribution of the collagen network to the total stress expresses in terms of a symmetric matrix,

$$\boldsymbol{\sigma}^{\rm c}=\mathbb{E}^{\rm c}(\boldsymbol{\epsilon}):\boldsymbol{\epsilon},\quad \left[\begin{array}{c}\sigma_{11}\\ \sigma_{22}\\ \sigma_{33}\end{array}\right]=\left[\begin{array}{ccc}E^{\rm c}_{11}&E^{\rm c}_{12}&E^{\rm c}_{12}\\ E^{\rm c}_{21}&E^{\rm c}_{22}&E^{\rm c}_{23}\\ E^{\rm c}_{21}&E^{\rm c}_{32}&E^{\rm c}_{22}\end{array}\right]\left[\begin{array}{c}\epsilon_{11}\\ \epsilon_{22}\\ \epsilon_{33}\end{array}\right] \tag{12.2.21}$$

with coefficients,

$$\begin{aligned} E^{\rm c}_{11}&=\frac{K^{\rm c}}{80}\Big(16-10\,\cos\underline{\theta}_m-5\,\cos(3\underline{\theta}_m)-\cos(5\underline{\theta}_m)\Big)=\frac{K^{\rm c}}{5}\left(1-(\cos\underline{\theta}_m)^5\right)\\ E^{\rm c}_{22}&=E^{\rm c}_{33}=3\,E^{\rm c}_{23}=\frac{K^{\rm c}}{10}\Big(19+18\,\cos\underline{\theta}_m+3\,\cos(2\underline{\theta}_m)\Big)\Big(\sin\frac{\underline{\theta}_m}{2}\Big)^6\\ E^{\rm c}_{12}&=E^{\rm c}_{13}=\frac{K^{\rm c}}{480}\Big(32-30\,\cos\,\underline{\theta}_m-5\,\cos(3\underline{\theta}_m)+3\,\cos(5\underline{\theta}_m)\Big)\,. \end{aligned} \tag{12.2.22}$$

The efficiency of a reinforcement

Let us assume a planar reinforcement defined by a distribution density function. Assume the material to be subjected to uniaxial traction. The efficiency of the reinforcement may be defined by the ratio of the Young's modulus of the anisotropic material over the Young's modulus of the associated isotropic reinforcement.

12.2.3.3 Interplay between the stiffness of the fiber network and chemical effects

The model may display *a swelling induced stiffening* by fiber recruitment and, conversely, *a shrinking induced softening* by fiber deactivation.

Indeed, consider the material to undergo uniaxial traction while swelling emanates from some chemomechanical process. Swelling will imply the lateral strains to become less contractive. Therefore, more collagen fibers will be activated and the angle $\underline{\theta}_m$ of the cone of active fibers will be larger. Consequently, the axial stiffness is certainly going to increase. Simulations in Chapter 17 show that this self-contained stiffening/softening effect is significant: a piece of articular cartilage in contact with a bath of controlled chemical composition is subjected to a given axial strain. When the ionic strength of the bath increases, the lateral strain and the volume of the cartilage decrease, and the cone of mechanically active fibers reduces, Figs. 17.13.2–17.13.4.

12.2.3.4 The apparent Poisson's ratio of the dry tissue

Stress in soft tissues is considered to be contributed additively by the matrix (ground substance) and the collagen network. Therefore the stiffness of the cartilage is the sum of the apparent stiffnesses of the ground substance and of the collagen network, $\mathbb{E}^{\rm car} = \mathbb{E}^{\rm gs} + \mathbb{E}^{\rm c}$. The apparent isotropic tensor moduli $\mathbb{E}^{\rm gs}$ of the ground substance are defined by the Lamé moduli,

$$\lambda = n^{\rm gs}\,\Lambda_{\rm gs}, \quad \mu = n^{\rm gs}\,M_{\rm gs}\,. \tag{12.2.23}$$

Here $\Lambda_{\rm gs}$ and $M_{\rm gs}$ are the intrinsic Lamé moduli of the matrix, and $n^{\rm gs}$ its volume fraction. Similarly, the stiffness of the collagen network $\mathbb{E}^{\rm c}$ is given by (12.2.22), where $K^{\rm c}$,

$$K^{\rm c} = n^{\rm c}\,K_{\rm c}\,, \tag{12.2.24}$$

is the apparent modulus of collagen: $K_{\rm c}$ is the intrinsic modulus of a collagen fiber and $n^{\rm c}$ the volume fraction of collagen.

Leaving aside for now chemomechanical couplings, the constitutive equations in the principal strain axes may be cast in the format,

$$\boldsymbol{\sigma} = \mathbb{E}^{\rm car} : \boldsymbol{\epsilon}, \quad \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \end{bmatrix} = \begin{bmatrix} \lambda + 2\mu + E^{\rm c}_{11} & \lambda + E^{\rm c}_{12} & \lambda + E^{\rm c}_{12} \\ \lambda + E^{\rm c}_{21} & \lambda + 2\mu + E^{\rm c}_{22} & \lambda + E^{\rm c}_{23} \\ \lambda + E^{\rm c}_{21} & \lambda + E^{\rm c}_{32} & \lambda + 2\mu + E^{\rm c}_{22} \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \end{bmatrix}. \tag{12.2.25}$$

Under symmetric loading about the axis 1, the strain energy associated with the stiffness $\mathbb{E}^{\rm car}$ defined by (12.2.25),

$$\tfrac{1}{2}\,E^{\rm car}_{11}\,\epsilon^2_{11} + 2\,E^{\rm car}_{12}\,\epsilon_{11}\,\epsilon_{22} + (E^{\rm car}_{22} + E^{\rm car}_{23})\,\epsilon^2_{22}\,, \tag{12.2.26}$$

is positive if

$$E^{\rm car}_{11} > 0, \quad 2\,(E^{\rm car}_{12})^2 - E^{\rm car}_{11}\,(E^{\rm car}_{22} + E^{\rm car}_{23}) < 0\,. \tag{12.2.27}$$

The latter inequality can be rephrased as,

$$\Delta = 2\,(\nu^{\rm car})^2 - \frac{E^{\rm car}_{11}}{E^{\rm car}_{22} + E^{\rm car}_{23}} < 0\,, \tag{12.2.28}$$

in terms of an aggregate Poisson's ratio,

$$\nu^{\rm car} = \frac{E^{\rm car}_{12}}{E^{\rm car}_{22} + E^{\rm car}_{23}}\,. \tag{12.2.29}$$

For $K^{\rm c}/\mu$ below 43.21, $1 - 2\,\nu^{\rm car}$ remains positive, Fig. 12.2.4. Conversely for $K^{\rm c}/\mu$ larger than 43.21, $1 - 2\,\nu^{\rm car}$ becomes negative for some range of angles $\underline{\theta}_m$, that is, for some range of lateral contraction defined by the ratio $-\epsilon_{22}/\epsilon_{11} = (\cot\underline{\theta}_m)^2$. Said otherwise, the ratio $-\epsilon_{22}/\epsilon_{11}$ should be larger than some threshold, about 0.12, for $1 - 2\,\nu^{\rm car}$ to have a chance to be negative.

In fact, the smallest value of $K^{\rm c}/\mu$ for which $1 - 2\,\nu^{\rm car}$ vanishes corresponds to uniaxial traction, and then $-\epsilon_{22}/\epsilon_{11} = (\cot\underline{\theta}_m)^2 = 1/2$, that is $\underline{\theta}_m$=54.74°.

In all circumstances, the quantity Δ defined by (12.2.28) is negative, so that the strain energy function, and by the same token the aggregate stiffness $\mathbb{E}^{\rm car}$ remain positive definite.

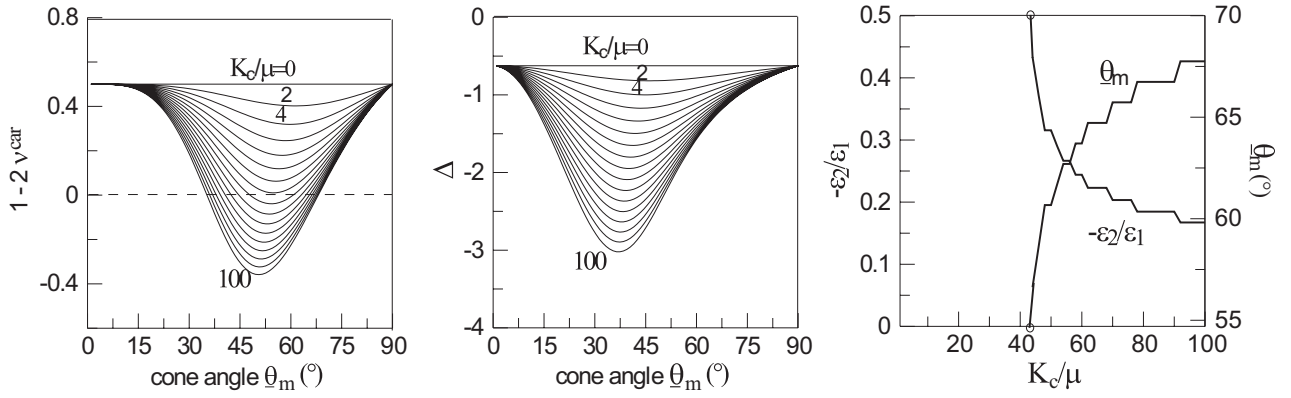

Fig. 12.2.4: While the Poisson's ratio of the cartilage (aggregate matrix and collagen network) can become larger than $1/2$, for a sufficiently large relative stiffness of collagen with respect to matrix, the strain energy function remains positive. Poisson's ratio of matrix $\nu = 0.25$.

12.2.4 Conewise nonlinear stress-strain response of collagen fibers

We now return to the energy (12.2.3) in exponential form. For uniaxial traction (symmetry about the axis 1), the activation criterion relies on the elongation L,

$$L = \langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\mathrm{c}} \rangle = \langle \epsilon_{11} \, (\cos \underline{\theta})^2 + \epsilon_{22} \, (\sin \underline{\theta})^2 \rangle \, . \tag{12.2.30}$$

The strain energy per unit volume of tissue,

$$\mathcal{W}^{\mathrm{c}}(\boldsymbol{\epsilon}) = n^{\mathrm{c}} \int_{\mathbb{S}^2} w_{\mathrm{c}}(L) \, \frac{d\underline{S}}{4\pi}, \tag{12.2.31}$$

provides the stress of the collagen network,

$$\begin{aligned} \boldsymbol{\sigma}^{\mathrm{c}} &= \frac{\partial \mathcal{W}^{\mathrm{c}}(\boldsymbol{\epsilon})}{\partial \boldsymbol{\epsilon}} \\ &= \int_{\mathbb{S}^2} K^{\mathrm{c}} \, \exp(k_{\mathrm{c}} \, L^2) \, L \, \underline{\mathbf{M}}_{\mathrm{c}} \, \frac{d\underline{S}}{4\,\pi} \\ &= \frac{K^{\mathrm{c}}}{4\,\pi} \int_0^{\pi} d\underline{\theta} \, \sin \underline{\theta} \, \exp(k_{\mathrm{c}} \, L^2) \, L \int_0^{2\pi} d\underline{\phi} \, \underline{\mathbf{M}}_{\mathrm{c}}, \end{aligned} \tag{12.2.32}$$

namely in component form,

$$\sigma^{\mathrm{c}}_{ij} = K^{\mathrm{c}} \int_0^{\pi/2} d\underline{\theta} \, \sin \underline{\theta} \, \exp(k_{\mathrm{c}} \, L^2) \, L \begin{cases} (\cos \underline{\theta})^2, & i = j = 1; \\ (\sin \underline{\theta})^2/2, & i = j = 2, 3; \\ 0, & i \neq j \, . \end{cases} \tag{12.2.33}$$

In order to perform a Gauss-Legendre integration, the stress is cast in the format,

$$\sigma^{\mathrm{c}}_{ij} = K^{\mathrm{c}} \int_0^{1} dx \, \exp(k_{\mathrm{c}} \, L^2) \, L \begin{cases} x^2, & i = j = 1; \\ (1 - x^2)/2, & i = j = 2, 3; \\ 0, & i \neq j \, , \end{cases} \tag{12.2.34}$$

where

$$L = \langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\mathrm{c}} \rangle = \langle \epsilon_{11} \, x^2 + \epsilon_{22} \, (1 - x^2) \rangle \, . \tag{12.2.35}$$

12.2.5 Random planar directional distribution of collagen fibers

The collagen fibers are now assumed to be randomly oriented in the plane 2-3. The unit vector $\underline{\mathbf{m}}_{\mathrm{c}}$ indicating the direction of a collagen fiber is expressed in terms of the angle $\underline{\phi} \in [0,\, 2\,\pi[$,

$$\underline{\mathbf{m}}_{\mathrm{c}} = \begin{bmatrix} 0 \\ \cos\underline{\phi} \\ \sin\underline{\phi} \end{bmatrix} . \tag{12.2.36}$$

Let us record the directional integrations over space directions of the second order tensor $\underline{\mathbf{M}}_{\mathrm{c}} = \underline{\mathbf{m}}_{\mathrm{c}} \otimes \underline{\mathbf{m}}_{\mathrm{c}}$,

$$\int_{\mathbb{S}^1} \underline{\mathbf{m}}_{\mathrm{c}} \otimes \underline{\mathbf{m}}_{\mathrm{c}} \, \frac{d\underline{\phi}}{2\pi} = \int_0^{2\pi} \underline{\mathbf{m}}_{\mathrm{c}} \otimes \underline{\mathbf{m}}_{\mathrm{c}} \frac{d\underline{\phi}}{2\pi} = \frac{\mathbf{I}^{\parallel}}{2} \,, \tag{12.2.37}$$

and of the fourth order tensor $\underline{\mathbf{M}}_{\mathrm{c}} \otimes \underline{\mathbf{M}}_{\mathrm{c}}$,

$$\int_{\mathbb{S}^1} \underline{\mathbf{M}}_{\mathrm{c}} \otimes \underline{\mathbf{M}}_{\mathrm{c}} \, \frac{d\underline{\phi}}{2\pi} = \frac{1}{8} \left(\mathbf{I}^{\parallel} \otimes \mathbf{I}^{\parallel} + 2\, \mathbf{I}^{\parallel} \,\overline{\underline{\otimes}}\, \mathbf{I}^{\parallel} \right) . \tag{12.2.38}$$

Here $\mathbf{I}^{\parallel}$ is the planar second order identity tensor. The expression (12.2.38) results from the component relations,

$$\frac{1}{2\pi} \int_0^{2\pi} \underline{m}_{ci}\, \underline{m}_{cj}\, \underline{m}_{ck}\, \underline{m}_{cl} \, d\underline{\phi} = \begin{cases} 3/8, & i = j = k = l, \\ 1/8, & i = j \neq k = l, \\ 0, & \text{otherwise}\,. \end{cases} \tag{12.2.39}$$

12.2.5.1 Conewise linear stress-strain response of planar collagen fibers

If *all* fibers are in extension, then integration over space directions of the strain energy and of its first and second derivatives,

$$\begin{cases} n^{\mathrm{c}} \displaystyle\int_{\mathbb{S}^1} w_{\mathrm{c}} \, \frac{d\underline{\phi}}{2\pi} \\ n^{\mathrm{c}} \displaystyle\int_{\mathbb{S}^1} \frac{\partial w_{\mathrm{c}}}{\partial \boldsymbol{\epsilon}} \, \frac{d\underline{\phi}}{2\pi} \\ n^{\mathrm{c}} \displaystyle\int_{\mathbb{S}^1} \frac{\partial^2 w_{\mathrm{c}}}{\partial \boldsymbol{\epsilon}\, \partial \boldsymbol{\epsilon}} \, \frac{d\underline{\phi}}{2\pi} \end{cases} = \frac{K^{\mathrm{c}}}{8} \begin{cases} \frac{1}{2} \left(\mathbf{I}^{\parallel} : \boldsymbol{\epsilon} \right)^2 + \boldsymbol{\epsilon} : \boldsymbol{\epsilon} \,, \\ \left(\boldsymbol{\epsilon} : \mathbf{I}^{\parallel} \right) \mathbf{I}^{\parallel} + 2\, \boldsymbol{\epsilon} \,, \\ \mathbf{I}^{\parallel} \otimes \mathbf{I}^{\parallel} + 2\, \mathbf{I}^{\parallel} \,\overline{\underline{\otimes}}\, \mathbf{I}^{\parallel} \,, \end{cases} \tag{12.2.40}$$

yields an isotropic stiffness with equal Lamé moduli,

$$\lambda^{\mathrm{c}} = \mu^{\mathrm{c}} = \frac{K^{\mathrm{c}}}{8} \,, \tag{12.2.41}$$

that is, with a Poisson's ratio equal to 0.25.

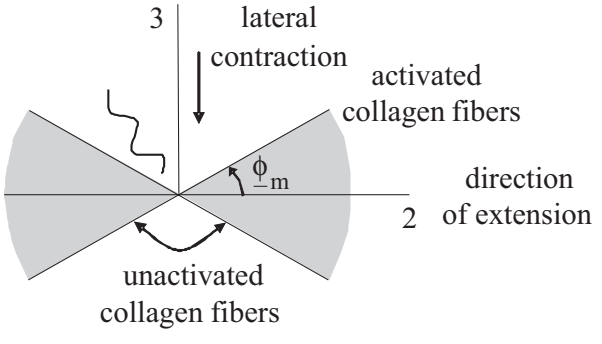

Fig. 12.2.5: Fans of activation of a planar network of collagen fibers in axial extension and lateral contraction.

Let us consider now extension along the direction 2, with symmetry about this axis. Of course, if the transverse directions undergo extension, we recover the isotropic stiffness. If the transverse directions undergo contraction then, the fibers which undergo extension,

$$\boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\rm c} \ \geq 0 \quad \Rightarrow \quad \cot^2 \underline{\phi} = \frac{\underline{m}_{\rm c2}^2}{\underline{m}_{\rm c3}^2} \geq \cot^2 \underline{\phi}_m = \frac{-\epsilon_{33}}{\epsilon_{22}} \,, \tag{12.2.42}$$

form two symmetric cones of half angle $\underline{\phi}_m$ about the extension direction, as shown in Fig. 12.2.5,

$$\underbrace{\underline{\phi} \in [-\underline{\phi}_m, \underline{\phi}_m] \cup [\pi - \underline{\phi}_m, \pi + \underline{\phi}_m]}_{\text{fans of extension}} \,. \tag{12.2.43}$$

In the principal axes of strain, we just need to calculate three components of the stiffness in view of the symmetry about the axis 2. Therefore, the contribution of the collagen network to the total stress expresses in terms of a symmetric matrix,

$$\boldsymbol{\sigma}^{\rm c} = \mathbb{E}^{\rm c}(\boldsymbol{\epsilon}) : \boldsymbol{\epsilon}, \quad \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & E^{\rm c}_{22} & E^{\rm c}_{23} \\ 0 & E^{\rm c}_{32} & E^{\rm c}_{33} \end{bmatrix} \begin{bmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \end{bmatrix} , \tag{12.2.44}$$

with coefficients,

$$\begin{aligned} E^{\rm c}_{22} &= \frac{K^{\rm c}}{16\pi} \left(12\, \underline{\phi}_m + 8\, \sin(2\underline{\phi}_m) + \sin(4\underline{\phi}_m) \right) \\ E^{\rm c}_{33} &= \frac{K^{\rm c}}{16\pi} \left(12\, \underline{\phi}_m - 8\, \sin(2\underline{\phi}_m) + \sin(4\underline{\phi}_m) \right) \\ E^{\rm c}_{23} &= E^{\rm c}_{32} = \frac{K^{\rm c}}{16\pi} \left(4\underline{\phi}_m - \sin(4\underline{\phi}_m) \right) . \end{aligned} \tag{12.2.45}$$

12.2.5.2 Conewise nonlinear stress-strain response of planar collagen fibers

We now return to the energy (12.2.3) in exponential form. For uniaxial traction (symmetry about the axis 2), the activation criterion relies on the elongation L,

$$L = \langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\rm c} \rangle = \langle \epsilon_{22}\, (\cos \underline{\phi})^2 + \epsilon_{33}\, (\sin \underline{\phi})^2 \rangle \,. \tag{12.2.46}$$

The strain energy per unit volume of tissue,

$$\mathcal{W}^{\rm c}(\boldsymbol{\epsilon}) = n^{\rm c} \int_{\mathbb{S}^1} w_{\rm c}(L)\, \frac{d\underline{\phi}}{2\pi}, \tag{12.2.47}$$

provides the stress of the collagen network,

$$\begin{aligned} \boldsymbol{\sigma}^{\rm c} &= \frac{\partial \mathcal{W}^{\rm c}(\boldsymbol{\epsilon})}{\partial \boldsymbol{\epsilon}}, \\ &= \frac{K^{\rm c}}{2\pi} \int_0^{2\pi} d\underline{\phi}\, \exp(k_{\rm c}\, L^2)\, L\, \underline{\mathbf{M}}_{\rm c}, \\ \sigma^{\rm c}_{ij} &= 2\, \frac{K^{\rm c}}{\pi} \int_0^{\pi/2} d\underline{\phi}\, \exp(k_{\rm c}\, L^2)\, L \begin{cases} (\cos \underline{\phi})^2, & i = j = 2; \\ (\sin \underline{\phi})^2, & i = j = 3; \\ 0, & i = 2, j = 3\,. \end{cases} \end{aligned} \tag{12.2.48}$$

In order to perform a Gauss-Legendre integration, the stress is expressed in the format,

$$\sigma^{\rm c}_{ij} = 2\, \frac{K^{\rm c}}{\pi} \int_0^1 \frac{\sqrt{2}\, dx}{\sqrt{1 - \dfrac{x^2}{2}}}\, \exp(k_{\rm c}\, L^2)\, L \begin{cases} (1 - x^2)^2, & i = j = 2; \\ x^2\, (2 - x^2), & i = j = 3; \\ 0, & i = 2, j = 3\,, \end{cases} \tag{12.2.49}$$

where

$$L = \langle \boldsymbol{\epsilon} : \underline{\mathbf{M}}_{\rm c} \rangle = \langle (1 - x^2)^2\, \epsilon_{22} + x^2\, (2 - x^2)\, \epsilon_{33} \rangle \,. \tag{12.2.50}$$

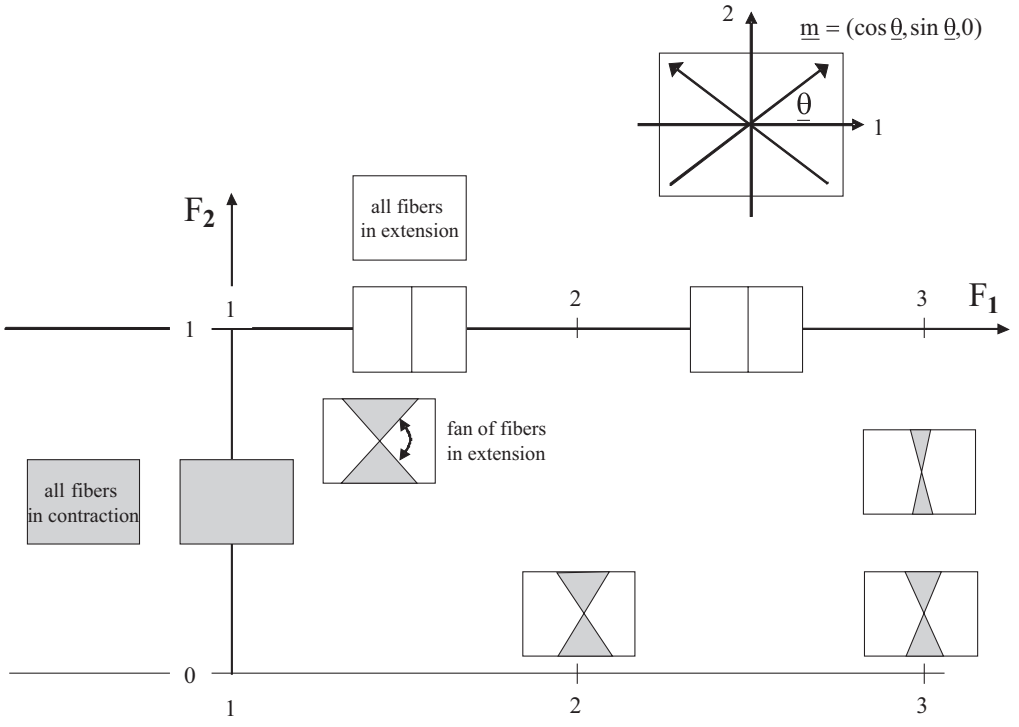

Fig. 12.2.6: Biaxial loading in the plane of the fibers with $F_1 = 1 + \epsilon_1 \geq 1$ and $0 < F_2 = 1 + \epsilon_2 \leq 1$ components of the deformation gradient along the axes (1,2). Close to the reference state, the size of the fans of fibers in extension depends discontinuously on the exact departure from this reference state, namely $\sin \underline{\theta} = 1/\sqrt{1 - \epsilon_2/\epsilon_1}$.

12.2.5.3 Fans in extension: nonlinearity due to progressive fiber recruitment

Assume the material to undergo biaxial extension along the symmetry axes as sketched in Fig. 12.2.6, with $F_1 \geq 1$ and $F_2 \leq 1$ the components of the deformation gradient along these axes. The fibers oriented towards the axis 1 are likely to undergo extension while those along the axis 2 are likely to undergo contraction. The transformed length of a unit segment $\underline{\mathbf{m}} = (\cos \underline{\theta}, \sin \underline{\theta}, 0)$ has square $\ell^2 = \underline{\mathbf{m}} \cdot \mathbf{C} \cdot \underline{\mathbf{m}} = F_1^2 + \sin^2 \underline{\theta}\,(F_2^2 - F_1^2)$. The deformed segments within the fan $(-\underline{\theta}, \underline{\theta})$ with $\sin^2 \underline{\theta} = (F_1^2 - 1)/(F_1^2 - F_2^2)$ have a length greater than 1.

Therefore, at the beginning of a biaxial experiment, the fibers are not all active. The fibers get recruited progressively as the deformation F_1 increases. There is thus a purely geometrical nonlinear response, explaining in part the existence of a toe.

12.3 Directional models of tissues

12.3.1 Directional distribution of collagen fibers in cornea

In some tissues, the directional distribution of collagen fibers is strongly heterogeneous. For example, the corneal stroma and the annulus fibrosus are built by the superposition of lamellae. In each lamella, the fibers are strictly parallel. In the center of the tissues, the fiber directions alternate from one lamella to the other. At the boundaries, the arrangement may not be so regular. More details are provided in Chapter 19.

Perhaps it is appropriate here to highlight the two concepts of spatial heterogeneity and anisotropy. The first step is the choice of a representative elementary volume to which we refer, in a continuum context, as a point. Anisotropy is a pointwise, or local, property. If the size of the RVE is equal to, or smaller than, the width of a lamella, then the material considered can be seen as a fiber reinforced material. It is described as transversely isotropic, the symmetry axis being the fiber direction. If the size of the RVE encompasses two lamellae, the material we consider now is reinforced by two families of fibers which are not parallel: such a material is referred to as clinotropic. Incidentally, note that these two families of fibers may or may not be mechanically equivalent.

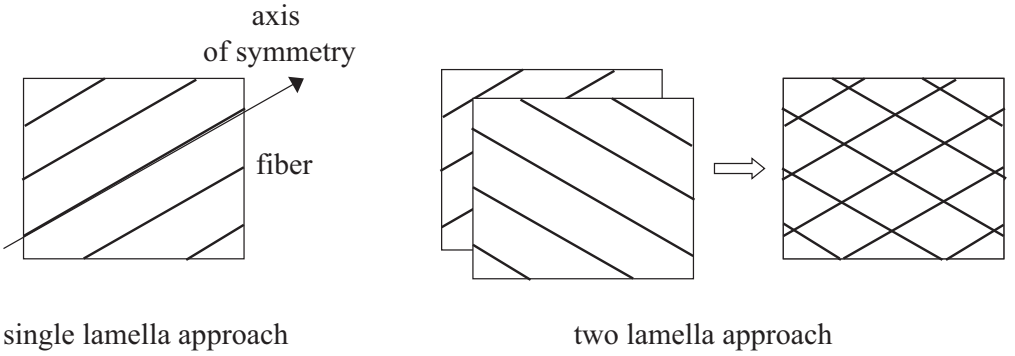

Fig. 12.3.1: The corneal stroma is formed by the superposition of lamellae. The direction of the fiber reinforcement alternates over two adjacent lamellae. In the single lamella approach, the material is transversely isotropic at the lamellar scale, while, in the two lamella approach, it is clinotropic at the associated scale.

As a further example, outside the realm of the corneal structure, one may consider a stack of layers, or deck of cards, which are parallel and individually isotropic. If the RVE encompasses several layers, the material at hand is again transversely isotropic but the symmetry axis is now the normal to the layers. While a fiber reinforced material deforms by shear parallel to the fibers (which define the axis of material symmetry), the deck of cards deforms by shear parallel to the plane of the cards (which is orthogonal to the axis of material symmetry).

When the size of the RVE is equal to, or smaller than, the width of a lamella, a strong spatial heterogeneity is encountered along a path going from one lamella to its neighbor. On the other hand, the spatial heterogeneity along a path connecting two successive RVEs is much smaller when the latter encompasses two lamellae. These two points of view sketched in Fig. 12.3.1 are often referred to respectively as the *single lamella approach* and the *two lamella approach*. As an approximation, it is often assumed that the fibers in the next neighbor lamellae are parallel and mechanically equivalent. Then, in the two lamella approach, no heterogeneity across the depth is encountered.

12.3.2 Continuous planar directional distributions of collagen fibers

While Section 12.2 addresses isotropic directional distributions of collagen fibers, here are instances of non isotropic distributions specifically tailored to lamellar tissues. Emphasis is laid on three points:

- the directional distribution describing the alternate directions of adjacent lamellae, including some dispersion;
- the change of the directional distribution in the plane of the cornea from the corneal center to the periphery;
- the depth dependence along the corneal axis from the anterior side to the posterior side.

As a typical instance along this line, Pinsky et al. [2005] start from the lamellar energy and deduce the stromal energy by a directional planar distribution of fibers. For that purpose, they define a projection plane $\underline{x}-\underline{y}$ orthogonal to the corneal axis $\underline{z}$. At a point $\underline{\mathbf{x}}$, the probability to have a fiber in the direction $\underline{\theta}$ is denoted by $\mathcal{D}(\underline{\mathbf{x}},\underline{\theta})$. The stromal energy is contributed by the matrix energy which depends on the point through the local mechanical properties and the local strain and by the fibril energy which depends in addition on the fibril direction,

$$\underline{\mathcal{W}}_{\text{stroma}} = \underline{\mathcal{W}}_{\text{matrix}}(\underline{\mathbf{x}}) + \int_0^{\pi} \underline{\mathcal{W}}_{\text{fibril}}(\underline{\mathbf{x}},\underline{\theta})\,\mathcal{D}(\underline{x},\underline{y},\underline{\theta})\,d\underline{\theta}\,. \tag{12.3.1}$$

In a polar coordinate system $(\underline{x},\underline{y}) \to (R,\underline{\phi})$, the probability density function $\mathcal{D}$ adopts the format of a sort of normal distribution,

$$\mathcal{D}(R,\underline{\phi},\underline{\theta}) = \frac{1}{\pi}\begin{cases} \big(\cos\underline{\theta}\big)^{2n} + \big(\sin\underline{\theta}\big)^{2n} + c_1, & 0 \le R \le 4, \\ \big(\sin(\underline{\theta}-\underline{\phi})\big)^{2n} + c_2, & 5.5 \le R \le 6.5, \end{cases} \tag{12.3.2}$$

where c_1 and c_2 are such that the cumulative distribution function $D(R,\underline{\phi},\underline{\theta}) = \int_0^{\underline{\theta}} \mathcal{D}(R,\underline{\phi},\theta)\,d\theta$ satisfies the consistency condition $D(R,\underline{\phi},\pi) = 1$. The complete relation for the radius R [unit : mm] over $]4,5.5]$ and $]6.5,8]$ ensures a smooth transition from an orthogonal to a tangential fibril distribution. A planar isotropic density is retrieved for the exponent n equal to 0. Higher values of n increase the non uniformity of the angular fibril distribution. A value of $n = 4$ is found to fit best the data by Aghamohammadzadeh et al. [2004].

A general comparison of discrete and continuous directional distributions of fibers is exposed in Bischoff [2006]. He delineates the single lamellar approach and the multilamellar approach that are characterized by unimodal

distributions and bimodal distributions, respectively. The considered distribution densities are a priori non planar and expressed as $\mathcal{D} = \mathcal{D}(\underline{\theta}, \underline{\phi})$ in spherical coordinates. However the examples that are worked out are independent of $\underline{\phi}$ and symmetric in $\underline{\theta}$ over the range $-\pi/2 \le \underline{\theta} \le \pi/2$. Typically unimodal normal distribution densities centered around $\underline{\theta}_0$ and with standard deviation σ adopt the format,

$$\frac{\mathcal{D}(\underline{\theta})}{\mathcal{D}_N} = \frac{1}{\sigma\sqrt{2\pi}} \exp\Big(- \frac{(\underline{\theta} - \underline{\theta}_0)^2}{(\sqrt{2}\,\sigma)^2}\Big), \quad \int_{-\pi/2}^{\pi/2} \mathcal{D}(\underline{\theta})\, d\underline{\theta} = 1\,, \tag{12.3.3}$$

where

$$\int_{\underline{\theta}_0 - \infty}^{\underline{\theta}_0 + \infty} \frac{\mathcal{D}(\underline{\theta})}{\mathcal{D}_N}\, d\underline{\theta} = 1, \quad \int_{\underline{\theta}_0 - \sigma}^{\underline{\theta}_0 + \sigma} \frac{\mathcal{D}(\underline{\theta})}{\mathcal{D}_N}\, d\underline{\theta} = 0.683, \quad \frac{1}{\mathcal{D}_N} = \frac{1}{2}\Big(\mathrm{erf}\big(\frac{\pi/2 - \underline{\theta}_0}{\sqrt{2}\,\sigma}\big) + \mathrm{erf}\big(\frac{\pi/2 + \underline{\theta}_0}{\sqrt{2}\,\sigma}\big)\Big)\,. \tag{12.3.4}$$

For bimodal normal distribution densities centered around the angles $\underline{\theta}_1$ and $\underline{\theta}_2 > \underline{\theta}_1$,

$$\frac{\mathcal{D}(\underline{\theta})}{\mathcal{D}_N} = \frac{1}{\sigma\sqrt{2\pi}} \exp\Big(- \frac{(\underline{\theta} - \underline{\theta}_1)^2}{(\sqrt{2}\,\sigma)^2}\Big) + \frac{1}{\sigma\sqrt{2\pi}} \exp\Big(- \frac{(\underline{\theta} - \underline{\theta}_2)^2}{(\sqrt{2}\,\sigma)^2}\Big), \quad \int_{-\pi/2}^{\pi/2} \mathcal{D}(\underline{\theta})\, d\underline{\theta} = 1\,, \tag{12.3.5}$$

where

$$\int_{\underline{\theta}_1 - \infty}^{\underline{\theta}_2 + \infty} \frac{\mathcal{D}(\underline{\theta})}{\mathcal{D}_N}\, d\underline{\theta} = 2, \quad \frac{1}{\mathcal{D}_N} = \frac{1}{2}\Big(\mathrm{erf}\big(\frac{\pi/2 - \underline{\theta}_1}{\sqrt{2}\,\sigma}\big) + \mathrm{erf}\big(\frac{\pi/2 + \underline{\theta}_1}{\sqrt{2}\,\sigma}\big) + \mathrm{erf}\big(\frac{\pi/2 - \underline{\theta}_2}{\sqrt{2}\,\sigma}\big) + \mathrm{erf}\big(\frac{\pi/2 + \underline{\theta}_2}{\sqrt{2}\,\sigma}\big)\Big)\,. \tag{12.3.6}$$

Li and Tighe [2006]b use an angular distribution density around the angles 0° and 90° defined by three parameters, namely N_t the total number of lamellae, N_c a normalizing constant and C a constant affecting the pattern of the distribution. The number of lamellae around the angle $\underline{\theta}$ is defined in an exponential format,

$$N(\underline{\theta}) = \begin{cases} \mathrm{int}\left\{ \dfrac{N_t}{2N_c} \exp(-\dfrac{\underline{\theta}^2}{C}) \right\}, & |\underline{\theta}| \le \pi/4, \\ \mathrm{int}\left\{ \dfrac{N_t}{2N_c} \exp(-\dfrac{(\underline{\theta} - \pi/2)^2}{C}) \right\}, & |\underline{\theta} - \pi/2| \le \pi/4, \end{cases} \tag{12.3.7}$$

where the operator 'int' means integer part of its argument.

Note that the distribution densities above actually refer to a reference configuration and the directional integrations are performed with respect to this configuration.

12.3.3 A directional model of active rod-like cells

In a series of papers, Zahalak and co-workers present experimental results and propose models of tissues reconstituted from cells and ECM that aim to simulate natural tissues, in particular their mechanical changes during development and wound healing. Zahalak et al. [2000] address the mechanical behavior of a tissue composed of a matrix interspersed with fibroblasts. Cells with generic direction $\mathbf{m}$ are oriented spatially according to the directional distribution density $\mathcal{D}(\mathbf{m})$. The overall viscoelastic properties of the tissue matrix-contractile cells composite derive from the basic assumptions below:

- the total stress $\boldsymbol{\sigma}$ is the sum of the matrix and cell stresses, $\boldsymbol{\sigma}^M$ and $\boldsymbol{\sigma}^C$, respectively;
- the strain is homogeneous in the matrix and cells, and equal to the macroscopic strain $\boldsymbol{\epsilon}$. The fact that, at high cell density, cells tend to form a continuum suggests that the assumption is acceptable;
- the cells and the ECM are viscoelastic. The ECM stress is defined by Fung's quasi-linear viscoelastic model, which is detailed in Section 8.6;
- the cells (fibroblasts) are rods, developing active contractile forces, characterized mechanically by a Hill muscle model.

The cells behave as rods of initial length l_0 and section S_0. The force F each of them can sustain is aligned with their direction $\mathbf{m}$ and its intensity depends on length change $l/l_0 - 1$ which may be expressed via the strain $\boldsymbol{\epsilon}$ as $\boldsymbol{\epsilon} : (\mathbf{m} \otimes \mathbf{m})$. Let N_C be the number of cells in the reference volume V_0. Then the stress they carry is obtained by integration over the unit sphere,

$$\boldsymbol{\sigma}^C = \frac{N_C}{V_0}\, l_0 \int_{\mathbb{S}^2} \mathbf{m} \otimes \mathbf{m}\; F(\mathbf{m} \cdot \boldsymbol{\epsilon} \cdot \mathbf{m})\; \mathcal{D}(\mathbf{m})\; dS\,. \tag{12.3.8}$$

In fact, based on their background, Zahalak et al. [2000] consider that the elongated cells behave mechanically as muscle cells, which are described by a passive elasticity (PE) in parallel with a branch containing in series an elastic element (SE) and a contractile viscous element (CE), as sketched in Fig. 8.6.1 where the notation is displayed. The intensity of the contractile force is actually related to the concentration of a diffusible stimulant/activator like bovine serum. Note that the matrix phase is not present in muscles.

Let F_P and F_A be the forces acting respectively on the passive branch and active branch of the parallel model, and F_0 be the isometric contractile force. In linearized form,

$$F_P = E_P\,(l - l_0), \quad F_A = E_S\,(l_{SE} - l_{SE0}), \quad \frac{d}{dt} l_{CE} = \frac{1}{\eta_C}\,(F_A - F_0)\,, \tag{12.3.9}$$

with η_C cell's viscosity, that may also be cast as the product of a relaxation time τ_C and of the Young's modulus E_S, and

$$F = F_P + F_A, \quad l = l_{SE} + l_{CE}\,. \tag{12.3.10}$$

Combining these relations yields a first order differential equation linking the force F acting over the cell to its length l,

$$\frac{dF}{dt} + \frac{F}{\tau_C} = \frac{F_0}{\tau_C} + l_0(E_S + E_P)\frac{d}{dt}\frac{l}{l_0} + \frac{l_0\,E_P}{\tau_C}(\frac{l}{l_0} - 1)\,. \tag{12.3.11}$$

The tissue fabric is assumed not to change, or equivalently, no re-structuration takes place. Since $l/l_0 - 1 = \boldsymbol{\epsilon} : (\mathbf{m} \otimes \mathbf{m})$, integration over cells of the above differential equation provides now a first order differential equation linking the cell stress $\boldsymbol{\sigma}^C$ and the strain $\boldsymbol{\epsilon}$,

$$\frac{d\boldsymbol{\sigma}^C}{dt} + \frac{\boldsymbol{\sigma}^C}{\tau_C} = \frac{3\sigma_0}{\tau_C}\mathbf{A} + \Big(\kappa\frac{d}{dt} + \frac{\omega}{\tau_C}\Big)\,\mathbf{B} : \boldsymbol{\epsilon}, \tag{12.3.12}$$

with $\sigma_0 = (N_C/V_0)\,l_0\,F_0/3$, $\kappa = (N_C/V_0)\,l_0^2(E_S + E_P)$, $\omega = (N_C/V_0)\,l_0^2\,E_P$, and $\mathbf{A}$ and $\mathbf{B}$ respectively second order and fourth order fabric tensors,

$$\mathbf{A} = \int_{\mathbb{S}^2} \mathbf{m}\otimes\mathbf{m}\;\mathcal{H}(\mathbf{m}\cdot\boldsymbol{\epsilon}\cdot\mathbf{m})\,\mathcal{D}(\mathbf{m})\;dS, \quad \mathbf{B} = \int_{\mathbb{S}^2} \mathbf{m}\otimes\mathbf{m}\otimes\mathbf{m}\otimes\mathbf{m}\;\mathcal{H}(\mathbf{m}\cdot\boldsymbol{\epsilon}\cdot\mathbf{m})\,\mathcal{D}(\mathbf{m})\;dS\,, \tag{12.3.13}$$

where $\mathcal{H}$ denotes the Heaviside step function. When the cell directional distribution is isotropic, the fabric tensors simplify as indicated in Section 12.2.2. The stress can be expressed in integral form,

$$\boldsymbol{\sigma}^C(t) - \boldsymbol{\sigma}^C(-\infty) = \int_{-\infty}^{t} e^{-(t-u)/\tau_C}\,\Big(\frac{3\sigma_0}{\tau_C}\mathbf{A}(u) + \Big(\kappa\frac{d}{du} + \frac{\omega}{\tau_C}\Big)\,\mathbf{B}(u) : \boldsymbol{\epsilon}(u)\Big)\;du\,, \tag{12.3.14}$$

its reference value $\boldsymbol{\sigma}^C(t = -\infty)$ presumably vanishing.

In a similar approach that does not refer to hyperelasticity, Sacks [2003] calculates the stress along the scheme (12.3.8) by integrating over space the uniaxial contribution of each fiber of planar collagenous tissues. Still, his analysis does not involve rate effects.

12.4 The mechanical response of individual fibers

12.4.1 The toe region, nonlinearity and fiber uncrimping

Fiber activation is considered by Lanir [1979], [1983] via the *uncrimping strain*[12.2 12.3]. His analysis is used in particular by Sacks [2003] and Bischoff [2006].

[12.2] Miyazaki and Hayashi [1999] isolate individual fibers (1 µm in diameter) from fascicles (300 µm in diameter). While the individual fibers show almost linear behavior, the fascicles and bulk tendons where the fibrils and fibers are crimped display a toe region. A mechanical isolation method of fibers was observed not to introduce damage, and preferred to enzymatic digestion.

[12.3] From the tensile experiments of Kempson et al. [1973] on articular cartilages, Silver and Bradica [2002] deduce *linear* stress-strain curves for strains larger than a few percent both in the direction of the fibrils and in the orthogonal direction, with a modulus linking the axial strain and stress of about 7 GPa and 2 GPa, respectively. They indicate that the former value is similar to that of tendons of rat and turkey and twice that of skin.

Let L_0, L_s and L be respectively the initial (crimped), straightened (taut) and actual fiber lengths. The fiber becomes stretched when its length L reaches the value L_s. With the stretch ratios,

$$\frac{L}{L_0} = \frac{L}{L_s} \times \frac{L_s}{L_0} \quad \Leftrightarrow \quad \lambda = \lambda_f \, \lambda_s \,, \tag{12.4.1}$$

are associated the strains $E = (\lambda^2 - 1)/2$, $E_f = (\lambda_f^2 - 1)/2$ and $E_s = (\lambda_s^2 - 1)/2$ which are linked together,

$$2\,(E - E_s) = \lambda^2 - \lambda_s^2 = \lambda_s^2\,(\lambda_f^2 - 1) = 2\,E_f\,(1 + 2\,E_s)\,. \tag{12.4.2}$$

The nonlinear response under tension is wholly attributed to the progressive fiber recruitment, that is, uncrimping. The load necessary to reach uncrimping is considered negligible. In other words, the response is linear once all the fibers are uncrimped. Thus the fiber stress is taken as a linear function of the strain $\langle E_f \rangle$,

$$\sigma_f = K\,\langle E_f \rangle\,, \tag{12.4.3}$$

where K is the fiber modulus.

The stretch at which the fiber uncrimps is described by a probability density function $\mathcal{P}(E_s)$. Sacks [2003] and Bischoff [2006] use the Gamma function,

$$\mathcal{P}(E_s) = \frac{1}{\beta}\,\frac{1}{\Gamma(\alpha)}\,\Big(\frac{E_s}{\beta}\Big)^{\alpha-1}\,\exp(-\frac{E_s}{\beta})\,, \tag{12.4.4}$$

with α and β positive parameters, and $\Gamma(\alpha) = \int_0^\infty \exp(-x)\,x^{\alpha-1}\,dx$ the Gamma function. The density function $\mathcal{P}$ has mean value $\int_0^\infty E_s\,\mathcal{P}(E_s)\,dE_s = \alpha\,\beta$ and standard deviation $\int_0^\infty (E_s - \alpha\,\beta)^2\,\mathcal{P}(E_s)\,dE_s = \alpha\,\beta^2$. The density function $\mathcal{P}(E_s)$ vanishes at $E_s = 0$ and at $E_s = \infty$. It has a maximum $(\alpha-1)^{\alpha-1}\,\exp(1-\alpha)/\beta/\Gamma(\alpha)$ inversely proportional to β at a strain $E_s = \beta\,(\alpha - 1)$ proportional to β.

Sverdlik and Lanir [2002] use a beta probability density function, and Hurschler et al. [2003] a Weibull probability density function,

$$\mathcal{P}(\lambda_s) = \mathcal{H}(\frac{\lambda_s - \gamma}{\delta})\;\frac{\beta}{\delta}\,\Big(\frac{\lambda_s - \gamma}{\delta}\Big)^{\beta-1}\,\exp\Big(-(\frac{\lambda_s - \gamma}{\delta})^\beta\Big)\,, \tag{12.4.5}$$

defined by three parameters: $\beta > 0$ and $\delta > 0$ are shape and scale parameters related to the toe, $\gamma > 0$ is the *location parameter*, that is the stretch at which the first fiber begins to bear load. The cumulative distribution function associated with the Weibull distribution density,

$$P(\lambda) = \int_\gamma^\lambda \mathcal{P}(\lambda_s)\,d\lambda_s = 1 - \exp\Big(-(\frac{\lambda - \gamma}{\delta})^\beta\Big) \in [0, 1[\,, \tag{12.4.6}$$

represents the percentile of fibers that carry load. Note that this relation can be inverted, yielding the stretch for which a given percentile of fibers is under load.

The stress contributed by a collagen fiber is

$$\sigma(E) = \int_0^E \sigma_f(\langle E_f \rangle)\,\mathcal{P}(E_s)\,dE_s\,, \tag{12.4.7}$$

or, for Hurschler et al. [2003],

$$\sigma(\lambda) = \mathcal{H}(\lambda - \gamma)\;\int_\gamma^\lambda \sigma_f(\lambda_f)\,\mathcal{P}(\lambda_s)\,d\lambda_s\,. \tag{12.4.8}$$

The extraction of the parameters and reference length for 'slack' (crimped) and preloaded fibers is discussed in Hurschler et al. [2003]. Given that the parameters characterize the toe region, a too large pre-load decreases their accuracy and significance. Additional information on small-deformation modulus of calf skin may be found in Kronick [1988].

The analysis is extended to include viscous effects by assuming a time-dependent straightened length L_s in e.g., Sverdlik and Lanir [2002] and de Vita and Slaughter [2006].

Coupled with a fiber directional distribution $\mathcal{D}(\underline{\mathbf{m}}_\mathrm{c})$, the collagen stress $\underline{\underline{\boldsymbol{\tau}}}^\mathrm{c}(\mathbf{E}_\mathrm{G})$ at the overall strain $\mathbf{E}_\mathrm{G}$ has the tensor form,

$$\underline{\underline{\boldsymbol{\tau}}}^\mathrm{c}(\mathbf{E}_\mathrm{G}) = n^\mathrm{c}\,\int_{\mathbb{S}^2}\,\underline{\mathbf{m}}_\mathrm{c} \otimes \underline{\mathbf{m}}_\mathrm{c}\;\sigma\big(E(\mathbf{E}_\mathrm{G}, \underline{\mathbf{m}}_\mathrm{c})\big)\;\mathcal{D}(\underline{\mathbf{m}}_\mathrm{c})\;dS\,, \tag{12.4.9}$$

where n^c is the collagen volume fraction. More generally, this formula can be extended to account for a strain energy $\underline{\mathcal{W}}_\mathrm{c} = \underline{\mathcal{W}}_\mathrm{c}(\mathbf{E}_\mathrm{G}, \underline{\mathbf{m}}_\mathrm{c})$ expressed in terms of anisotropic scalar invariants,

$$\underline{\underline{\boldsymbol{\tau}}}^\mathrm{c}(\mathbf{E}_\mathrm{G}) = n^\mathrm{c}\,\int_{\mathbb{S}^2}\,\frac{\partial \underline{\mathcal{W}}_\mathrm{c}}{\partial \mathbf{E}_\mathrm{G}}(\mathbf{E}_\mathrm{G}, \underline{\mathbf{m}}_\mathrm{c})\;\mathcal{D}(\underline{\mathbf{m}}_\mathrm{c})\;dS\,. \tag{12.4.10}$$

12.4.2 Intrinsic viscous behavior of collagen fibrils

Time dependence of the mechanical response of soft tissues emanates from several sources. A first source is due to the fact that soft tissues are fluid saturated. Another source is the intrinsic viscous response of collagen fibers. The latter has been analyzed for various tissues where it is expected to play a key role, e.g., muscles and tendons. It has been also considered for cornea and articular cartilages.

Boyce et al. [2007] detect a rate-dependent response in bovine cornea submitted to various stress rates. For the same axial stress of 400 kPa, the strain is equal to 0.05 for a stress rate of 3.5 kPa/s and to 0.04 for a stress rate of 350 kPa/s. A quasi-linear viscous stress-strain constitutive model (QLV) is used in an attempt to display the observed rate-dependency. Specifically, the stress response is assumed in the form (8.3.33),

$$\underline{\underline{\boldsymbol{\tau}}}(t) = \underline{\underline{\boldsymbol{\tau}}}^{\mathrm{e}}(t) + \int_0^t \frac{dE_r}{dt}(t-u)\, \underline{\underline{\boldsymbol{\tau}}}^{\mathrm{e}}(u)\, du\,, \tag{12.4.11}$$

in terms of the reduced relaxation function $E_r(t)$ defined by (8.5.10), namely

$$E_r(t) = \frac{1 + a_v\,(E_1(t/\tau_2) - E_1(t/\tau_1))}{1 + a_v\,\mathrm{Ln}\,(\tau_2/\tau_1)}\,, \tag{12.4.12}$$

with $E_1(t) = \int_t^\infty \exp(-u)/u\, du$, a_v a dimensionless positive constant and τ_1 and τ_2 two relaxation times. As an alternative choice that also ensures the consistency condition $E_r(0) = 1$, one may consider the expression,

$$E_r(t) = \frac{a_{v0} + a_{v1}\,\exp(-t/\tau_1) + a_{v2}\,\exp(-t/\tau_2)}{a_{v0} + a_{v1} + a_{v2}}\,, \tag{12.4.13}$$

with a_{v0}, a_{v1} and a_{v2} dimensionless positive constants.

The elastic response $\underline{\underline{\boldsymbol{\tau}}}^{\mathrm{e}} = 2\,\partial\underline{\mathcal{W}}/\partial\mathbf{C}$ follows from the energy decomposition (12.3.1). The matrix energy is isotropic neo-Hookean as indicated by (6.4.7),

$$\underline{\mathcal{W}}_{\mathrm{matrix}} = \frac{\mu}{2}\,(\mathrm{tr}\,\mathbf{C} - 3) + \frac{\mu}{2\,\gamma}\left((\det\mathbf{C})^{-\gamma} - 1\right), \tag{12.4.14}$$

with μ a constant stiffness and $\gamma > 0$ a positive exponent. The strain energy of individual fibrils is integrated over space directions as indicated by (12.3.1) with the fibril energy $\underline{\mathcal{W}}_{\mathrm{fibril}}$ in a format slightly modified with respect to (19.19.72) through the introduction of the material parameter β,

$$\underline{\mathcal{W}}_{\mathrm{fibril}}(I_4 = \mathbf{C} : \underline{\mathbf{M}}_{\mathrm{c}}) = \alpha\left(\exp(\beta(I_4 - 1)) - \beta\, I_4\right). \tag{12.4.15}$$

For cornea strips, Boyce et al. [2007] obtain the following elastic parameters, namely $\mu = 10$ kPa, $\alpha = 2.32$ kPa, $\beta = 30.4$, $\gamma = 0.49$, and the viscoelastic parameters are listed in Table 8.5.1.

12.5 Fabric tensors

A number of physical properties involve not only scalars, but also vectors and tensors of various orders. Indeed, at any point of a material, or biological tissue, the thermal, hydraulic and elastic properties may depend on the space direction. A proper model traces these directional properties back to the microstructure at a certain length scale. Fabric tensors aim at representing the heterogeneous directional features that give rise to anisotropy at a larger scale.

12.5.1 Elementary examples of fabric tensors

Instead of the familiar *structural* anisotropy defined in terms of planes and axes of symmetry, the anisotropic character of the mechanical and transport properties may be defined by a traceless symmetric second order tensor $\mathbf{G}$. This tensor is a fabric tensor, namely a macroscopic description of microstructural features,

$$\text{microstructural properties} \xrightarrow{\mathbf{G}} \text{macroscopic level}$$

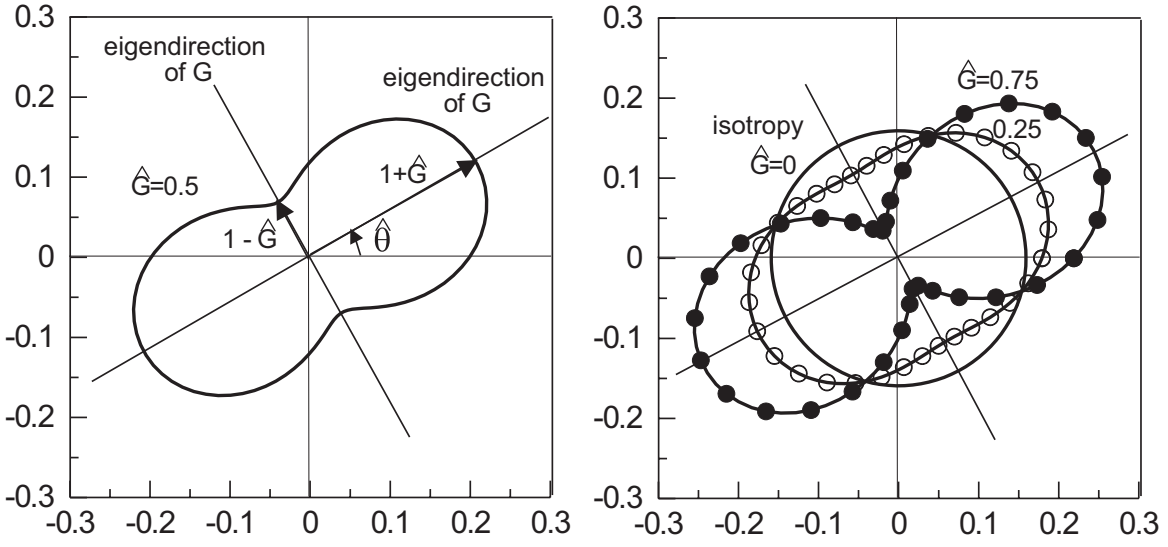

Fig. 12.5.1: 2D representation of the directional distribution density $D(\mathbf{m})$, Eqn (12.5.2), for $\hat{\theta} = \pi/6$, $\hat{G} = 0,\ 0.25,\ 0.5,\ 0.75$. The isotropic reference corresponds to $\hat{G} = 0$.

such as the directional distribution of contact forces in granular materials, Oda et al. [1982], or of damage in the form of continuously distributed voids or micro-cracks, Valanis [1990], or the average distance between two interfaces of a constituent in a composite material such as bone, Harrigan and Mann [1984].

In Section 5.2.11, an anisotropic elastic model based on such a fabric tensor is shown to be a special case of orthotropic elasticity. The eigendirections of the fabric tensor fix the orthotropy directions of the elastic properties and its eigenvalues are related to the directional heterogeneity of the elastic moduli.

In a stereological analysis of a scalar quantity $\mathcal{D}(\mathbf{m})$, directionally dependent but symmetric with respect to the origin, $\mathcal{D}(-\mathbf{m}) = \mathcal{D}(\mathbf{m})$, the fabric tensor defines the spherical harmonics of order 2,

$$\mathcal{D}(\mathbf{m}) = \mathcal{D}_0 + \mathbf{m} \cdot \mathbf{G} \cdot \mathbf{m}, \tag{12.5.1}$$

where $\mathcal{D}_0$ is the unweighted average of $\mathcal{D}$. The fabric tensor is required to be a deviator (or traceless tensor) so as to ensure the independence, or orthogonality in a certain sense, of the terms in the series.

In a plane, the directional distribution (12.5.1) may be recast in the format,

$$D(\mathbf{m}) = \frac{1}{2\,\pi}[1 + \hat{G}\cos(2(\theta - \hat{\theta}))] \tag{12.5.2}$$

If the distribution is isotropic, then $\hat{G} = 0$. Since the second order tensor $\mathbf{G}$ is traceless and symmetric, its eigenvalues are defined by a single scalar, say $\hat{G}$, with $-1 \le \hat{G} \le 1$, and its eigenvectors by a single angle, say $\hat{\theta}$, Fig. 12.5.1. The extrema of $2\,\pi\,\mathcal{D}(\mathbf{m})$, namely $1 \pm \hat{G} \in [0, 2]$, are reached along the orthogonal eigendirections of $\mathbf{G}$.

How does this type of anisotropy affect the physical properties of materials? As an illustration, Section 5.2.11 explores the implications for elastic properties. Section 12.5.2 below introduces finer descriptions that involve higher harmonics of even order, and accompanying traceless tensors of like orders.

Data of various physical origins help capture the notion of fabric tensors:

- in order to characterize the evolving anisotropy in granular materials, Bathurst and Rothenburg [1990] sample the directional distribution of contact normals at three stages, namely in the initial isotropic assembly of elliptical particles, after biaxial compression and after shearing;
- Nakayama et al. [1996] consider plates of thickness e which are perforated along a regular rectangular grid by cylindrical voids of diameter d. The plate can be covered by the repetition along the axes of the unit cell shown in Fig. 12.5.2. Let $\mathbf{e}_i$, $i \in [1, 2]$, be the axes of the perforation, $\mathbf{e}_3$ be the normal to the plate, and Ω_i be the surface ratio along a plane of normal $\mathbf{e}_i$, $i \in [1, 3]$,

$$\Omega_1 = \frac{d\,e}{2\,L_2\,e} = \frac{1}{2}\,\frac{d}{L_2}\,, \quad \Omega_2 = \frac{d\,e}{2\,L_1\,e} = \frac{1}{2}\,\frac{d}{L_1}\,, \quad \Omega_3 = \frac{\pi\,(d/2)^2\,e}{(2\,L_1)\,(2\,L_2)\,e} = \frac{\pi}{16}\,\frac{d^2}{L_1\,L_2}\,. \tag{12.5.3}$$

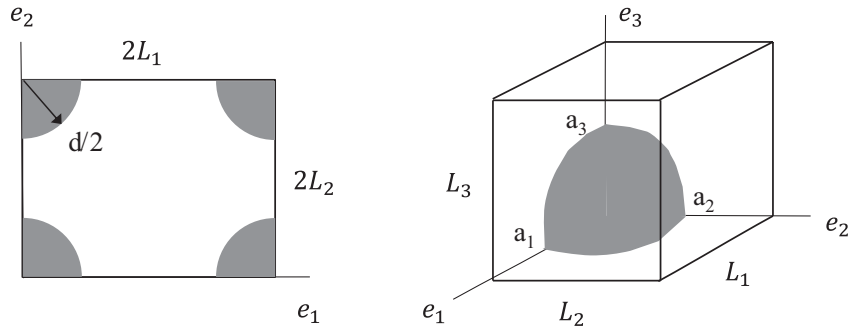

Fig. 12.5.2: Illustration of the notion of fabric tensors on a representative elementary volume ("unit cell") of perforated plates and porous solids.

A fabric tensor $\mathbf{B}$ may be defined from the 'damage' tensor $\mathbf{\Omega} = \sum_{i=1}^{3} \Omega_i \, \mathbf{e}_i \otimes \mathbf{e}_i$ as follows:

$$\mathbf{B} = g\,\mathbf{I} + \operatorname{dev}\mathbf{\Omega}, \quad g^2 = 1 - \frac{1}{3}\operatorname{dev}\mathbf{\Omega} : \operatorname{dev}\mathbf{\Omega}\,, \tag{12.5.4}$$

with the normalization $\operatorname{tr}\mathbf{B}^2 = 3$.

- For a three-dimensional solid with elliptical voids along three orthogonal directions, the eigenvalues of the damage tensor read, Nagaki et al. [1993],

$$\Omega_1 = \frac{\pi}{4}\,\frac{a_2\,a_3}{L_2\,L_3}\,, \quad \Omega_2 = \frac{\pi}{4}\,\frac{a_1\,a_3}{L_1\,L_3}\,, \quad \Omega_3 = \frac{\pi}{4}\,\frac{a_1\,a_2}{L_1\,L_2}\,. \tag{12.5.5}$$

12.5.2 Higher order fabric tensors

Consider $\pm\mathbf{m}^{(1)}$, $\pm\mathbf{m}^{(2)}$, $\cdots$ $\pm\mathbf{m}^{(N)}$ to be N observed data in the form of unit vectors. In order to characterize these raw data, various moments and directional distribution functions may be defined along the terminology of the seminal work of Kanatani [1984] of which the following section provides a brief summary. These representations are invariant with respect to coordinate transformations and, due to the assumed symmetry with respect to the origin, they involve only even tensors. Although the directional dependence of a typical distribution function f is denoted by $f(\mathbf{m})$, it should be understood as $f(\mathbf{m}\otimes\mathbf{m})$ in view of the symmetry with respect to the origin.

Three kinds of fabric tensors of arbitrary ranks are considered. While the actual data $\mathcal{M}$ collected in the tensors of first kind are irregular, the fabric tensors of second kind and third kind propose smoother directional distributions. The former tensors are based on a single rank. At variance, the tensors of the third kind involve several ranks and they are especially tailored to further refinements of higher ranks. Much like in Fourier series, estimating the coefficients involved in these approximations in terms of the actual data $\mathcal{M}$ requires an inversion of the formulas.

12.5.2.1 Fabric tensors of the first kind

The moment tensor, or fabric tensor, of the first kind and even rank n,

$$\mathcal{M}_{i_1 i_2 \cdots i_n} = \frac{1}{N}\sum_{\alpha=1}^{N} m_{i_1}^{(\alpha)}\, m_{i_2}^{(\alpha)} \cdots m_{i_n}^{(\alpha)} = \int_{\mathbb{S}^2} m_{i_1}\, m_{i_2} \cdots m_{i_n}\, \mathsf{d}(\mathbf{m})\, dS\,, \tag{12.5.6}$$

is symmetric under exchange of any two indices. The trace of $\mathcal{M}_{i_1 i_2 \cdots i_n}$ obtained by contracting indices pairwise is equal to 1 so that the actual distribution function $\mathsf{d}(\mathbf{m})$ is normalized[12.4],

$$\int_{\mathbb{S}^2} \mathsf{d}(\mathbf{m})\, dS = 1\,. \tag{12.5.7}$$

[12.4] The sum (12.5.6) extends over the N data α of the sample. The task of performing the integration over the unit sphere of the right-hand side of (12.5.6) is considered in Section 12.1.2.

This sample mean is of course distinct from the *unweighted* average obtained by integration over the unit sphere,

$$\frac{1}{4\,\pi}\int_{\mathbb{S}^2} m_{i_1}\,m_{i_2}\,\cdots\,m_{i_n}\,dS\,. \tag{12.5.8}$$

In place of the algebraic sum (12.5.6), one may think to express the directional information via a distribution function, the prototype being the Dirac delta function,

$$\mathsf{d}(\mathbf{m})=\frac{1}{N}\sum_{\alpha=1}^{N}\delta(\mathbf{m}-\mathbf{m}^{(\alpha)}),\quad \int_{\mathbb{S}^2}\mathsf{d}(\mathbf{m})\,dS=1,\quad \int_{\mathbb{S}^2} m_{i_1}\,m_{i_2}\cdots m_{i_n}\,\mathsf{d}(\mathbf{m})\,dS=\mathcal{M}_{i_1i_2\cdots i_n}\,. \tag{12.5.9}$$

Note the expression of the Dirac distribution in spherical coordinates, $\delta(\mathbf{m}-\mathbf{m}^{(\alpha)})=\delta(\theta-\theta^{(\alpha)})\,\delta(\phi-\phi^{(\alpha)})/\sin\theta^{(\alpha)}$.

12.5.2.2 Fabric tensors of the second kind

Instead of the actual distribution $\mathsf{d}(\mathbf{m})$ which is very irregular, alternative descriptions of the observed data derive by smoothing. As an example, mimicking a truncated Fourier expansion, let

$$\mathcal{D}(\mathbf{m})=\frac{1}{4\,\pi}\left(E_0+E_{i_1i_2}\,m_{i_1}\,m_{i_2}+\cdots+E_{i_1i_2\cdots i_n}\,m_{i_1}\,m_{i_2}\cdots m_{i_n}\right). \tag{12.5.10}$$

The approximation $\mathcal{D}(\mathbf{m})$ to $\mathsf{d}(\mathbf{m})$ is defined in the sense of the method of least squares, that is, the coefficients of $\mathcal{D}(\mathbf{m})$ are chosen so as to minimize the integral,

$$\int_{\mathbb{S}^2}\left(\mathcal{D}(\mathbf{m})-\mathsf{d}(\mathbf{m})\right)^2 dS\,. \tag{12.5.11}$$

Clearly, the coefficients $E_{\ldots}$ are not unique since $m_{i_1}m_{i_2}\,I_{i_1i_2}=1$, etc. In fact, 1, $m_{i_1}\,m_{i_2}$, $\cdots$ and $m_{i_1}\,m_{i_2}\cdots m_{i_n}$ are not independent. To obtain an approximation of the nth order, it is sufficient to consider the highest order term only,

$$\mathcal{D}(\mathbf{m})=\frac{1}{4\,\pi}\,F_{i_1i_2\cdots i_n}\,m_{i_1}\,m_{i_2}\cdots m_{i_n}\,. \tag{12.5.12}$$

The coefficient $F_{i_1i_2\cdots i_n}$ of the fabric tensor of the second kind of rank n is defined via the minimization (12.5.11) which yields, with help of (12.5.9),

$$F_{j_1j_2\cdots j_n}\int_{\mathbb{S}^2} m_{j_1}\,m_{j_2}\cdots m_{j_n}\,m_{i_1}\,m_{i_2}\cdots m_{i_n}\,\frac{dS}{4\,\pi}=\mathcal{M}_{i_1i_2\cdots i_n}\,, \tag{12.5.13}$$

with $\mathcal{M}_{i_1i_2\cdots i_n}$ defined by (12.5.6). With help of (12.2.14), the above relation can be inverted to yield $F_{j_1\,j_2\cdots j_n}$, e.g., in the simplest case $n=2$, $F_{i_1i_2}=(15/2)\left(\mathcal{M}_{i_1i_2}-I_{i_1i_2}/5\right)$. A general inversion formula has been derived by Kanatani [1984],

$$F_{i_1i_2\cdots i_n}=\frac{2\,n+1}{2^n}\left(\begin{array}{c}2\,n\\ n\end{array}\right)\left(\mathcal{M}_{i_1i_2\cdots i_n}+a^n_{n-2}\,I_{(i_1i_2}\,\mathcal{M}_{i_3\cdots i_n)}+\cdots+a^n_0\,I_{(i_1i_2}\,I_{i_3i_4}\cdots I_{i_{n-1}i_n)}\right), \tag{12.5.14}$$

the parentheses meaning 'totally symmetric part', see, e.g., (12.2.15), and $\left(\begin{array}{c}p\\ q\end{array}\right)=p!/(q!(p-q)!)$ denoting the binomial coefficient, and the coefficients $a^{\cdot}_{\cdot}$ being defined by (12.5.27) below.

Tensors of the second kind are compact, but they are strictly tied to the rank n, and they provide no clue to the higher approximation of rank $n+2$. Ideally, a formulation should be both compact and lend itself to easy higher order approximations. For that purpose, the expansion (12.5.10) is reconsidered by constraining the successive terms to be independent. Then each term can be defined independently.

12.5.2.3 Fabric tensors of the third kind

If the terms of the polynomial expansion (12.5.10) are independent, it is easy to define successive approximations of increasing order. By independent, we mean orthogonal in the sense of the unweighted integral (12.5.8). For example, independence of the terms of order $n-2$ and order n holds if

$$G_{j_1\,j_2\cdots j_n}\int_{\mathbb{S}^2} m_{j_1}\,m_{j_2}\cdots m_{j_n}\,m_{i_1}\,m_{i_2}\cdots m_{i_{n-2}}\,\frac{dS}{4\,\pi}=0\,. \tag{12.5.15}$$

The condition implies that the symmetric tensor coefficients $G_{\cdots}$ are *deviators, i.e., any contraction (and summation over mute indices) over two indices makes the coefficients to vanish*. Indeed, setting $i_1 = i_2$, $\cdots$, $i_{n-3} = i_{n-2}$ and summation over the repeated indices yields $G_{j_1\,j_2\cdots j_n}\int_{\mathbb{S}^2} m_{j_1}\,m_{j_2}\cdots m_{j_n}\,dS = 0$. With help of (12.2.14) which provides an explicit expression of the latter integral, and in view of the symmetry of $G_{j_1\,j_2\cdots j_n}$, the constraint becomes $G_{j_1\,j_1\cdots j_{n-1}j_{n-1}} = 0$. Contraction of $i_3 = i_4$, $\cdots$, $i_{n-3} = i_{n-2}$ in (12.5.15) yields $G_{j_1j_2\cdots j_n}\int_{\mathbb{S}^2} m_{j_1}\,m_{j_2}\cdots m_{j_n}\,m_{i_1}\,m_{i_2}\,dS = 0$, that, with help of (12.2.14), reduces to $G_{i_1i_2i_3i_3\cdots j_{n-1}j_{n-1}} = 0$. Again contraction of $i_5 = i_6$, $\cdots$, $i_{n-3} = i_{n-2}$ in (12.5.15) yields $G_{j_1j_2\cdots j_n}\int_{\mathbb{S}^2} m_{j_1}\,m_{j_2}\cdots m_{j_n}\,m_{i_1}\,m_{i_2}\,m_{i_3}\,m_{i_4}\,dS = 0$, that, with help of (12.2.14), reduces to $G_{i_1i_2i_3i_4i_5i_5\cdots j_{n-1}j_{n-1}} = 0$, and so on until

$$G_{i_1i_2i_3i_4\cdots j_{n-4}j_{n-3}j_{n-1}j_{n-1}}=0\,, \tag{12.5.16}$$

the position of the indices being arbitrary in view of the symmetry of the tensor coefficients $G_{\cdots}$ $\square$. The deviator tensor coefficient $G_{j_1j_2\cdots j_n}$ has $2\,n+1$ independent components. The component form of the deviator part $\mathbf{G} = \operatorname{dev}\mathbf{E}$ of a symmetric tensor $\mathbf{E}$ is denoted by the index symbol $\{\ \}$, Kanatani [1984],

$$G_{\{i_1i_2\cdots i_n\}} = c_0^n\,E_{i_1i_2\cdots i_n} + c_2^n\,I_{(i_1i_2}\,E_{i_3\cdots i_n)j_1j_1} + \cdots + c_n^n\,I_{(i_1i_2}\,I_{i_3i_4}\cdots I_{i_{n-1}i_n)}\,E_{j_1\,j_1\cdots j_{n-1}j_{n-1}}\,, \tag{12.5.17}$$

the coefficients $c_0^n = 1$ and c_m^n, $m > 0$, being defined so that the above expression (12.5.17) actually yields a deviator, namely

$$\left(\begin{array}{c}2\,n-1\\ m\end{array}\right)c_m^n = (-1)^{m/2}\left(\begin{array}{c}n\\ m\end{array}\right)\left(\begin{array}{c}n-1\\ m/2\end{array}\right). \tag{12.5.18}$$

For example, for $n = 2$ and $n = 4$,

$$\begin{aligned}&\operatorname{dev}\boldsymbol{\mathcal{M}} = \boldsymbol{\mathcal{M}} - \frac{1}{3}\,\mathbf{I}\,,\\ &\operatorname{dev}\boldsymbol{\mathcal{M}}\otimes\boldsymbol{\mathcal{M}} = \boldsymbol{\mathcal{M}}\otimes\boldsymbol{\mathcal{M}} - \frac{1}{7}\,(\mathbf{I}\otimes\boldsymbol{\mathcal{M}} + \boldsymbol{\mathcal{M}}\otimes\mathbf{I} + 2\,\mathbf{I}\,\underline{\overline{\otimes}}\,\boldsymbol{\mathcal{M}} + 2\,\boldsymbol{\mathcal{M}}\,\underline{\overline{\otimes}}\,\mathbf{I}) + \frac{1}{35}\,(\mathbf{I}\otimes\mathbf{I} + 2\,\mathbf{I}\,\underline{\overline{\otimes}}\,\mathbf{I})\,,\end{aligned} \tag{12.5.19}$$

accounting for the definition (12.5.6), which implies in particular $\mathcal{M}_{i_3i_4j_1j_1} = \mathcal{M}_{i_3i_4}$, $\mathcal{M}_{j_1\,j_1j_3j_3} = 1$. The tensor product $\underline{\overline{\otimes}}$ is defined componentwise as $(\mathbf{A}\,\underline{\overline{\otimes}}\,\mathbf{B})_{i_1i_2i_3i_4} = (A_{i_1i_3}\,B_{i_2i_4} + A_{i_1i_4}\,B_{i_2i_3})/2$.

When the $G_{\cdots}$ are deviators, the two approximations below are equivalent,

$$\mathcal{D}(\mathbf{m}) = \frac{G^{(0)}}{4\,\pi}\left\{\begin{array}{ccccccc}1 &+& G_{i_1i_2}\,m_{i_1}\,m_{i_2} &+&\cdots&+& G_{i_1i_2\cdots i_n}\,m_{i_1}\,m_{i_2}\cdots m_{i_n}\,,\\ 1 &+& G_{i_1i_2}\,m_{\{i_1}\,m_{i_2\}} &+&\cdots&+& G_{i_1i_2\cdots i_n}\,m_{\{i_1}\,m_{i_2}\cdots m_{i_n\}}\,.\end{array}\right. \tag{12.5.20}$$

In view of the orthogonality of the terms in $(12.5.20)_1$, the coefficients are defined by (12.5.13). Inversion of this relation with help of (12.2.14) yields now, instead of (12.5.14), Kanatani [1984],

$$G_{i_1i_2\cdots i_n} = \frac{2\,n+1}{2^n}\left(\begin{array}{c}2\,n\\ n\end{array}\right)\mathcal{M}_{\{i_1i_2\cdots i_n\}}\,,\quad \mathcal{M}_{i_1i_2\cdots i_n} = \frac{1}{G^{(0)}}\int_{\mathbb{S}^2} m_{i_1}\,m_{i_2}\cdots m_{i_n}\,\mathcal{D}(\mathbf{m})\,dS\,. \tag{12.5.21}$$

Then, using (12.5.17) and (12.5.21), the three first deviators $G_{\cdots}$ associated with the tensor coefficients $\mathcal{M}_{\cdots}$ may be listed, namely for $n = 0$,

$$G^{(0)} = \int_{\mathbb{S}^2}\mathcal{D}(\mathbf{m})\,dS = 1\,, \tag{12.5.22}$$

for $n = 2$,

$$\begin{aligned}G^{(2)}_{i_1i_2} &= \frac{15}{2}\big(\mathcal{M}_{i_1i_2} - \frac{1}{3}\,I_{i_1i_2}\big)\,,\\ \mathbf{G}^{(2)} &= \frac{15}{2}\big(\boldsymbol{\mathcal{M}} - \frac{1}{3}\,\mathbf{I}\big)\,,\\ \mathbf{G}^{(2)} &= \frac{15}{2}\int_{\mathbb{S}^2}\operatorname{dev}(\mathbf{m}\otimes\mathbf{m})\;\mathcal{D}(\mathbf{m})\,dS\,,\end{aligned} \tag{12.5.23}$$

and, for $n = 4$,

$$\begin{aligned} G^{(4)}_{i_1 i_2 i_3 i_4} &= \frac{315}{8}\big(\mathcal{M}_{i_1 i_2 i_3 i_4} - \frac{6}{7}\, I_{(i_1 i_2}\, \mathcal{M}_{i_3 i_4)} + \frac{3}{35}\, I_{(i_1 i_2}\, I_{i_3 i_4)}\big) \\ &= \frac{315}{8}\big(\mathcal{M}_{i_1 i_2 i_3 i_4} \\ &\qquad -\frac{1}{7}\,(I_{i_1 i_2}\, \mathcal{M}_{i_3 i_4} + I_{i_1 i_3}\, \mathcal{M}_{i_2 i_4} + I_{i_1 i_4}\, \mathcal{M}_{i_2 i_4} + \mathcal{M}_{i_1 i_2}\, I_{i_3 i_4} + \mathcal{M}_{i_1 i_3}\, I_{i_2 i_4} + \mathcal{M}_{i_1 i_4}\, I_{i_2 i_4}) \\ &\qquad +\frac{1}{35}\,(I_{i_1 i_2}\, I_{i_3 i_4} + I_{i_1 i_3}\, I_{i_2 i_4} + I_{i_1 i_4}\, I_{i_2 i_3})\big)\,, \\ \mathbf{G}^{(4)} &= \frac{315}{8}\big(\boldsymbol{\mathcal{M}} \otimes \boldsymbol{\mathcal{M}} - \frac{1}{7}\,(\mathbf{I} \otimes \boldsymbol{\mathcal{M}} + \boldsymbol{\mathcal{M}} \otimes \mathbf{I} + 2\,\mathbf{I} \underline{\overline{\otimes}}\, \boldsymbol{\mathcal{M}} + 2\,\boldsymbol{\mathcal{M}}\, \underline{\overline{\otimes}}\, \mathbf{I}) + \frac{1}{35}\,(\mathbf{I} \otimes \mathbf{I} + 2\,\mathbf{I} \underline{\overline{\otimes}}\, \mathbf{I})\big)\,, \\ \mathbf{G}^{(4)} &= \frac{315}{8}\int_{\mathbb{S}^2} \operatorname{dev}\,(\mathbf{m} \otimes \mathbf{m} \otimes \mathbf{m} \otimes \mathbf{m})\; \mathcal{D}(\mathbf{m})\, dS\,. \end{aligned} \tag{12.5.24}$$

The distribution function with two spherical harmonics may then be cast in tensor format,

$$\mathcal{D}(\mathbf{m}) = \frac{G^{(0)}}{4\,\pi}\,\big(1 + \mathbf{G}^{(2)} : (\mathbf{m} \otimes \mathbf{m}) + (\mathbf{m} \otimes \mathbf{m}) : \mathbf{G}^{(4)} : (\mathbf{m} \otimes \mathbf{m})\big)\,. \tag{12.5.25}$$

Once the fabric tensor $G_{...}$ of the third kind of rank n is known, the fabric tensor $F_{...}$ of the second kind of identical rank follows,

$$F_{i_1 i_2 \cdots i_n} = G_{i_1 i_2 \cdots i_n} + I_{(i_1 i_2}\, G_{i_3 \cdots i_n)} + \cdots + I_{(i_1 i_2}\, I_{i_3 i_4} \cdots I_{i_{n-1} i_n)}\,. \tag{12.5.26}$$

Comparison of (12.5.14) and (12.5.21) provides the coefficients a,

$$\frac{2\,n+1}{2^n}\left(\begin{array}{c} 2\,n \\ n \end{array}\right) a^n_m = \sum_{k=m \text{ even}}^{n} \frac{2\,k+1}{2^k}\left(\begin{array}{c} 2\,k \\ k \end{array}\right) c^k_{k-m}\,. \tag{12.5.27}$$

12.6 Spatial homogenization over cells and ECM

In order to derive mechanical properties, the solid skeleton which occupies only a volume fraction of the overall tissue is often considered itself as a two-phase material, Weng [1984], Jain et al. [1988]. One phase is the matrix phase (extracellular matrix ECM consisting mainly of collagen fibers and other macromolecules), the other phase is the inclusion phase (biological cell). Typically, mathematical cells composed of the inclusion and surrounding ECM are given various geometrical forms, from cubes to 14-sided polyhedron, that repeat by periodicity over the three-dimensional space. El-Kareh et al. [1993] use cubic cells to estimate the diffusivity of solutes in tissues while Secomb and El-Kareh [2001] use 14-sided polyhedrons to estimate elastic properties. While the cells are formed by isotropic inclusions and matrix, the resulting material displays cubic symmetry. When the above cells are randomly oriented, it is a simple matter to obtain the Voigt and Reuss bounds of the isotropic elastic moduli and transport coefficients, and an additional effort provides the Hashin-Shtrikman bounds.

Secomb and El-Kareh [2001] consider cells of very soft tissues to be incompressible because the hydraulic permeability of their membrane is low, say about $1.35 \times 10^{-13}\,\mathrm{m/Pa/s}$. On the other hand, their shear modulus is about a tenth of the shear modulus of the extracellular matrix, typically 100 Pa for the cells of glands and brain matter. Thus the overall bulk modulus of these tissues is controlled by the cell and cell volume fraction and the shear modulus by the ECM and ECM volume fraction. Assuming a bulk modulus of the cell about $4.4 \times 10^3\,\mathrm{Pa}$, a specific surface area of the cell membrane about $10^{-6}\,\mathrm{m}$ (assuming a cell size of 10 μm), the characteristic time of diffusion across the cell membrane is as high as 28 min.

Chapter 13

Electro-chemomechanical couplings

13.1 Chemomechanical couplings in engineering and biology

Chemomechanical couplings occur in many engineering and biological fields. A typical instance is swelling that has relevance in active clays and polymers inter alia. *Gels* are also highly susceptible of swelling. Gels are aqueous environments that contain soluble components, e.g., metallic ions, and insoluble structural molecules. Articular cartilages and corneal stroma are instances of *extracellular* biological gels in which the structural molecules are located outside the cells, forming the extracellular matrix. By contrast, the muscle is an *intracellular* gel in which the myosin filament has a diameter comparable to that of collagen in articular cartilage.

Swelling in non-ionic polymers is traditionally traced to the volume exclusion concept according to which, in a very dilute solution in a good solvent, each molecule tends to exclude all others from the volume it occupies, Flory [1953]. In ionic polymers, electrical repulsion between fixed charges provides another source of swelling. The presence of mobile ions, required by electroneutrality, shields these repulsive forces but is not sufficient to abolish their effects, unless at very high concentrations, a configuration coined *hypertonic state*.

Electro-chemomechanical couplings are also exploited by engineers. For example, electromigration is used to remediate soils polluted by heavy metals and electroosmosis to consolidate soils.

In biological tissues, couplings arise as processes to maintain a certain equilibrium: swelling of articular cartilages opposes the water depletion that would occur due to mechanical compression. In some instances, they are driving processes: the cardiac function is a typical process of electro-chemomechanical coupling. A common feature to most, if not all, these examples is the presence of *fixed electrical charges* that play a key role in promoting the couplings.

Reverse couplings, e.g., mechanoelectric feedback, are less studied. They appear nevertheless to be at work in many instances of the development of biological organs. Indeed, while *in vitro* cultures of engineered soft tissues are able to induce cell proliferation, the mechanical properties of the tissues are not satisfactory. *Mechanobiology* aims at defining mechanical loading programs to be applied to the cultures so as to improve these properties.

13.2 Molar volumes, electrostriction

13.2.1 Molar masses and molar volumes

The molar masses of a few chemicals are recorded in Table 13.2.1. They can be contrasted with the large molar masses of macromolecules of biological interest recorded in Table 13.2.2.

Table 13.2.1: Molar masses (gm) and apparent molar volumes (cm^3) of some ions at low ionic strength.

Species	H_2O	Na^+	Ca^{2+}	K^+	H^+	OH^-	Cl^-
Molar mass	18	23	40.1	39.1	1	17	35.5
Molar volume	18	2.37	1.7	12.8	4.1	-7.8	15.4

Table 13.2.2: Molar masses (kg) of some macromolecules of biological interest.

Species	PGs	Collagen	Albumin	Dextran	IGF-1	Insulin
Molar mass	2000	285	66	10-70	8	5

The apparent molar volumes of dissolved species are not constant, even under isothermal conditions. The apparent molar volumes of electrically neutral species, like NaCl and KCl, depend on their own molalities, Lobo [1990]. In a solution, due to *electrostriction*, a charged ion is attracted so strongly by counterions that, at low concentration, the ionic bond implies a reduction in volume with respect to the two independent species. The apparent molar volume of some ions can result to be negative. As the concentration increases, the phenomenon is counteracted by the repulsion between ions whose electrical charges are of the same sign.

As a rough approximation, the molar volumes in Table 13.2.1 are equal to the values corresponding to quasi-distilled water, which can be considered meaningful at low ionic concentrations (up to 0.1 M).

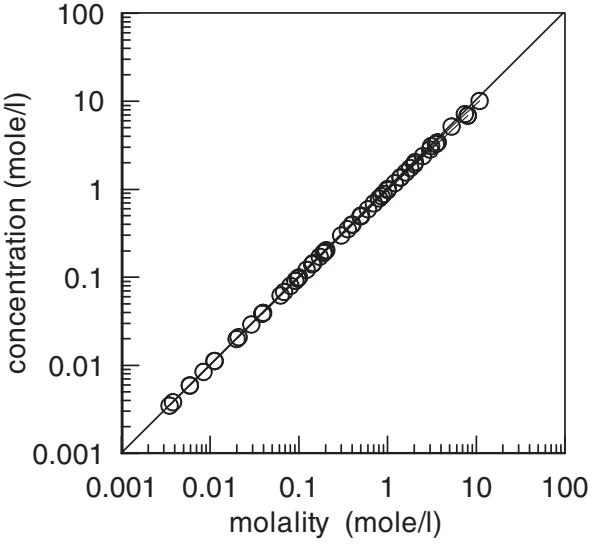

Fig. 13.2.1: Molality and concentration as defined by Eqn (13.2.1) differ only at large concentrations of sodium chloride. The molar volumes are shown in Fig. 13.2.2.

13.2.2 The molar volume of dissolved salts

An electrolyte contains a volume of water V_w=1 liter=1000 cm^3 in which N moles of salt are dissolved in dissociated form. This amount of salt is measured through its molality m [unit : mole/liter], or concentration c [unit : mole/liter],

$$\text{molality } m = \frac{\text{nb. of moles } N}{\text{volume of water } V_w}; \quad \text{concentration } c = \frac{\text{nb. of moles } N}{\text{volume of solution } V}. \tag{13.2.1}$$

Fig. 13.2.1 shows that molality and concentration differ only at large concentrations.

Let $\hat{v}$ be the molar volume of the solute. Since

$$V = V_w + N\,\hat{v}\,, \tag{13.2.2}$$

then molality and concentration can be expressed in terms of each other,

$$c = \frac{m}{1 + m\,\hat{v}}, \quad m = \frac{c}{1 - c\,\hat{v}}\,. \tag{13.2.3}$$

Based on data in Lobo [1990], the analytical expressions below provide approximations to the molar volumes [unit : cm^3/mole], of three compounds, namely sodium chloride NaCl, hydrochloric acid HCl and sodium hydroxide NaOH, as a function of their molality [unit : mole/liter]:

$$\begin{aligned} \hat{v}_{\rm NaCl} &= 17.04 + 1.58\,m_{\rm NaCl} - 0.192\,m_{\rm NaCl}^2\,; \\ \hat{v}_{\rm HCl} &= 18.18 + 0.55\,m_{\rm HCl} - 0.035\,m_{\rm HCl}^2\,; \\ \hat{v}_{\rm NaOH} &= -4.61 + 1.98\,m_{\rm NaOH} - 0.085\,m_{\rm NaOH}^2\,. \end{aligned} \tag{13.2.4}$$

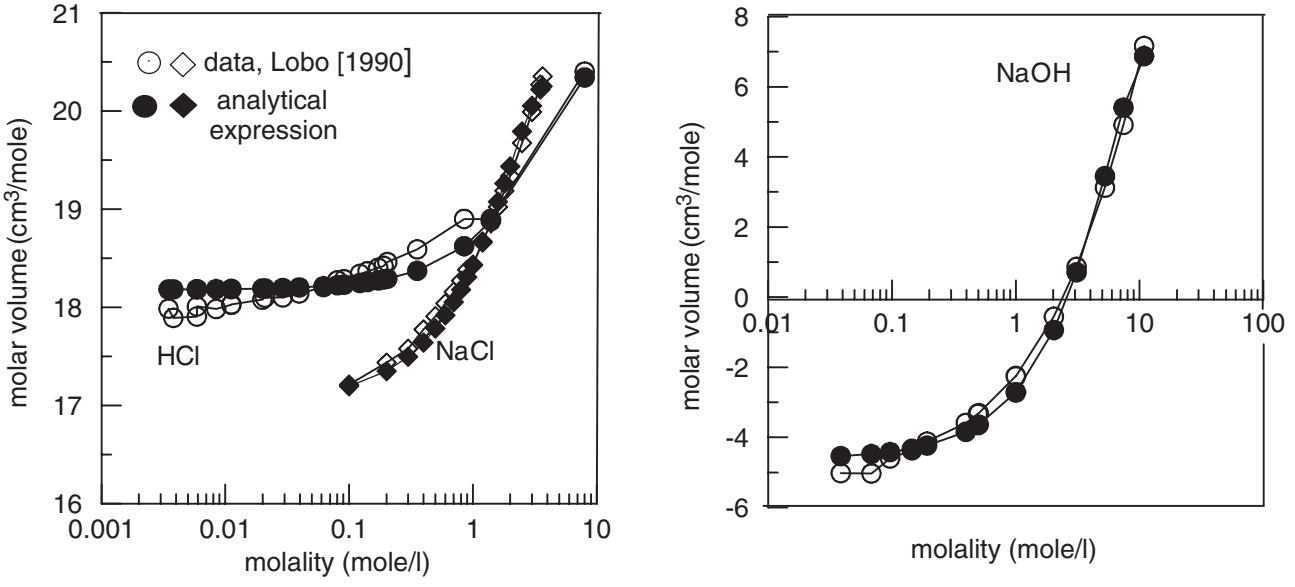

Fig. 13.2.2: Molar volumes of salts as a function of molality. Data at 25°C (open symbols) by Lobo [1990], p. 532 for HCl, p. 1640 for NaCl and p. 1807 for NaOH, and approximations (solid symbols) by Eqn (13.2.4).

The above expressions displayed in Fig. 13.2.2 hold for molalities below the solubility limit, that is, they assume the salt to be completely dissolved.

13.2.3 The molar volume of dissolved ions

The molar volume of the chloride anion $\hat{v}_{\mathrm{Cl}}$ may be considered to be fairly constant, namely $\hat{v}_{\mathrm{Cl}} \simeq 15.4\,\mathrm{cm}^3$. As a first approximation, it can be assumed to be known. Then

$$\begin{aligned} \hat{v}_{\mathrm{Na}} &= \hat{v}_{\mathrm{NaCl}}(m_{\mathrm{NaCl}}) - \hat{v}_{\mathrm{Cl}}\,; \\ \hat{v}_{\mathrm{H}} &= \hat{v}_{\mathrm{HCl}}(m_{\mathrm{HCl}}) - \hat{v}_{\mathrm{Cl}}\,; \\ \hat{v}_{\mathrm{OH}} &= \hat{v}_{\mathrm{NaOH}}(m_{\mathrm{NaOH}}) - \hat{v}_{\mathrm{NaCl}}(m_{\mathrm{NaCl}}) + \hat{v}_{\mathrm{Cl}}\,. \end{aligned} \tag{13.2.5}$$

The ionic molar volumes, based on the approximations (13.2.4), can be observed to have significative variations with ionic strength, Fig. 13.2.3. The range of the molar volume of the hydroxyl OH^- ion is especially large. The increase of the molar volume with the concentration of sodium chloride seems to indicate that attraction between hydroxyl anion and sodium cation is more important than the repulsion between hydroxyl anion and chloride anion.

13.3 Electrokinetic processes

Electrokinetics has been used in various directions that take advantage, enhance or decrease some properties of media with fixed charges. The modeling of electrokinetic remediation processes has so far mainly assumed a rigid solid skeleton. Advection of contaminants by water flow is accounted for, but models differ in the way they include ionic mobility of the various species present in the pore fluid and in the number of electrochemical reactions included. A terminology has emerged that highlights the key physical properties that are triggered. *Electroosmosis* denotes the process of transport of water into low permeability media in order to remove soluble electrically neutral species, Fig. 13.3.1. *Electromigration* on the other hand addresses the removal of ionic species. Note that higher concentrations enroll more electromigration than electroosmosis.

In order to improve the efficiency of remediation processes, enhancement techniques are tested, like
- addition of acid at cathode to desorb cations,

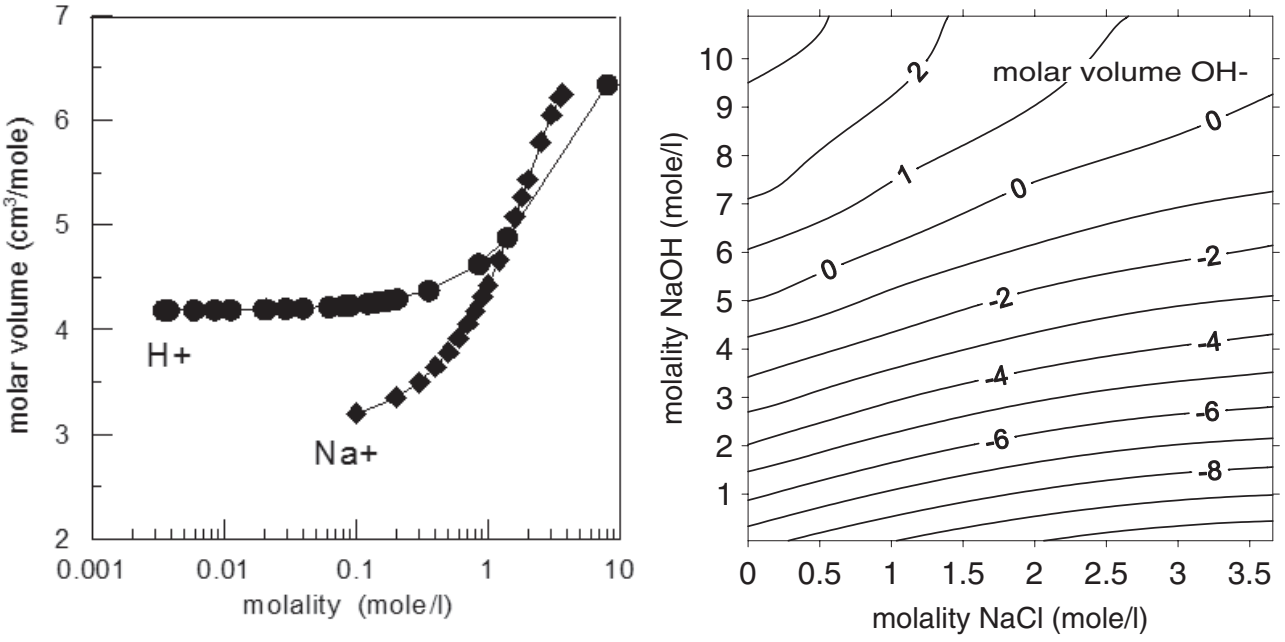

Fig. 13.2.3: Molar volumes of ions (cm^3) as a function of molality as described by Eqn (13.2.5).

- addition of EDTA[13.1] that enhances complexation of desorbed cations, Yeung et al. [1996], Alshawabkeh et al. [1999], and
- use of semi-permeable membranes close to cathode and optimization of the position of electrodes, Alshawabkeh et al. [1999].

Indeed, there are two keys to successful electrokinetic remediation of metal-contaminated media: first to extract the cations from solid phase, second to keep the desorbed cations in fluid phase so as to move them to electrodes either by electromigration to cathode or by electroosmosis when complexated. Of course, addition of acid is of theoretical help in both steps, but the quantity required increases prohibitively for media with high buffer capacity[13.2]. Moreover acids are hazardous substances. That is one of the reasons of the use of a strong anionic complexing agent by Yeung et al. [1996].

Alternative substances, like polyphosphates, are used to increase the negative charge for specific purpose, e.g., enhance the adsorption of heavy metals.

13.3.1 Laboratory setups

Electrodes are endowed with reservoirs that allow to circulate an electrolyte of controlled chemical composition. This separation between electrodes and medium avoids heating and desiccation, desaturation and cracking. Reservoirs are separated from the medium by a filter permeable to water and ions. In fact, electroosmosis depletes water from the anode region and moves it towards the cathode, Fig. 13.3.1 : control of the electrolyte circulating in the reservoir allows to provide water at the anode and dispose of water at the cathode. Additional passive electrodes positioned along the sample allow measurements.

A typical electrokinetic experiment proceeds as follows. The initial state is usually homogeneous and defined by a given concentration of cations, anions and pH. A difference of electrical potential is applied between the electrodes. The pore pressures at the electrodes are maintained at a reference value, say zero, assuming a one-dimensional

[13.1] EDTA = ethylene-diamine-tetra-acetate.

[13.2] The pKa of an acid is the value of pH at which it is half dissociated, the concentrations of the acid and its conjugate base being equal: according to the Henderson-Hasselblach equation, pH=pKa+log([acid]/[base]). The titration curve displays an inflection at the pKa. The *buffer capacity* of a system is defined as the amount of strong acid that causes this system to have a pH increase of one unit. A substance is an efficient buffer in a range of pH if it has its pKa in this zone. Indeed, then the amount of substance necessary to change the pH is large. For example, the plasma has a pH between 7.35 and 7.45, corresponding to a concentration of hydrogen ions of 40 nM, and it is buffered efficiently by phosphate and carbonate ions which have their pKa's in this range, namely pKa(H_2CO_3)=6.35, pKa($H_2PO_4^-$)=6.82. Incidentally, note that the cytoplasm is somehow more acidic, with a pH between 7 and 7.30, the stomach is very acidic, with a pH about 2, while the small intestine is basic, with a pH about 8.

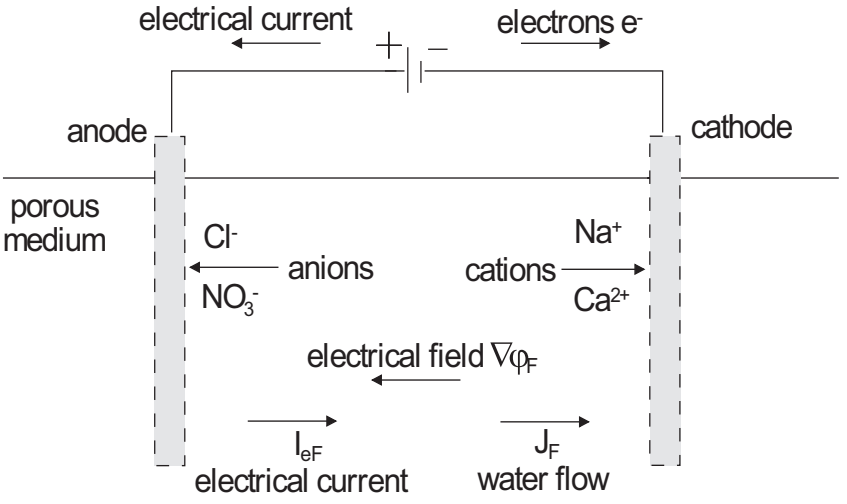

Fig. 13.3.1: Sketch of electrokinetic remediation. By convention, the electrical current in the circuit flows in the direction opposite to electrons. By *electromigration*, cations move towards the cathode and anions move towards the anode with velocities depending on individual *ionic mobilities*. *Electroosmosis* implies water flow towards the cathode, when the acidity is not too high, i.e., overall electrical charge above isoelectric point. For higher acidity, a *reverse* osmotic flow occurs.

analysis. The boundary conditions for the ionic species at the electrodes are of two types: either the concentrations are prescribed initially and, during the experiments, the ionic fluxes are free, or the concentrations are continuously monitored in the reservoirs.

If the electrodes are metallic, oxidation-reduction reactions take place (Me≡ metal):

$$\begin{aligned} \mathrm{Me} &\rightarrow \mathrm{Me}^{z^+} + \mathrm{z}\ \mathrm{e}^- \text{ oxidation at anode,} \\ \mathrm{Me} &\leftarrow \mathrm{Me}^{z^+} + \mathrm{z}\ \mathrm{e}^- \text{ reduction at cathode.} \end{aligned}$$

Laboratory experimental setups use graphite passive electrodes to avoid spreading of parasite ions into the medium.

13.3.2 Development of an acid front

A significant step forward in the understanding of electrokinetic processes is due to the contribution of Acar et al. [1994]. They show that the most prominent phenomenon is the development of an acid front starting close to the anode and moving towards the cathode, Fig. 13.3.2. An electrolytic decomposition of water in hydrogen and hydroxyl ions takes place at the electrodes[13.3],

$$\begin{aligned} 2\,\mathrm{H_2O} - 4\,e^- &\rightarrow \mathrm{O_2}\uparrow + 4\,\mathrm{H^+} \quad \text{oxidation at anode} \\ 4\,\mathrm{H_2O} + 4\,e^- &\rightarrow 2\,\mathrm{H_2}\uparrow + 4\,\mathrm{OH^-} \quad \text{reduction at cathode} \end{aligned} \tag{13.3.1}$$

The mobility of these ions is high with respect to that of other ions and, once generated, they move in the medium by saltation from one water molecule to the other, advection of the pore fluid, fickian diffusion and migration due to electrical field. In fact, the hydrogen ion $\mathrm{H^+}$ is not stable in aqueous solutions and it would be more appropriate to consider the ion hydronium $\mathrm{H_3O^+}$, although even this form does not represent the complexity of aqueous solutions, Alberty [2003].

The acid front created by the motion of hydrogen ions $\mathrm{H^+}$ towards the cathode and the basic front created by the motion of hydroxyl ions $\mathrm{OH^-}$ towards the anode are *not symmetric*:

- first, because the mobility of the former is much larger, and,
- second, because the motion of the $\mathrm{H^+}$'s (respectively $\mathrm{OH^-}$) is assisted (respectively opposed) by electroosmosis, Fig. 13.3.2.

[13.3] According to Faraday's law of equivalence of mass and charge, if the efficiency of the reaction is one, the flux per unit area of ion i [unit : mole/s/m^2] created at the electrodes is equal to $\mathbf{J}_i = \mathbf{I}_{\mathrm{ew}}/(z_i\,\mathrm{F})$, with $i = \mathrm{H^+}$, $z_i = 1$ at anode, $i = \mathrm{OH^-}$, $z_i = -1$ at cathode, where $\mathbf{I}_{\mathrm{ew}}$ is the electrical current density [unit : A/m^2] and F Faraday's equivalent charge [unit : C/mole].

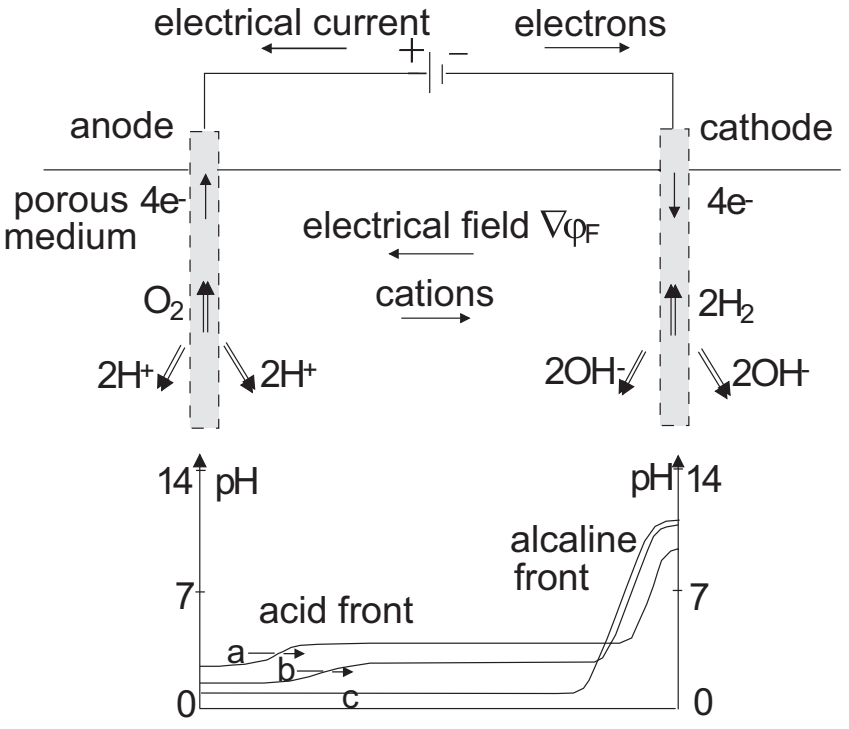

Fig. 13.3.2: Schematization of electrokinetic remediation by Acar et al. [1994]. An acid front due to freed hydrogen ions H^+ is created at the anode and it propagates towards the cathode. A basic front due to freed hydroxyl ions OH^- is also created at the cathode and it propagates towards the anode. However, the motions are not symmetric and the acid front is faster than the basic front: first, because the mobility of hydrogen ions is 1.76 higher than that of hydroxyl ions; second because electroosmosis implies, below the isoelectric point, a water flow towards the cathode, therefore amplifying the motion of cations and opposing that of anions. However, high pH prevalent close to the cathode might jeopardize the efficiency of the process and precipitate metal hydroxides.

Table 13.3.1[13.4] shows the diffusion coefficients and ionic mobilities of common ions in a blank (dilute) solution. The actual diffusion is hindered in porous media in general, and in the extracellular matrix in particular. This hindrance is quantified by a tortuosity factor. The *effective* diffusion coefficients and ionic mobilities are obtained by multiplication of their counterparts in a blank solution by the tortuosity factor.

Table 13.3.1: Ionic diffusion coefficients D [unit : $10^{-10}\,m^2/s$] and mobilities $u = D\,|\zeta|F/RT$ [unit : $10^{-9}\,m^2/s/V$] in water at 25 °C ($F/RT = 0.02568\,1/volt$).

Ion	Na^+	Ca^{2+}	Cl^-	H^+	OH^-	NO_3^-	SO_4^-
D	13.3	7.92	20.3	93.09	52.77	6.33	5.30
u	51.75	61.75	79.0	362.5	205.5	74	82.5

13.3.3 Electroinjection

Electroinjection through electrical fields may be attempted to improve mechanical properties. Various types of *electrokinetic stabilization* may be devised:

i) electroosmotic consolidation where an electrical gradient is applied, without mechanical load, in order to extract pore fluid;

ii) use of electroosmotic flow to draw stabilizing chemicals into the medium;

[13.4] Voet and Voet [1998], p. 34, give slightly different values.

iii) triggering ionic migration by adding an acid at the cathode, extracting a minimum of fluid in order to minimize advection that opposes motion of anions towards the anode.

Modifications of transport and mechanical properties by pH may, or may not, be simultaneous. Acidification may change the sign of the electroosmotic coefficient and give rise to reverse osmosis.

13.4 Nanoscopic aspects

13.4.1 The fixed electrical charge

Many tissues, like articular cartilage and cornea, and geological materials, like clays, are not electrically neutral due to uncompensated termination sites. Since these sites are usually negatively charged at standard pH, cations desorb from the water phase. A list of common exchangeable cations includes

$$\mathrm{Ca}^{2+}, \mathrm{Mg}^{2+}, \mathrm{H}^{+}, \mathrm{K}^{+}, \mathrm{NH}_4^{+}, \mathrm{Na}^{+}\,, \tag{13.4.1}$$

while

$$\mathrm{SO}^{2-}, \mathrm{Cl}^{-}, \mathrm{PO}_4^{3-}, \mathrm{NH}_4^{-}\,, \tag{13.4.2}$$

are common exchangeable anions. The ability of a material to exchange cations (respectively anions) is characterized by its *cation exchange capacity* (respectively, *anion retention capacity*).

The terminology adopted to quantify the electrical charges depends on the volume accounted for, Fang [1997], p. 101. In any event, all structural charges, within and on the solid, as well as adsorbed H^+ are included. When the volume is limited by the Stern layer[13.5], the transition pH between a negative and a positive overall charge is termed *point of zero electrical charge*. When, as in the definition of the ζ-potential, the reference volume extends further to the plane of shear between solid and fluid, the charge changes sign together with the ζ-potential at the pH called *isoelectric point*.

Fixed charge, mobile ions, permanent charge, variable charge

To fix the terminology, let us note that the charge of the solid is called *fixed charge*, as opposed to the *mobile charge* of ions. The part of the charge of the solid which is insensitive to pH is referred to as *permanent fixed charge*, while the part which changes with pH is called *variable fixed charge*.

The negatively charged proteoglycans

The proteoglycans are responsible for the swelling behavior of biological tissues as they repel themselves and originate a 'chemical' pressure. The repulsion force is however shielded by the presence of ions: in the hypertonic state (high ionic concentration), the repulsive force is minimum and the structure tends to collapse. The proteoglycans are macromolecules of molar mass 2×10^6 gm, with *effective* concentration (=concentration×valence) of 0.1 to 0.2 M. Their mass is contributed for 85% by glycosaminoglycans (GAGs) and for 15% by proteins. GAGs contain 80% of chondroitin sulfates of charge -2 and 20% of keratan sulfate of charge -1, so that the valence of PGs varies from -6000 to -8000.

13.4.2 Mechanisms due to pH

As they move away from the anode, hydrogen ions H^+ in the electrolyte solution extract cations absorbed in or on the fixed charge. Desorbed into the electrolyte, these cations will be attracted to the cathode where they can be disposed of. The basic property in force is that, at pH 7 or higher, the materials are negatively charged on their surface. So in a superficial view, cations H^+ are much more likely to absorb to the materials than anions OH^-, which are a priori electrically repelled. Said otherwise, acid solutions are able to dissolve metallic cations. pH decrease, i.e. acidification of the tissue, is required to desorb metallic ions and solubilize them in pore fluid, while precipitation of metallic cations occurs as the pH increases.

A more precise description of the effects of hydrogen ions on negatively charged structures follows. At pH 7 or higher, hydroxyl OH^- termination sites are present on their surfaces. As pH increases, the dissociation/deprotonation $\mathrm{Me-OH} \rightarrow \mathrm{Me-O}^- + \mathrm{H}^+$, or $\mathrm{Me-OH}^- + \mathrm{OH}^- \rightarrow \mathrm{Me-O}^{2-} + \mathrm{H_2O}$, that turns the charge more negative, is favored (Me is a metal, e.g., Si).

[13.5] The Stern layer consists of tightly bound cations surrounding the GAGs, see Fig. 13.4.1.

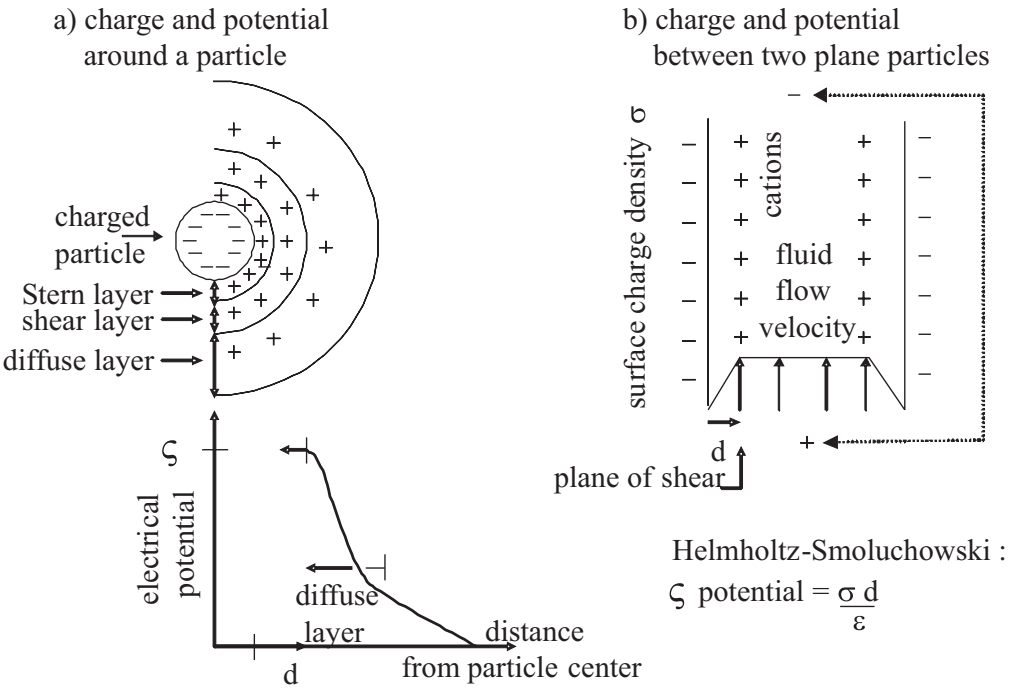

Fig. 13.4.1: The measure of the electrical charge depends on the distance d from the particle surface, σ surface charge density, ϵ permittivity. Some notions of electrostatics are provided in Section 13.6.

On the other hand, as pH decreases, fixation of H^+/protonation, makes the overall charge less negative, and even positive. In fact, fixation of H^+ on these sites, $Me-OH^- + H^+ \rightarrow Me-HOH$, further weakens internal bonds and leads to the release in the solution (dissolution) of multivalent ions, which become exchangeable, and possibly might further precipitate. Small radius multivalent ions, like Al^{3+}, play a prominent role here in reducing the absorbed water content for several reasons. First, they require less volume and, second, the repulsive electrical forces that would be due to three monovalent cations vanish.

The desorption into the solution of a metallic ion with valence n decreases the acidity of the solution, while the absorption increases the acidity:

$$\begin{aligned} &\text{desorption}: \ \text{pH} \nearrow \quad \text{X}-\text{tissue} + n\,\text{H}^+ \longrightarrow \text{H}_n-\text{tissue} + \text{X}^{n+} \\ &\text{absorption}: \ \text{pH} \searrow \quad \text{X}-\text{tissue} + n\,\text{H}^+ \longleftarrow \text{H}_n-\text{tissue} + \text{X}^{n+} \end{aligned} \tag{13.4.3}$$

Alternatively, protons might only replace a univalent cation which is released into solution, e.g.,

$$\text{K}-\text{tissue} + \text{H}^+\text{OH}^- \longrightarrow \text{H}-\text{tissue} + \text{K}^+\text{OH}^- . \tag{13.4.4}$$

While complexation of Na^+ and K^+ is known to be small, it dominates the aqueous behavior of Al^{3+}, see Section 13.5.2. Therefore, only a part of the released cations is uncomplexed. Only this part can become exchangeable, that is, can enter the interlayer space of the charged structure.

13.5 Hydration, hydrolysis, complexation and solubility

In water, a cation of charge z exists

- in hydrated form, a bond with the water molecule being established;
- in free (uncomplexed) form M^{z^+} and
- in complexed forms with n hydroxyl anions OH^-, namely $(M(OH)_n)^{z^+-n^-}$, $n = 1, 2, \cdots, z, \cdots$

Being solid, the complexed form which is neutral plays a special role, e.g., gibbsite $Al(OH)_3$ or lead hydroxide $Pb(OH)_2$. Each complexed form is in equilibrium with its dissociated form.

(Nonhydrated) ionic radii of cations are smaller than their parent atoms, and the converse holds for anions. Moreover, upon hydration the size of some metallic ions may increase significantly, as indicated by Table 13.5.1 and this large size may lead to steric exclusion from certain domains which can be reached through dedicated channels of definite size.

Table 13.5.1: Ranges of non hydrated and hydrated ionic radii [unit : Å=0.1 nm], from several sources including Mitchell [1993], p. 40. As a reference, the size of the water molecule is about 3.6 Å.

Ion	Na^+	K^+	Ca^{2+}	Mg^{2+}	O^{2-}	Cl^-	OH^-	H^+	H_3O^+
Nonhydrated radius	1	1.4-1.6	1-1.3	0.6-0.9	1.4	1.81	1.33	0.8	1.15
Hydrated radius	3.6-7.9	3- 5.33	4.1-9.6	4.3-11.8	–	3	3	9	2.8

13.5.1 Solvation and hydration

The water molecule is highly polar. Two of the six electrons of the outer shell of the oxygen atom participate to create covalent bonds with the two hydrogen atoms: in a covalent bond the atoms share pairs of electrons. Due to the remaining six electrons on the inner and outer shells, the covalent bond O-H has a ionic character as if the end O was negatively charged with a charge $-2\delta = -0.6$ and the ends H positively charged with a charge $\delta = 0.3$ as sketched in Fig. 13.5.1. Altogether, the spatial distribution of electrical charges turns the water molecule into a dipole of dipolar moment equal to 6.2×10^{-30} C×m.

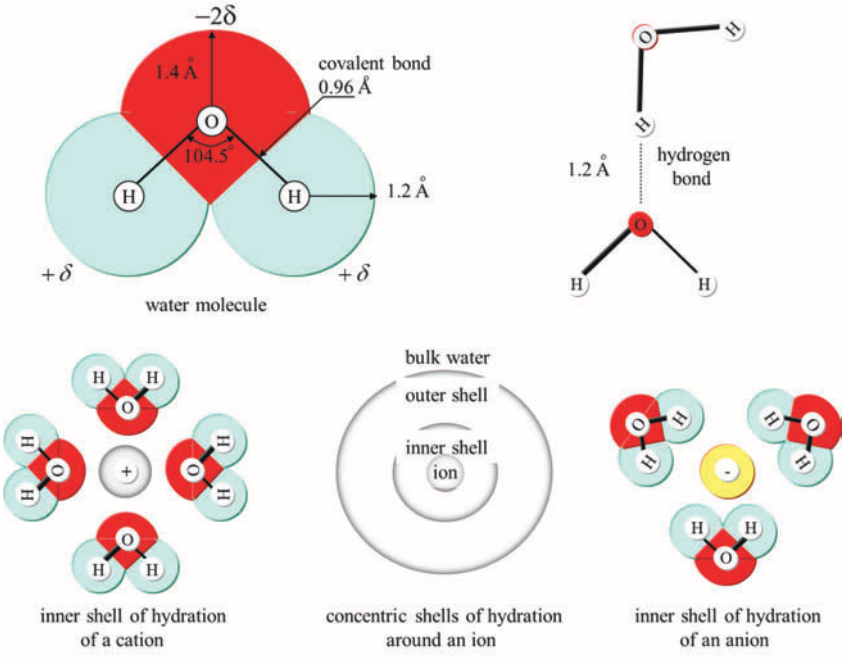

Fig. 13.5.1: The water molecule has polar properties. The hydrogen and oxygen atoms retain a part of the charge which is at the root of the formation of hydrogen bonds and hydration of cations and anions. Here only the inner hydration shells are shown while an outer less ordered hydration shell serves as a transition with the random arrangement of bulk water.

In pure water, the hydrogen ions establish a *hydrogen bond* with oxygen atoms of other water molecules. Hydrogen bonds are much weaker than covalent bonds and, although their lifetime is short (order of a few picoseconds), their numbers may strengthen considerably the stability of water. Chemists have tried to elucidate, through molecular dynamics simulations, the existence of structures, that is, of specific arrangements, or *clusters*, of water molecules. The idea revolves of course on the time scale and volume scale under consideration. The end result is that *pure*

water does not seem to show signs of the existence of stable clusters in the sense that hydrogen bonds are continually broken and rebuilt in a few picoseconds.

The dipolar property and the hydrogen bonds are thought to be responsible for the large latent heat of vaporization of water equal to 43.5 kJ/mole, as indicated in Fig. 3.2.2. In absence of hydrogen bonds, the boiling temperature is estimated to about be −90 °C.

Polar substances and ions *hydrate* when immersed in water. Loosely speaking, water is sometimes referred to as the universal solvent. This solvation property is due to the high dielectric constant of water: the electric force between charged species is screened by water and so is their interaction energy. Section 13.6.1 provides some details on this issue. Since the cohesion force is low in water, ionic species attract much less than in other solvents and may remain separated.

In addition, solvated ions interact with a polar solvent like water. In presence of ions, the poles of the solvent are attracted by the opposite charge: ions are thus surrounded by water molecules, a feature termed hydration.

The standard hydration energy is measured as the enthalpy ΔH yielded (in the form of heat) when the ion in gaseous form is immersed in water. The total energy released (when $\Delta H < 0$) however should involve also the change of internal structure of the chemical. The quantity that gives a measure of the order of the structure is the entropy S. Entropy increases as disorder increases. Therefore the variation of entropy from the gaseous phase to the hydrated state where motions are restrained by the ion-dipole bonds is certainly negative, $\Delta S < 0$. The total measure of energy that is released (absorbed) during the process is the variation of free enthalpy ΔG (also called chemical potential) equal, at constant temperature, to $\Delta H - T\,\Delta S$. A process is said to be spontaneous, and exergonic, if $\Delta G < 0$. Despite the fact that $\Delta S < 0$, hydration is exergonic. For a cation M of valence z,

$$\underset{\text{spontaneous if } \Delta G<0}{\textbf{hydration}} \qquad \mathrm{M}^{z^+} \;+\; n\,\mathrm{H_2O} \;\rightleftharpoons\; \mathrm{M(H_2O)}_n^{z^+}, \tag{13.5.1}$$

and ΔG [unit : kJ/mole] is estimated as $-686\,z^2/r' + 5.44 \;<\; 0$, r' [unit : Å] being the modified ionic radius.

13.5.2 Hydrolysis and complexation

When the energy provided by immersion is larger, it can be sufficient to delete $n = 1,\, 2 \cdots$ z bonds O-H and, instead of hydration, *hydrolysis* occurs[13.6]:

$$\textbf{hydrolysis}: \quad \mathrm{M}^{z^+} \;+\; n\,\mathrm{H_2O} \;\rightleftharpoons\; \mathrm{X}_n \;+\; n\,\mathrm{H}^+, \tag{13.5.2}$$

with $\mathrm{X}_n \equiv (\mathrm{M(OH)}_n)^{z^+-n^-}$. The concentration of water, $[\mathrm{H_2O}]$= 55 mole/liter, is inserted into the constant of equilibrium to yield

$$K_n = [\mathrm{X}_n][\mathrm{H}^+]^n/[\mathrm{M}^{z^+}]\,. \tag{13.5.3}$$

The above reaction is itself equivalent to the sum of the two reactions

$$\begin{aligned} &n\,\mathrm{H_2O} \;\rightleftharpoons\; n\,\mathrm{OH}^- + n\,\mathrm{H}^+, \quad (K^{\mathrm{c}}_{\mathrm{dis}})^n = ([\mathrm{H}^+]\,[\mathrm{OH}^-])^n = 10^{-14\,n} \\ &\mathrm{M}^{z^+} + n\,\mathrm{OH}^- \rightleftharpoons \mathrm{X}_n, \qquad\qquad K'_n = [\mathrm{X}_n]/([\mathrm{M}^{z^+}]\,[\mathrm{OH}^-]^n) \end{aligned} \tag{13.5.4}$$

so that $K_n = (K^{\mathrm{c}}_{\mathrm{dis}})^n\, K'_n$. If we consider that M^{z^+} comes from the dissolution of $\mathrm{X}_z = \mathrm{M(OH)}_z$, then

$$(\mathrm{X}_z)_{\mathrm{solid}} \;\rightleftharpoons\; \mathrm{M}^{z^+} + z\,\mathrm{OH}^-, \qquad K_{\mathrm{z}} = [\mathrm{M}^{z^+}]\,[\mathrm{OH}^-]^{\mathrm{z}}, \tag{13.5.5}$$

where the concentration X_z has been set to 1 because it is solid. The concentration of free $[\mathrm{M}^{z^+}]$ can be calculated as a function of the pH of the solution using $Y \equiv 10^{-\mathrm{pH}} = [\mathrm{H}^+]$, and then

$$[\mathrm{M}^{z^+}]_{\mathrm{free}} = K_z\,(K^{\mathrm{c}}_{\mathrm{dis}})^{-z}\,Y^z\,. \tag{13.5.6}$$

[13.6] A chemical reaction where $\mathrm{H_2O}$ is formed is called a *condensation* reaction, e.g., formation of a glycosidic bond by the junction of two monosaccharide units. Hydrolysis corresponds to the reverse reaction where bonds are broken by addition of water.

The total concentration of ions M^{z+} in solution is the sum of the free (uncomplexed) M^{z+} and of the hydroxy complexes X_n,

$$[M^{z+}]_{\text{solution}} = [\,Y^{z} \;+ \sum_{i=1,n}^{i\neq z} K_i\, Y^{z-i}\,]\, K_z\, (K^{c}_{dis})^{-z}\,. \tag{13.5.7}$$

Electroneutrality provides the equation for Y,

$$K_z\,(K^{c}_{dis})^{-z}\,[\,z\,Y^{z} \;+ \sum_{i=1,n}^{i\neq z} (z-i)\,K_i\,Y^{z-i}\,] \;+ Y \;-\; K^{c}_{dis}\,Y^{-1} \;=\; 0\,. \tag{13.5.8}$$

The example $M^{z+} = Al^{3+}$ is considered in Section 13.5.2.1. The free Al^{3+} in solution is minimal and very low in the range of pH from 4 to 9, Appelo and Postma [1993], p. 208, Mitchell [1993], p. 44. Solubility is high at low or high pH, Fig. 13.5.2(a).

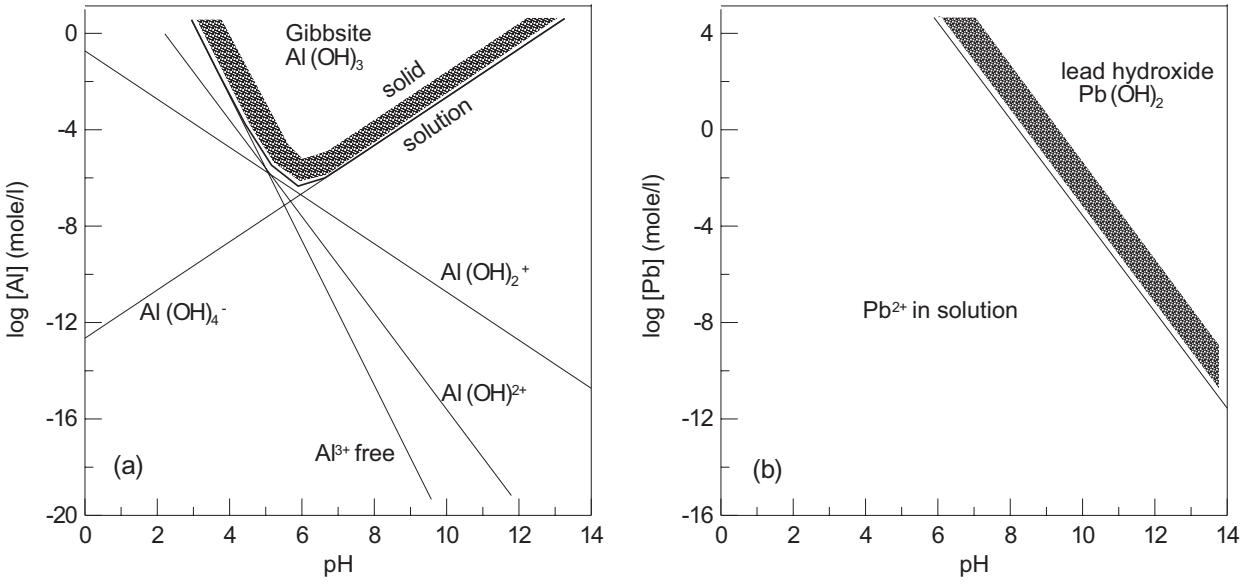

Fig. 13.5.2: (a) Gibbsite is in equilibrium with Al^{3+} in solution. The latter forms hydroxy complexes. The amount of free uncomplexed aluminum and hydroxy complexes is strongly dependent on pH. Equilibrium constants K_n defined by Eqn (13.5.3): $\log K_1$=-5, $\log K_2$=-10, $\log K_G$=-32.6, $\log K_4$=-22.

(b) Lead hydroxide is in equilibrium with Pb^{2+} in solution with an equilibrium constant $K_z = 2.8\times10^{-16}$ (mole/l)^3. The amount of free Pb^{2+} in solution is strongly pH-dependent, high in acid solutions and low in alkaline solutions.

13.5.2.1 Hydroxy complexes of aluminum

Complexation of dissolved Na^+ and K^+ is negligible but complexation dominates the aqueous solutions of Al^{3+}. Hydroxyalumina are the principal interlayer materials in acid geological materials, and hydroxymagnesium $Mg(OH)_2$ in alkaline geological materials.

Dissolution of gibbsite provides hydroxyl ions OH^- and so turns the solution more alkaline. Complexations have an opposite effect. Indeed, as an example, let us consider the dissolution of gibbsite $Al(OH)_3$,

$$Al(OH)_3 \;\rightleftharpoons\; Al^{3+} + 3\,OH^-\,, \quad K_G = [Al^{3+}]\,[OH^-]^3 = 10^{-32.6}\,. \tag{13.5.9}$$

In solution, Al^{3+} has a tendency to form hydroxy complexes $X_n = Al^{3+}(OH^-)_n$, $n = 1, 2, 4$, according to the reaction,

$$Al^{3+} + n\,H_2O \;\rightleftharpoons\; X_n + n\,H^+\,, \quad K_n = [X_n]\,[H^+]^n/[Al^{3+}]\,. \tag{13.5.10}$$

Each of these reactions is itself equivalent to the sum of the two reactions,

$$\begin{aligned} n\,H_2O \quad &\rightleftharpoons n\,OH^- + n\,H^+\,, \quad (K^c_{dis})^n = ([H^+]\,[OH^-])^n = 10^{-14n} \\ Al^{3+} + n\,OH^- \quad &\rightleftharpoons X_n, \qquad\quad K'_n = [X_n]/([Al^{3+}]\,[OH^-]^n) \end{aligned} \tag{13.5.11}$$

so that $K_n = (K^c_{dis})^n\,K'_n$.

Case A: the equilibrium constants K_n are known, $\log K_1 = -5$, $\log K_2 = -10$, $\log K_G = -32.6$, $\log K_4 = -22$. The equilibrium constants are measured in mole per liter, e.g., K_n [unit : $(\text{mole/l})^n$] and K_G [unit : $(\text{mole/l})^3$].

Let $Y \equiv 10^{-pH} = [H^+]$. For the complex n,

$$[X_n] = K_n\,K_G/(K^c_{dis})^3\,Y^{3-n} \quad \Leftrightarrow \quad \log[X_n] = \log K_n\,K_G/(K^c_{dis})^3 + (n-3)\,Y\,. \tag{13.5.12}$$

The concentration of free $[Al^{3+}]$ can be calculated from the pH using $K_G = [Al^{3+}]\,[OH^-]^3$, and then

$$[Al^{3+}]_{free} = K_G/(K^c_{dis})^3\,Y^3\,. \tag{13.5.13}$$

The total concentration of aluminum in solution is the sum of dissolved (free, uncomplexed) Al^{3+} and hydroxy complexes, Appelo and Postma [1993], p. 208,

$$[Al^{3+}]_{solution} = K_G/(K^c_{dis})^3[\,Y^3 + K_1\,Y^2 + K_2\,Y + K_4\,Y^{-1}\,]\,. \tag{13.5.14}$$

Electroneutrality of the solution

$$3\,[Al^{3+}] + 2\,[X_1] + [X_2] - [X_4] + [H^+] - [OH^-] = 0\,, \tag{13.5.15}$$

provides the equation for Y,

$$K_G/(K^c_{dis})^3[\,3\,Y^3 + 2\,K_1\,Y^2 + K_2\,Y - K_4\,Y^{-1}\,] + Y - K^c_{dis}\,Y^{-1} = 0\,. \tag{13.5.16}$$

Case B: the equilibrium constants K'_n are known.

Let $Y = 10^{14-pH} = [OH^-]^{-1}$. For the complex n,

$$[X_n] = K_G\,K'_n\,Y^{3-n} \quad \Leftrightarrow \quad \log[X_n] = \log K_G\,K'_n + (3-n)\,Y\,. \tag{13.5.17}$$

The concentration of free $[Al^{3+}]$ can be calculated from the pH using $K_G = [Al^{3+}]\,[OH^-]^3$, and then

$$[Al^{3+}]_{free} = K_G\,Y^3\,. \tag{13.5.18}$$

The total concentration of aluminum in solution is the sum of dissolved (free, uncomplexed) Al^{3+} and hydroxy complexes, Appelo and Postma [1993], p. 208,

$$[Al^{3+}]_{solution} = K_G[\,Y^3 + K'_1\,Y^2 + K'_2\,Y + K'_4\,Y^{-1}\,]\,. \tag{13.5.19}$$

Electroneutrality of the solution,

$$3\,[Al^{3+}] + 2\,[X_1] + [X_2] - [X_4] + [H^+] - [OH^-] = 0, \tag{13.5.20}$$

provides the equation for $Y = 10^{14-pH} = [OH^-]^{-1}$,

$$K_G[\,3\,Y^3 + 2\,K'_1\,Y^2 + K'_2\,Y - K'_4\,Y^{-1}\,] + 10^{-14}\,Y - Y^{-1} = 0\,. \tag{13.5.21}$$

13.5.2.2 Hydrolysis with single complex

Some low valence cations do not form complexes. If once again M^z is seen as coming from the dissolution of $X_z = M(OH)_z$, then

$$(X_z)_{solid} \quad \rightleftharpoons M^{z^+} + z\,OH^-, \quad K_z = [M^{z^+}]\,[OH^-]^z\,, \tag{13.5.22}$$

where the concentration of X_z has been set to 1 because it is solid. The concentration of free $[M^{z^+}]$ can be calculated from the pH using $Y \equiv 10^{-pH} = [H^+]$, and then

$$[M^{z^+}]_{free} = K_z\,(K^c_{dis})^{-z}\,Y^z, \quad \log[M^{z^+}]_{free} = \log K_z\,(K^c_{dis})^{-z} - z\,Y\,. \tag{13.5.23}$$

For example for lead $M^{z^+} = Pb^{2+}$, $z = 2$ and $K_z = 2.8 \times 10^{-16}\,(\text{mole/l})^3$. The solubility thus decreases when pH increases, i.e. the solubility is high at low pH only, Fig. 13.5.2(b).

13.5.3 Individual and simultaneous solubilities of NaCl and KCl

Under standard conditions of ambient temperature and pressure (temperature =25°C= 298.15 K, pressure = 10^5 Pa), the maximum mass of NaCl dissolved *in one liter of distilled water* is 360 gm, that is 6.15 moles, corresponding to the molar fraction $x_{\rm Na}^{\rm sat} = 0.091$, i.e. $x_{\rm w}^{\rm Na-sat} = 0.819$, since the molar masses of the sodium ion $\widehat{m}_{\rm Na}$ and of the chloride ion $\widehat{m}_{\rm Cl}$ are equal to 23 gm and 35.5 gm respectively. The molar volume of dissolved salt varies from about 17 $\rm cm^3$ at low molarity to about 21 $\rm cm^3$ at high molarity, Fig. 13.2.3. Here, we admit a fixed value of $\hat{v}_{\rm NaCl}$=20 $\rm cm^3$. The molar volume of the fluid phase varies from 18 $\rm cm^3$ for distilled water to $0.91 \times 18 + 0.09 \times \hat{v}_{\rm NaCl}$=18.2 $\rm cm^3$, which gives a saturated salt concentration equal to 5 moles, or also 115 gm of Na^+ *per liter of solution* (≡ fluid phase, or electrolyte).

The maximum mass of KCl dissolved in one liter of distilled water is 342 gm, that is 4.58 moles, since $\widehat{m}_{\rm K}$ = 39.1 gm. Admitting also a molar volume of dissolved salt of $\hat{v}_{\rm KCl}$=20 $\rm cm^3$, we obtain now: molar fraction of potassium $x_{\rm K}^{\rm sat} = 0.071$, i.e. $x_{\rm w}^{\rm K-sat} = 0.858$, molar volume of the fluid phase $\hat{v}_{\rm F}$=18.15 $\rm cm^3$, concentration of potassium equal to 3.91 moles, that is 153 gm of K^+ per liter of solution.

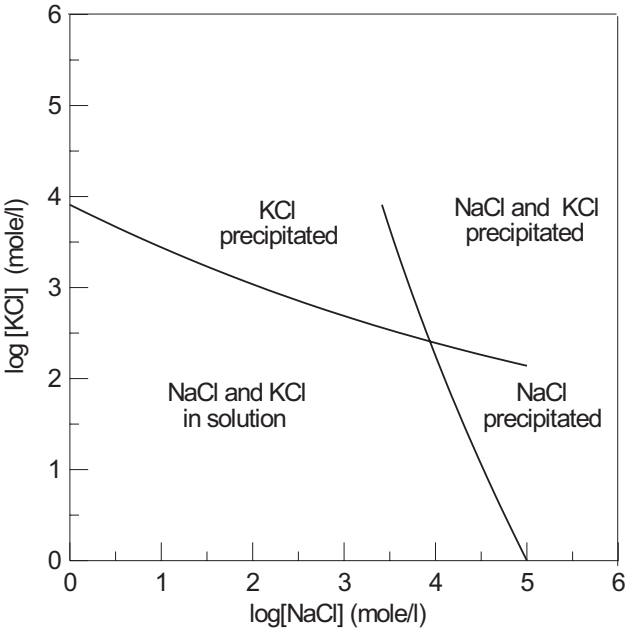

Fig. 13.5.3: Solubility limits for an electrolyte with the two salts NaCl and KCl under standard conditions of temperature and pressure.

When they are dissolved together, the saturated values vary with the concentrations as displayed by Fig. 13.5.3. Indeed, the above remarks can be rephrased in terms of *solubility constants* $K_{\rm NaCl}$ and $K_{\rm KCl}$ of individual salts. For example, NaCl dissolves spontaneously or saturates in distilled water, that is, an addition of salt in water precipitates, according to the following rule,

$$\begin{aligned} {\rm NaCl} &\rightarrow {\rm Na^+ + Cl^-} \quad \text{if} \quad [{\rm Na^+}][{\rm Cl^-}] < K_{\rm NaCl}, \\ {\rm NaCl} &\rightleftharpoons {\rm Na^+ + Cl^-} \quad \text{if} \quad [{\rm Na^+}][{\rm Cl^-}] = K_{\rm NaCl}\,. \end{aligned} \tag{13.5.24}$$

Accounting for electroneutrality, the solubility constant $K_{\rm NaCl}$ for NaCl is equal to $5.0^2 = 25.0$ (mole/liter of solution)^2, and the solubility constant $K_{\rm KCl}$ for KCl is equal to $3.91^2 = 15.29$ (mole/liter of solution)^2.

Now assume water to be NaCl-saturated, that is $[{\rm Na^+}]\,[{\rm Cl^-}] = K_{\rm NaCl}$, with $[{\rm Cl^-}] = [{\rm Na^+}] + [{\rm K^+}]$, but not KCl-saturated. The concentration of dissolved Na^+ is

$$[{\rm Na^+}] = -\frac{[{\rm K^+}]}{2} + \left(\frac{[{\rm K^+}]^2}{4} + K_{\rm NaCl}\right)^{1/2}. \tag{13.5.25}$$

Addition of KCl results in precipitation of Na^+ and in dissolution of K^+ because the concentration of chloride increases. The concentrations of dissolved ions vary as $([{\rm K^+}] + 2\,[{\rm Na^+}])\,d[{\rm Na^+}] + [{\rm Na^+}]\,d[{\rm K^+}]$=0.

Conversely, if water is first KCl-saturated, any addition of NaCl will result in precipitation of K^+ and in dissolution of Na^+. The concentration of dissolved K^+ is

$$[K^+] = -\frac{[Na^+]}{2} + \left(\frac{[Na^+]^2}{4} + K_{KCl}\right)^{1/2} . \tag{13.5.26}$$

The concentrations of dissolved ions vary as $([Na^+] + 2\,[K^+])\,d[K^+] + [K^+]\,d[Na^+]=0$. In both cases, water will end up to be KCl- and NaCl-saturated when $[Na^+]\,[Cl^-] = K_{NaCl}$ and $[K^+]\,[Cl^-] = K_{KCl}$, that is for

$$[K^+] = \frac{K_{KCl}}{(K_{KCl} + K_{NaCl})^{1/2}}, \quad [Na^+] = \frac{K_{NaCl}}{(K_{KCl} + K_{NaCl})^{1/2}} , \tag{13.5.27}$$

and then the precipitates are in equilibrium with the dissolved salts,

$$KCl + Na^+ \quad \rightleftharpoons NaCl + K^+ . \tag{13.5.28}$$

The above remarks have implicitly assumed that salt precipitation/dissolution is instantaneous. Alternatively, if the precipitation/dissolution is not instantaneous, the above relations can be viewed as steady states or equilibria. At a sufficiently small time scale, precipitation/dissolution is governed by a kinetic equation of identical order n_{NaCl} in Na^+ and Cl^+ and defined by the precipitation constant k_{NaCl}, namely

$$\frac{d}{dt}[NaCl] = -\frac{d}{dt}[Na^+] = -\frac{d}{dt}[Cl^-] = k_{NaCl}\,\left(([Na^+]\,[Cl^-])^{n_{NaCl}} - (K_{NaCl})^{n_{NaCl}}\right) . \tag{13.5.29}$$

13.6 Some basic notions of electrostatics

13.6.1 Permittivity and relative permittivity

Charged molecules exert a mutual force on each other. The permittivity ϵ [unit : F/m or $C^2/J/m$] measures the influence on this force by the medium in which they are bathed. Indeed, according to Coulomb's law, the electrostatic force $F = Q\,Q'/(4\,\pi\,\epsilon\,r^2)$ between two charges Q and Q' is proportional to the square of the inverse of their distance r. The interaction energy $Q\,Q'/(4\,\pi\,\epsilon\,r)$ is proportional to the inverse of their distance. This interaction energy is equal to the work done by the charge Q' in presence of the electrical potential ϕ (equal to $\phi(r)$ at the position of Q') generated by the charge Q, or by the charge Q in presence of the electrical potential ϕ' (equal to $\phi'(r)$ at the position of Q) generated by the charge Q'.

The permittivity of the vacuum ϵ_0 is equal to 8.8542×10^{-12} $C^2/J/m$. The permittivity of solvents is introduced through the relative permittivity (or dielectric constant) ϵ_r as $\epsilon = \epsilon_0\,\epsilon_r$. Table 13.6.1 indicates that the relative permittivity is affected by temperature. The high value of the relative permittivity of water with respect to a few organic solvents can be appreciated from Table 13.6.2. The consequences on its high solvation properties are commented in Section 13.5.1.

Table 13.6.1: Dependence of the relative permittivity of water ϵ_r with respect to temperature.

Temperature (°C)	0	20	25	60
ϵ_r	88	80.1	78.5	67

Table 13.6.2: Relative permittivity of some organic compounds at 20 °C.

Water H_2O	Ethylene Glycol $C_2H_6O_2$	Ethanol C_2H_6O	Acetic acid $C_2H_4O_2$	Benzene C_6H_6	Heptane C_7H_{16}
80.1	37	24.3	6.1	2.3	1.9

13.6.2 Gauss's law and Poisson's equation

As indicated above, the electrical potential originated by a pointwise electrical charge Q located at $\mathbf{x}_Q$ is equal, at a distance r from the charge, to

$$\phi(r) = \frac{Q}{4\,\pi\,\epsilon\,r}\,. \tag{13.6.1}$$

The electrical field $\mathbf{E}$ associated with the electrical potential (13.6.1) is defined as $-\boldsymbol{\nabla}\phi$,

$$\mathbf{E}(r) = \frac{Q}{4\,\pi\,\epsilon\,r^2}\,\hat{\mathbf{r}}\,, \tag{13.6.2}$$

with $\hat{\mathbf{r}} = (\mathbf{x}-\mathbf{x}_Q)/|\mathbf{x}-\mathbf{x}_Q|$ the unit vector indicating the direction of the charge. **Gauss's law** states that the total electric flux through a closed surface ∂V is equal to the total charge inside the volume V,

$$\int_{\partial V} \epsilon\,\mathbf{E}\cdot d\mathbf{A} = \int_V I_{\rm e}\,dV\,, \tag{13.6.3}$$

with $I_{\rm e}$ the electrical density [unit : $\mathrm{C/m^3}$]. This equation is easily proved for a pointwise charge. Indeed, on a sphere of radius r surrounding the charge, and parameterized by the angles $\alpha \in [0, 2\pi[$ and $\beta \in [0, \pi[$ as indicated in Section 12.1.2, the element of area is equal to $d\mathbf{A} = r^2\,\sin\beta\,d\alpha\,d\beta\,\hat{\mathbf{r}}$, and therefore $\mathbf{E}\cdot d\mathbf{A} = (Q/4\pi)\,\sin\beta\,d\alpha\,d\beta$.

With help of the Green's theorem, the surface integral transforms into a volume integral yielding finally, under sufficiently smooth conditions, **Poisson's equation** as a pointwise version of Gauss's law,

$$\mathrm{div}\,(\epsilon\,\mathbf{E}) = -\mathrm{div}\,(\epsilon\,\boldsymbol{\nabla}\phi) = I_{\rm e}\,. \tag{13.6.4}$$

As another consequence of Gauss's law, the potential due to a sphere of radius r_0 with a charge Q on its surface,

$$\phi(r) = \begin{cases} \dfrac{Q}{4\,\pi\,\epsilon\,r} & r \geq r_0, \\ \text{constant} & r \leq r_0, \end{cases} \tag{13.6.5}$$

is observed to be identical, outside the sphere, to that of a point charge. Indeed, according to Gauss's law (13.6.3), the electrical field depends only on the charge, not on the details of the spatial repartition of the charge inside the volume defined by the closed surface ∂V.

13.6.3 Characteristic time of electric relaxation

The length scale of interest in this textbook assumes that electroneutrality holds pointwise. As the analysis of the diffuse double layer in Exercise 13.1 shows, the property does not apply at the nanometer scale but we have no access to this scale in a macroscopic analysis.

Still, even at a macroscopic spatial scale, displacements of charges perturb local electroneutrality over a certain characteristic time $t_{\rm elec}$. This electric relaxation time is much smaller than the other characteristic times of interest in this work, in such a way that electroneutrality can be considered to hold pointwise and instantaneously.

Indeed, let $I_{\rm e}$ [unit : $\mathrm{coulomb/m^3}$] be the electrical density and $\mathbf{I}_{\rm e}$ [unit : $\mathrm{coulomb/m^2/s}$] the electrical current density. The electrical density is linked to the electrical potential ϕ [unit : volt] through the capacitance $G_{\rm e}$ [unit : F=coulomb/volt], namely $V\,I_{\rm e} = G_{\rm e}\,\phi$, where $V = L^3$ is the volume of interest. The capacitance depends on the permittivity ϵ of the solvent, and on the characteristic length of the capacitor, Eqn (13.E.15), say $G_{\rm e} \sim \epsilon\,L$. Moreover, the electrical current density depends linearly on the electrical field through the electrical conductivity $\sigma_{\rm e}$ [unit : ampère A/volt V/m], namely $\mathbf{I}_{\rm e} = -\sigma_{\rm e}\,\boldsymbol{\nabla}\phi$.

The conservation of the charge,

$$\frac{\partial I_{\rm e}}{\partial t} + \mathrm{div}\,\mathbf{I}_{\rm e} = 0\,, \tag{13.6.6}$$

becomes an equation of diffusion for the electrical potential,

$$\frac{G_{\rm e}}{V}\,\frac{\partial\phi}{\partial t} - \sigma_{\rm e}\,\mathrm{div}\,\boldsymbol{\nabla}\phi = 0\,, \tag{13.6.7}$$

which can be phrased in terms of a dimensionless space variable x/L and of a dimensionless time $t/t_{\rm elec}$,

$$t_{\rm elec} = \frac{G_{\rm e}\, L^2}{V\, \sigma_{\rm e}} \sim \frac{\epsilon}{\sigma_{\rm e}}\,. \tag{13.6.8}$$

For water at ambient temperature, $\epsilon \sim 7 \times 10^{-10}\,{\rm C}^2/{\rm J/m}$ according to Table 13.6.1. Moreover, according to Table 16.4.3, the electrical conductivity of articular cartilages takes values in the range $10^{-2} - 1\,{\rm A/V/m}$. Therefore, the electrical relaxation time ranges in the interval

$$t_{\rm elec} \in [10^{-9},\ 10^{-7}]\ {\rm s}\,. \tag{13.6.9}$$

This time scale is much smaller than the characteristic times of the other phenomena we are concerned with when studying the electro-chemomechanical couplings of soft tissues in a continuum perspective. Therefore, in this macroscopic analysis, electroneutrality can be considered safely to hold pointwise and instantaneously.

13.7 Semi-permeable membrane and osmotic effect

The notion of chemical potential has been shown in Chapter 10 to control the exchanges of mass between two compartments. It serves also as a vehicle to explain the phenomenon of osmosis.

Consider a bucket separated in two parts by a membrane impermeable to solute as sketched in Fig. 13.7.1[13.7]. Initially, the two sides of the membrane, numbered 1 and 2, have identical chemical content, water w (the solvent) and the neutral solute s, and are submitted to the same external pressure p. At any time, the molar fractions of water and salt satisfy the identities $x_1^{\rm w} + x_1^{\rm s} = 1$ and $x_2^{\rm w} + x_2^{\rm s} = 1$.

The *chemical potential* of water at pressure p and molar fraction $x^{\rm w}$ expresses as[13.8]

$$g^{\rm w} = \widehat{v}_{\rm w}\, p + R\,T\,{\rm Ln}\, x^{\rm w}, \tag{13.7.1}$$

with $\widehat{v}_{\rm w}$ molar volume of water, R is the universal gas constant and T the absolute temperature. Since only water can transfer through the membrane, chemomechanical *equilibrium* across the membrane is phrased in terms of the chemical potential of water only. The initial concentration of solute is very small, so that:

$$\text{Initial equilibrium}: \quad p_1 = p_2,\ x_1^{\rm w} = x_2^{\rm w} \sim 1,\ x_1^{\rm s} = x_2^{\rm s} \sim 0. \tag{13.7.2}$$

Solute is then added on side 1:

$$\text{Add solute}: \quad \Delta x_1^{\rm s} > 0 \ \Rightarrow \Delta x_1^{\rm w} = -\Delta x_1^{\rm s} < 0. \tag{13.7.3}$$

The short term rate of mass transfer of water through the membrane is assumed to be governed by the following law defined by a constant $k_{\rm H} > 0$ representative of the permeability of the membrane to water (motivation for and generalization of this law will be addressed later),

$$\begin{aligned} \text{Law of transfer}: \quad \frac{dm_1^{\rm w}}{dt} &= k_{\rm H}\,(\Delta g_2^{\rm w} - \Delta g_1^{\rm w}) \\ &= k_{\rm H}\,(\ 0\ - (-R\,T\,\Delta x_1^{\rm s})\ ) > 0 \quad \text{instantaneously.} \end{aligned} \tag{13.7.4}$$

Consequently observation leads to

Rule 1: *flow is directed towards the region of higher solute concentration.*

In the long range, a final equilibrium corresponding to a vanishing flow through the membrane gets established when the chemical potentials on each side of the membrane of water tend to a common value,

$$g_1^{\rm w} \sim \widehat{v}_{\rm w}\, p_1 - R\,T\,x_1^{\rm s} \ = \ g_2^{\rm w} \sim \widehat{v}_{\rm w}\, p_2 - R\,T\,x_2^{\rm s} \tag{13.7.5}$$

This result is encapsulated as

[13.7] Unlike the usual presentation which uses a thin U-shaped tube, gravity is neglected here and the mechanical loads are applied by external agents. In the usual presentation, the external load on both sides of the tube is the atmospheric pressure and the difference of pressures gives rise to different elevations of water on the two sides of the tube.

[13.8] In this section, we use *mole based* chemical potentials following the usual convention of textbooks of physical chemistry.

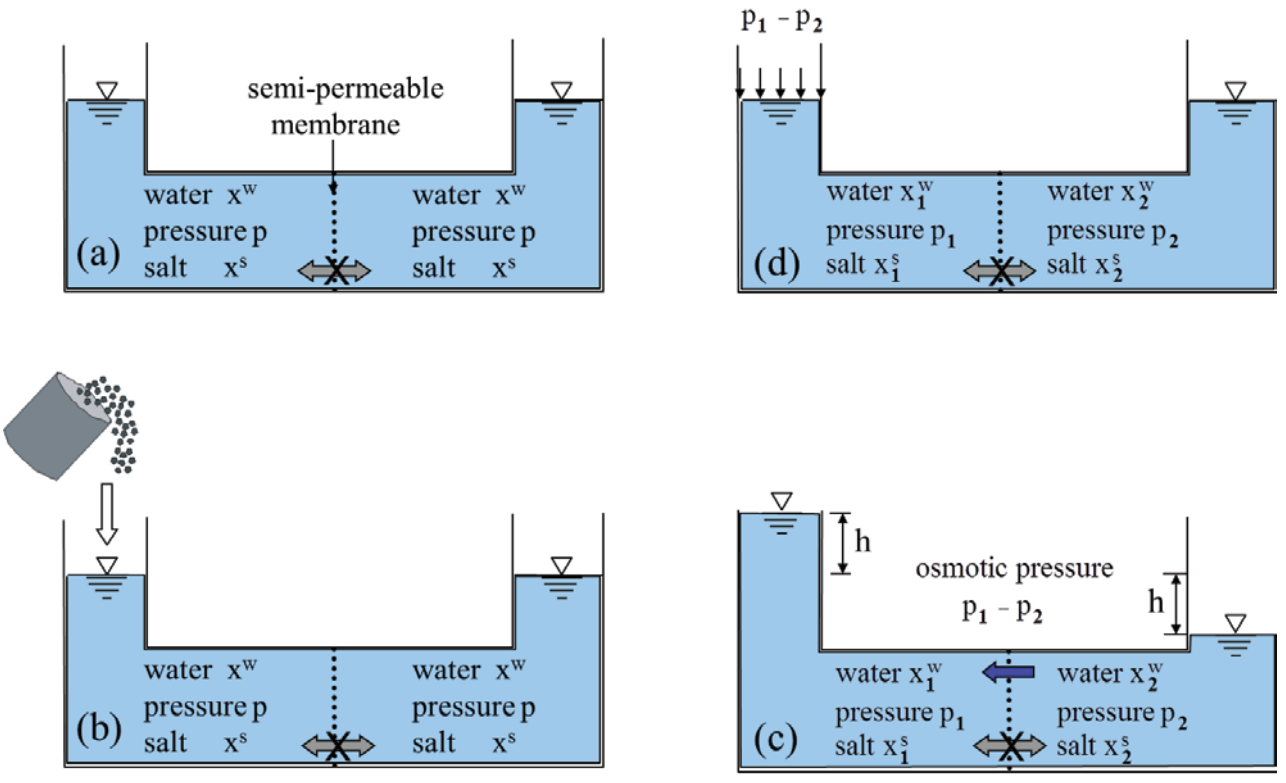

Fig. 13.7.1: Osmotic phenomenon via a semi-permeable membrane. (a) A membrane permeable to water only separates a bucket in two parts. Initially, the chemical contents and pressures are identical on both sides. (b) Addition of solute in side 1 triggers a transfer of water from side 2 to side 1. (c) The height of water, and its pressure, increases in side 1. The converse takes place in side 2. With g the acceleration of gravity and $2\,h$ the differential of water height, equilibrium (zero flow) requires the mechanical pressure difference $p_1 - p_2 = (p + \rho_w\, g\, h) - (p - \rho_w\, g\, h)$ to be equal to the chemical pressure difference $\pi \equiv RT\,(x_1^s - x_2^s)/\widehat{v}_w$. The osmotic effect is a typical instance of *chemomechanical coupling*. (d) An alternative way of reaching equilibrium at fixed height of water is to apply directly the osmotic pressure π to side 1. Then $p_1 = p + \pi$ and $p_2 = p$. If the applied pressure is larger than π, the *reverse osmosis* phenomenon briefly touched upon in Section 13.8 takes place: this phenomenon represents a basic example of *mechanochemical coupling*.

Rule 2 or van't Hoff law: *at equilibrium, pressure is higher where solute concentration is higher, namely*

$$p_1 - p_2 = RT\,(x_1^s - x_2^s)/\widehat{v}_w > 0. \tag{13.7.6}$$

Hence, osmotic effect has generated a counterflow to usual Darcy's flow.

The chemical potential may be phrased in terms of concentration $c^s = x^s/\widehat{v}_w$ instead of molar fraction. The quantity,

$$\pi = RT\,c^s\,. \tag{13.7.7}$$

is referred to as the osmotic pressure associated with the concentration c^s.

So far the membrane was assumed to be completely impermeable to solute. More generally the permeability of the membrane for the solute can be introduced via the *reflection coefficient* ω also called *osmotic coefficient* or *osmotic efficiency*. This coefficient is a property of both the membrane and the solute. It varies between 0 and 1: it is equal to 0 for a completely permeant solute and to 1 for an non-permeant solute (as assumed above). Then the law of transfer of water has to be modified. For that purpose we need the chemical potential of the solute. We adopt an approximative expression for dilute solution,

$$g^s \simeq RT\,\mathrm{Ln}\,x^s. \tag{13.7.8}$$

The general coupled mass transfer law is postulated as a linear combination of the differentials of the chemical

potentials,

$$\begin{aligned} \frac{dm_1^{\rm w}}{dt} &= k_{\rm H}(\Delta g_2^{\rm w} - \Delta g_1^{\rm w}) + k_{\rm ws}(\Delta g_2^{\rm s} - \Delta g_1^{\rm s}) \\ &= k_{\rm H}\,\widehat{v}_{\rm w}\big(\Delta p_2 - \Delta p_1 - \omega\,(\Delta\pi_2 - \Delta\pi_1)\big)\,, \end{aligned} \tag{13.7.9}$$

with the notation $k_{\rm ws} = k_{\rm H}\,x^{\rm s}\,(1-\omega)$, assuming the solute concentrations on the two sides to be close. Therefore for any noncompletely permeant solute, i.e., $\omega \neq 0$, a pressure differential proportional to the osmotic coefficient should be exerted to reach a steady state, that is, to stop water flow:

$$\Delta p_2 - \Delta p_1 = \omega(\Delta\pi_2 - \Delta\pi_1)\,. \tag{13.7.10}$$

The law of transfer for the solute involves its diffusion properties through the membrane,

$$\begin{aligned} \frac{dm_1^{\rm s}}{dt} &= k_{\rm sw}(\Delta g_2^{\rm w} - \Delta g_1^{\rm w}) + k_s(\Delta g_2^{\rm s} - \Delta g_1^{\rm s}) \\ &= k_{\rm sw}\,\widehat{v}_{\rm w}\big(\Delta p_2 - \Delta p_1 - Y\,(\Delta\pi_2 - \Delta\pi_1)\big)\,, \end{aligned} \tag{13.7.11}$$

with $Y \equiv 1 - k_{\rm s}/(x^{\rm s}\,k_{\rm sw})$. If $k_{\rm s}/k_{\rm sw} = k_{\rm ws}/k_{\rm H}$, then $Y = \omega$ and the solute is convected by the liquid through the membrane, with the proviso that $k_{\rm sw}$ is proportional to the solute concentration, as exposed in Section 15.8.3 which addresses the extravasation of blood and macromolecules through the vascular wall.

Complete equilibrium is defined by the equality of the chemical potentials of both water and salt and more generally of all (even partially) permeant species.

We have seen that osmosis requires a membrane to develop. Crucially, membranes are selective with respect to species. A species is endowed with a transfer time. An infinite transfer time practically prevents a species to cross the membrane. Transfer times depend inter alia on the size, polarity, molar mass of the species. Membranes may be well defined objects, natural like the ones that limit cells or engineered clay barriers to prevent leakage of pollutants. In cartilage, steric considerations prevent macromolecules to enter the space defined by collagen fibers. Electrical repulsion creates fictitious membranes which generate significant ionic disequilibria.

The osmosis phenomenon may be illustrated by the process of intravenous feeding. Hypertonic solutions lead to shrinking of the cells from which water is desorbed. Therefore administration of a hypertonic solution may be a cure against oedema (e.g., swelling of ankles or feet). Conversely, a hypotonic solution leads the cells to absorb water. A number of drinks like tea, apple juice, etc. are hypotonic.

13.8 Reverse or Inverse osmosis

Filtration, or inverse osmosis, actually known as reverse osmosis in the anglo-saxon world, is a process where water and solutes move through a membrane due to a pressure differential.

According to (13.7.9), the flows of liquid and solute, if the latter is permeant, are directed from the side of large $p - \omega\,\pi$ to the side of small $p - \omega\,\pi$.

This principle rules the mass exchanges in kidneys. Water and small solutes move from the capillaries to the tubules because blood pressure in the former is larger than fluid pressure in the latter. This process is not highly selective, and only the largest blood proteins or blood cells are not admitted in the tubules. In fact, only a part of the substances that transfer through this process are eliminated, e.g., urea. Indeed a percentage of water is next re-absorbed passively through osmosis, while glucose and amino acids are re-absorbed through dedicated active transporters.

Inverse osmosis is also an industrial process to desalinize water. It consists in applying a pressure of several atmospheres to the saline water (side 1 of the membrane) while the other side is at atmospheric pressure. As of spring 2008, the French company Degrémont was running over 250 desalinizing plants all over the world, using this principle with a pressure differential of about 10 atmospheres. Membranes used in that process should of course be highly selective with respect to sodium ions and chloride anions, and be inert with respect to acid-base reactions and chlorine.

Inverse osmosis is also at work in trees to drive water from salty soils. The solute concentration of xylem water is low, much lower than that of the soil, the roots coming into picture as a sort of semi-permeable membrane. Under equal fluid pressure, osmosis would dictate that water leaves the tree. To reverse this trend, the above industrial process would apply a positive pressure on the soil water. The alternative choice by nature in botany is to apply a

negative pressure in the tree. Equilibrium of the sap between the roots and the leaves, namely $p_r - \pi_r = \rho\, g\, h + p_l - \pi_l$ combined with equilibrium between the soil and the roots, namely $p_r - \pi_r = p_s - \pi_s$, together with the fact that the leaves and soil are at atmospheric pressure, namely $p_l = p_s (= p_{\text{atm}})$, implies $\rho\, g\, h = \pi_l - \pi_s > 0$, which is positive because the solute concentration of the cells of the leaves is high, much higher than the solute concentration of the water at the roots, Scholander et al. [1964].

13.9 Electrical repulsion and electrical shielding

Proteoglycans are negatively charged. Therefore adjacent branches repel one another. Electroneutrality is ensured by the presence of *counterions*, that is, ions of electrical charge opposite to that of the fixed charge. This repulsion tends to increase the volume of the tissue which is penetrated by water, as sketched in Fig. 13.9.1.

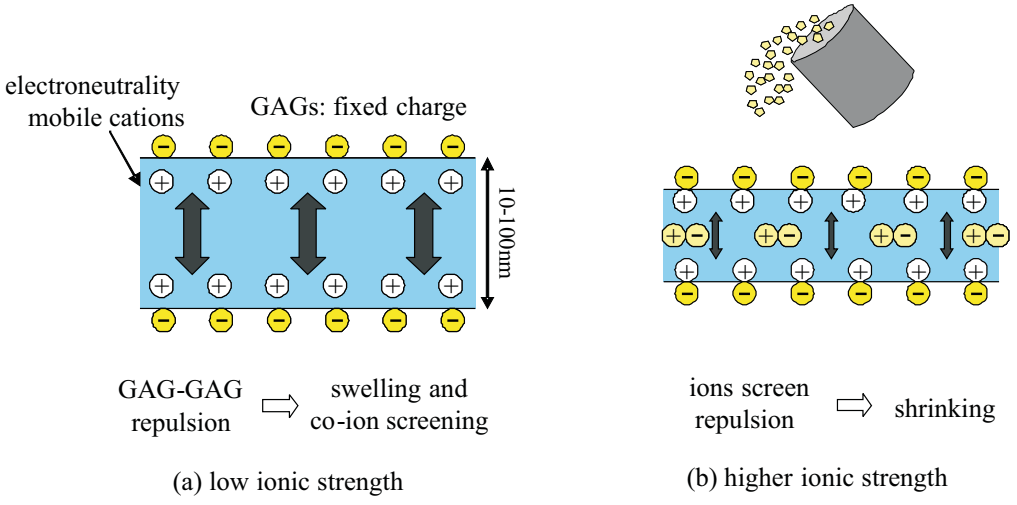

Fig. 13.9.1: Electrical repulsion maintains the fixed charges away from one another. Electroneutrality is ensured at some length scale by mobile ions that diffuse in the fluid. While cations sodium do not bind to GAGs, cations calcium do to some extent and hydrogen ions may even change the sign of the fixed charge. The presence of counterions decreases the electrical repulsion between fixed charges of identical sign and leads to macroscopic contraction.

Electrical repulsion is due to fixed charges, while electrical shielding is due to mobile ions. Observations show that

- the magnitude of the repulsion, and the distance between branches, decrease as the ionic concentration of the electrolyte, also called *ionic strength*, increases. In other words, counterions screen or shield the repulsion force;
- the magnitude of the shielding is ion-dependent, valence and hydrated size of the ions playing a role;
- however at sufficiently high ionic strength in the so-called hypertonic state, the ultimate shielding and distance between branches are essentially ion-independent.

The repulsion between two fixed electrical charges of identical signs depends on the dielectric constant of the electrolyte they bath in. Pure fluids have their own dielectric constants as indicated in Tables 13.6.1 and 13.6.2. Replacement of permeants in fixed charge materials leads to volume changes consistent with their respective dielectric constant. Data tend to show that the presence, and actual concentration, of ions in the permeant fluid modifies the dielectric constant of the electrolyte, Di Maio et al. [2004].

13.10 The pore composition in materials with fixed charge

Mechanical loading consists in monitoring some components of the load vector and the complementary components of the displacement vector. During quasi-static laboratory experiments, the mechanical load is applied either at once or incrementally. It would be transmitted instantaneously to any point of the specimen if the material was behaving like an elastic solid. However time dependence delays somehow the mechanical information applied at the boundary. This time dependence is due to either an intrinsic viscous behavior or to the fact that the specimen is a multiphase material.

Chemical loading is applied by putting the specimen in contact with a bath or reservoir of controlled chemical composition. The contact is not direct and a porous layer is often used as an interface. The interface being stiffer than the tissue is aimed at homogenizing the mechanical load and at smoothing the time profile of the changes of chemical composition in the bath.

The chemical information never transfers instantaneously to the specimen. The delay depends on the properties of the porous layer and on the size and geometry of the specimen. Indeed, chemicals need to move throughout the porous layer and next through the specimen before a steady state can be reached. The motion of the chemicals takes place within the fluid phase, under several modes, like diffusion, advection, electromigration, etc. Modeling of the transport issues is considered in Chapter 16.

The examples described below intend to

- quantify the effect of the overall ionic concentration;
- highlight the effects of the ionic concentration of individual species;
- contrast the influence of chemical loadings at *given mechanical load* and at *given strain*. The distinction between these two types of experimental conditions is obtained in situations as close as possible to a one-dimensional context. However, the actual mechanical behavior is always three-dimensional: in the oedometer, that provides the conditions for confined compression, lateral displacements are prevented so that the lateral strains vanish and therefore stresses develop as part of the material response.

These examples feature a geological material, namely *a chemically active clay*, and articular cartilages. Interestingly enough, the structural elements that control the electro-chemomechanical coupling have, for both materials, a nanometric length scale. The driving engine is the fixed electrical charge which is negative at neutral pH. Its sensitivity to the pH of the electrolyte depends on the details of the electrical charge. A lesson from these examples can be encapsulated in the following

Property: chemomechanical coupling versus pH sensitivity

Some materials with fixed charge can be highly sensitive to electro-chemomechanical coupling while displaying a low pH dependence, and conversely.

The first property is linked to the effective concentration of the charge, a volumetric property, while the second property is tied to the nature of the fixed charge, a surface property in geological materials.

13.10.1 Chemical consolidation and swelling in clays

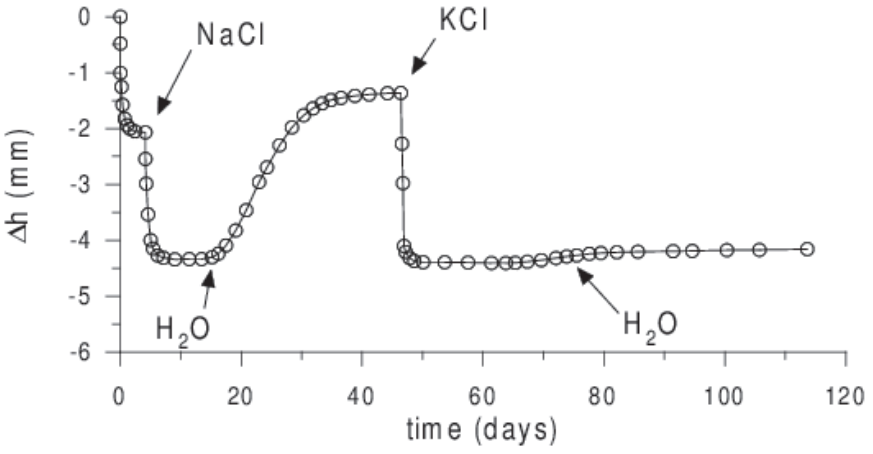
Smectites are clays formed by structural units, between which the bonds are weak, so that layers of absorbed water and cations may enter the interlayer space and produce swelling. Typically, when two ions have non-hydrated sizes that do not differ by more than 15% and valences by more than unity they can exchange in the clay sheets: this phenomenon called *isomorphous substitution* leaves the clay with a fixed negative charge at neutral pH.

13.10.1.1 Nanostructure of clays

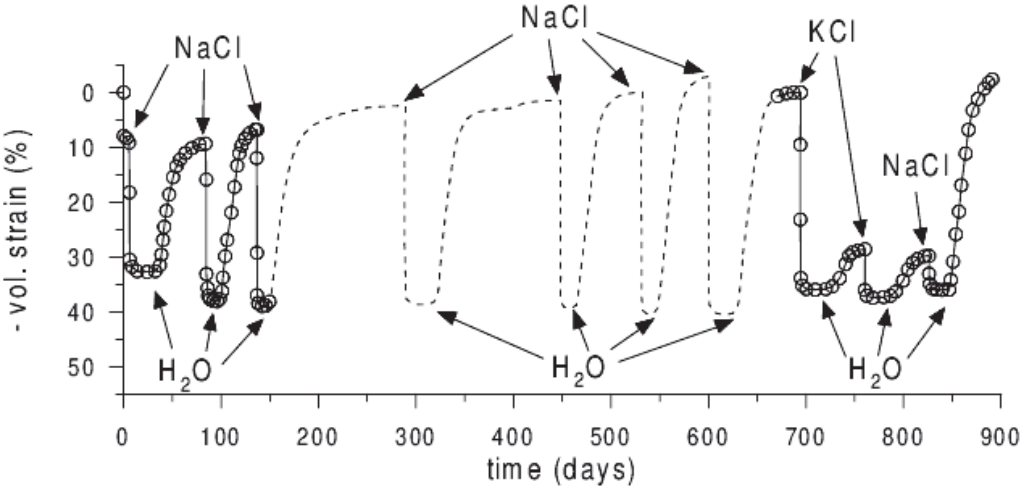
Fundamental to the understanding and modeling of chemically driven swelling of expansive clays are their microstructure and the organization of their pore space and water. For smectites, this microstructure is dominated by clusters of parallel platelets of clay mineral separated by 10-20 Å interlamellar pores filled with few one-molecule layers of water, called interlayer water or internal absorbed water. This water has properties such as density or viscosity which are slightly different from those of free water. Interlayer water does not flow even when subjected to high hydraulic gradients and it deforms together with the solid part of the clusters. Clusters are enveloped by external adsorbed water, up to seven molecular diameters in thickness. Montmorillonite clusters of width 1 to 10 µm may contain from 5 to 15 three-layer units and up to 1000 units in compacted clays. Clusters in kaolinites have width from 0.1 to 4 µm and thickness usually from 0.05 to 0.1 µm equivalent to 60 to 120 two-layer units.

Usually clusters are separated by pores with the characteristic size of the order of 1 micrometer and more. Water that resides in such pores is called free water. Indeed, this water can be displaced by ordinary hydraulic gradients.

Swelling of compacted clays develops in two distinct regimes. During swelling at the lowest water contents, called *crystalline swelling*, interlamellar space *ad*sorbs water until it is filled with three or four molecular water layers. After the interlamellar space has been saturated, water starts to *ad*sorb to the external surfaces of clay particles, producing *osmotic swelling*. However in the comments below we shall gather crystalline and osmotic swelling under the term *chemical swelling* and make no distinction between *adsorbed* and *absorbed* water, both being parts of the solid phase.



(a) Experimental data on Bisaccia clay, redrawn from Di Maio and Fenelli (1997).



(b) Experimental data on Ponza bentonite, redrawn from Di Maio (1998).

Fig. 13.10.1: Successive replacements of a pore solution by NaCl and KCl saturated solutions during oedometric tests at constant vertical stress of 40 kPa. Evolution of (a) the settlement and (b) the volumetric strain. Increase of salt concentration implies chemical consolidation. KCl solutions lead to larger contraction than NaCl. The volume change associated with cation exchange seems mostly reversible. Still, replacement of cations initially present in Ponza bentonite by cations Na^+ is slow, progressive, and several cycles are needed for the settlement to get steady. Reprinted with permission from Loret et al. [2004]a.

13.10.1.2 Modification of the ionic strength in homoionic clays

Montmorillonites are particularly sensitive to the composition of their pore water. Fig. 13.10.1(a) shows the time evolution of the vertical settlement in an oedometric test. The sample of 2 cm height is in contact with a reservoir of controlled chemical composition. Initially the reservoir is filled with distilled water (dw). The sample is first mechanically compressed by the application of an instantaneous load which results in a *mechanically induced consolidation* which tends to stabilize in few days. Next, while the load is kept unchanged, the water of the reservoir is NaCl-saturated. A significant *chemically induced consolidation* develops. The consolidation time is of about the same duration as for mechanical consolidation. When the reservoir electrolyte is refreshed, the sample undergoes a volume expansion termed *chemical swelling* that requires a few weeks to stabilize.

The volume change upon the chemical cycle turns out here to be positive (expansion). In general, it is the result of mechanisms which might compete or cooperate:

- cations are attracted by the *negatively charged clay clusters* and they are hydrated by absorbed water;
- the cations initially present around clusters may be 'displaced' by other ions which have a higher affinity for

the clay charge. Later in the context of the theory of mixtures, we shall use the terms 'transfer' and 'exchange' rather than 'displacement'. Ion exchange may result in an expansion or contraction;
- as a result of the osmotic effect, absorbed water between clay platelets is desorbed when the salt concentration in pore water increases. Desorption is accompanied by volume decrease and an increase of the overall stiffness of the clay. The converse phenomena take place when the ionic strength of pore water is decreased;
- irreversible contraction may develop, especially in presence of large mechanical stresses.

13.10.1.3 Ionic replacements in clays

Actually, the *reversible* or *irreversible* character of the material response to a chemical loading is difficult to be assessed because it involves a number of physical aspects, as well as microstructural features of the clays. Reversibility can be assumed as a first rough approximation. Let us illustrate this statement by an example.

Fig. 13.10.1(a) shows that saturation of the fresh reservoir by KCl results in about the same consolidation as that induced by NaCl yielding a unique hypertonic state. However later refreshment of the reservoir implies a very small swelling. The phenomenon is due to replacement of ions Na^+ by ions K^+, and this replacement contracts considerably the material behavior.

To recover approximately the initial volume, a complete *symmetric* chemical cycle should be performed, that is dw NaCl - dw KCl dw - NaCl dw, as witnessed by Fig. 13.10.1(b).

The latter figure shows that a number of cycles dw NaCl dw are necessary to reach steady state. This might be traced to the fact that the transfer times of ions from the interlayer water to the free water, and conversely, is long with respect to the time scale of the chemical cycles.

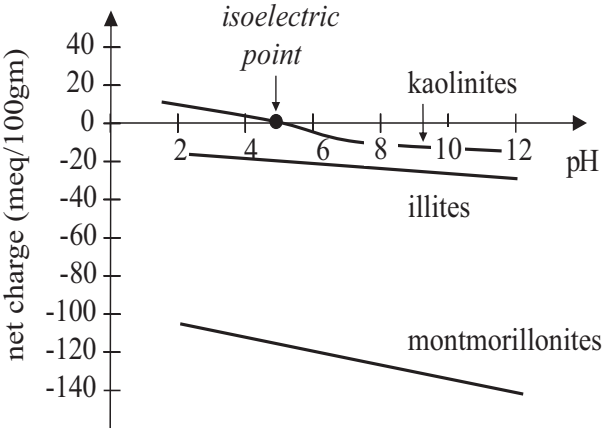


Fig. 13.10.2: Qualitative evolution of the electrical charge of clays as a function of pH, redrawn with permission from Loret et al. [2004]a, gathering information from several sources:
- the electrical charge is quantified through various measures, e.g., as a volumetric charge Q_e in milliequivalent (meq) per 100 gm of dry material=centimole/kg, or as surface charge σ_e in C/m^2;
- these two measures are related through the specific surface of dry material a [unit : m^2/kg] and Faraday's constant $F = 96485\,C/mole$ by $\sigma_e = Q_e\,F/a$;
- the valence ζ is equal to $10^{-5}\,Q_e\,\hat{m}$ where $\hat{m}$ is the molar mass of the dry material in gm;
- the specific surface a is about 10×10^3 to 20×10^3 m^2/kg for kaolinites, 65×10^3 to 100×10^3 m^2/kg for illites, 700×10^3 to 840×10^3 m^2/kg for montmorillonites.
For a montmorillonite of molar mass $\hat{m} = 382\,gm$, an electrical charge Q_e equal to -100 meq/100 gm=1 mole/kg is equivalent to $\sigma_e = -0.125\,C/m^2$ and to a valence $\zeta = -0.382$.

13.10.1.4 pH, electrical charge and isoelectric point

Kaolinites are more sensitive to pH than montmorillonites because the former have OH^- termination sites on the octahedral faces and edges while OH^- termination sites exist only on the edges for the latter. The faces are negatively charged at any pH. The edges contain silica and alumina and their charge is positive at low pH and negative at high pH. Montmorillonites and illites whose negative charge is due to isomorphous substitutions are actually sometimes called *fixed charge clays* while kaolinites whose negative charge is due to broken bonds are known as *variable charge*

clays. At low pH the charge of the latter becomes positive. A direct consequence is that contaminant cations like Pb^{2+} are more easily extracted/desorbed from kaolinites than from illites at low pH. Cation exchange for illites is practically independent of pH in contrast to kaolinites. Therefore acidification is not an efficient technique for the remediation of illites.

Montmorillonites are very active clays in the sense that a change of the pore liquid composition implies large volume changes at constant load. Kaolinites are much less affected by pore liquid composition.

Fig. 13.10.2 shows the change of the electrical charge of clays as a function of pH. The material properties that depend directly on the clay charge, like the ζ-potential and the electroosmotic coefficient, are pH-dependent: the dependence is strong for kaolinites where the charge may change sign but quite moderate for illites and montmorillonites where the charge is always negative.

These observations provide some elements of comparison with biological tissues endowed with a fixed charge. The charge of proteoglycans changes according to pH but it remains negative. At variance, collagen are positively charged at low pH, neutral at physiological pH, and negatively charged at high pH. The total charge of articular cartilage and corneal stroma changes sign much like in kaolinites.

13.10.2 Modification of the electrolyte circulating an articular cartilage

Much like for active clays, emphasis is laid on the effects of the overall ionic strength of the electrolyte circulating the cartilage and on the individual effects of cations. While the issue is addressed later in Chapter 14, it is important to make clear that the chemical composition of this electrolyte is not directly controllable. The cartilage can be thought of as being wrapped around by a semi-permeable membrane. In fact, only the chemical composition of the bath the cartilage sample is in contact with can be controlled. The composition of the electrolyte circulating the cartilage is the result of electro-chemomechanical couplings.

13.10.2.1 Homoionic cartilage

Articular cartilage is a porous medium that provides normal compliance so as to minimize friction at joints. The negatively charged proteoglycans (PGs) are a key constituent. The skeleton of cartilage is formed by collagen fibers which resist both the external loads and the chemical pressure exerted by PGs.

The latter depends much on the repulsive forces between PGs, which are themselves function of the ionic content of the electrolyte that circulates the cartilage. This electrolyte communicates with the synovial fluid. The macroscopic outcome of these nanoscale interactions is a compressive stress that decreases when the electrolyte changes from distilled water to a salt-saturated solution if the axial strain is kept constant.

Eisenberg and Grodzinsky [1985] performed confined compression tests on cylindrical samples, 9 mm in diameter and about 500 µm in thickness, in contact with a bath of controlled concentration in NaCl, Fig. 13.10.3. Mechanical loading is performed stepwise and, after each load increment, sufficient time is left to reach equilibrium: equilibrium requires about 15 mn for bovine articular cartilage. A similar incremental procedure is followed for changes in composition of the bath.

The axial stress-axial strain measurements of Eisenberg and Grodzinsky [1985] show that mechanical tests occur at approximately constant apparent moduli. Free swelling strains under confined compression are obtained by prolongating the linear stress-strain relation to zero axial stress. Of course, the amplitude of the swelling strain decreases when the salt concentration in the bath increases. Since collagen fibers are activated essentially under extension, the apparent elastic moduli even for small extensive strains are much larger than for contractive strains.

13.10.2.2 Tensile experiments

Akizuki et al. [1986], their Fig. 4, show chemical experiments where the strain is fixed in the direction of traction. They observe that, at relatively small strain, increasing the ionic strength of the bath implies an increase of the tension, while the opposite holds at larger strain. Owens et al. [1991] perform purely chemical tests at constant strain. Increase of the salt concentration in the bath reduces the stress: this feature is attributed to an increased *shielding* of the charged proteoglycans by the dissolved salt. For the point of view adopted below to be consistent with the experiments of both Akizuki et al. [1986] and Owens et al. [1991], the axial strain at which the latter perform their experiments should be relatively large.

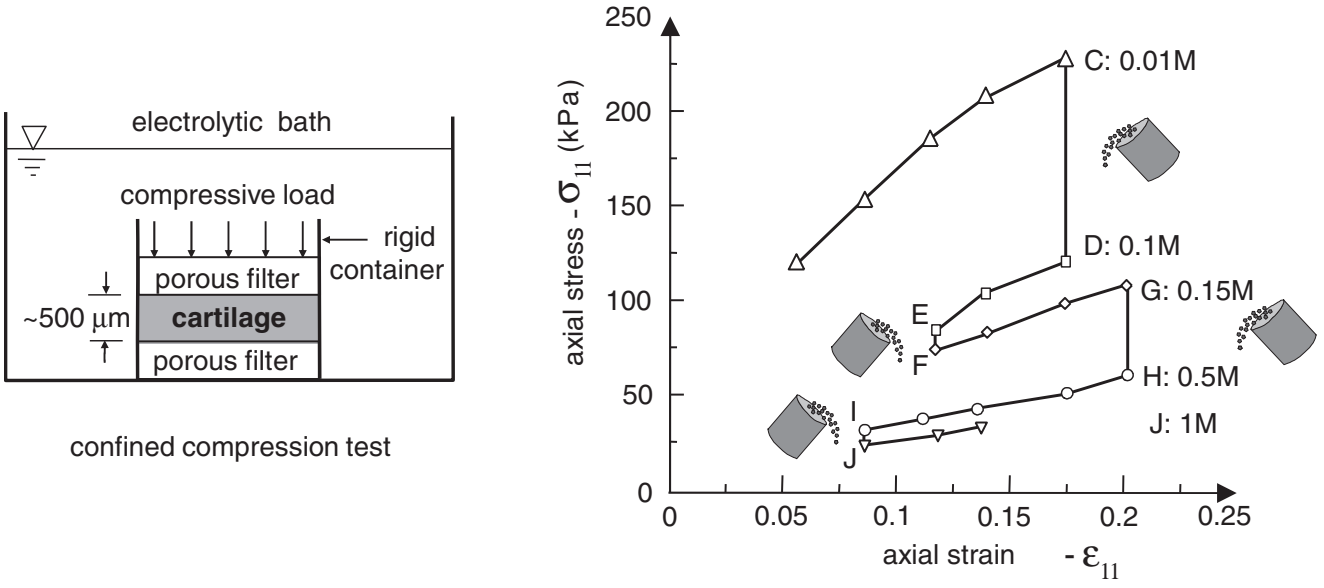

Fig. 13.10.3: Confined compression test on bovine articular cartilage by Eisenberg and Grodzinsky [1985], redrawn with permission from Loret et al. [2004]a. The sample is in contact with a bath of controlled ionic strength. Sufficient time is left after each modification of the ionic strength of the bath to reach steady state. The complex loading path involves successive confined compression at fixed ionic strength of the bath and increase in ionic strength of the bath at fixed strain. *Shielding* of negative charges of proteoglycans by the dissolved salt reduces the repulsive forces and the overall compressive stress. The apparent moduli are thus largest when the salt concentration of the electrolyte is minimal and lowest when the salt concentration of the electrolyte is maximal.

13.10.2.3 Ionic replacements in articular cartilages

Let us reconsider the experiments of Owens et al. [1991] under a different perspective. Owens et al. [1991] have performed uniaxial traction tests on specimens of bovine articular cartilages, harvested from the superficial zone of the medial patello-femoral groove, parallel to the split-line orientation. Subsequent to stress free swelling strain in quasi-distilled water, pre-equilibration is performed at a constant axial tensile strain of 5%. The ionic strength of the bath is then modified as indicated by Fig. 13.10.4. Data show that shielding by calcium ions is more important than by sodium ions, in the sense, that the induced mechanical effects are larger.

On the other hand, a number of experiments tend to indicate that the hypertonic state is universal: the nature of ions matter in the shielding process at low to moderate ionic strengths only. Consequently, except perhaps close to the hypertonic state, in articular cartilages like in clays, what matters is not only the overall strength of the electrolyte including all ions, but also the very concentration of each ionic species. Fig. 13.10.4 shows that the feature is particularly conspicuous at low ionic strength, point E in presence of calcium chloride versus point G in presence of sodium chloride. The tests of Owens et al. [1991] are used to infer the dependence of the effective pressure p_{eff} in terms of cations shown in Figs. 13.10.5 and 13.10.6.

13.10.2.4 A picture highlighting chemomechanical couplings

These observations prompt us to sketch the tensile response shown in Figs. 13.10.7 and 13.10.8. The existence of an intersection point, noted Ω in these sketches, between all mechanical tests at fixed ionic strength of the bath explains nicely the mixed chemomechanical tests of Akizuki et al. [1986], [1987].

In confined compression, the axial stress-axial strain relation at given ionic strength of the bath displays linearity up to 15% in the experiments of Eisenberg and Grodzinsky [1985]. On the other hand, uniaxial traction shows a nonlinear relation at small strain. This aspect is not displayed in the sketch of Fig. 13.10.8.

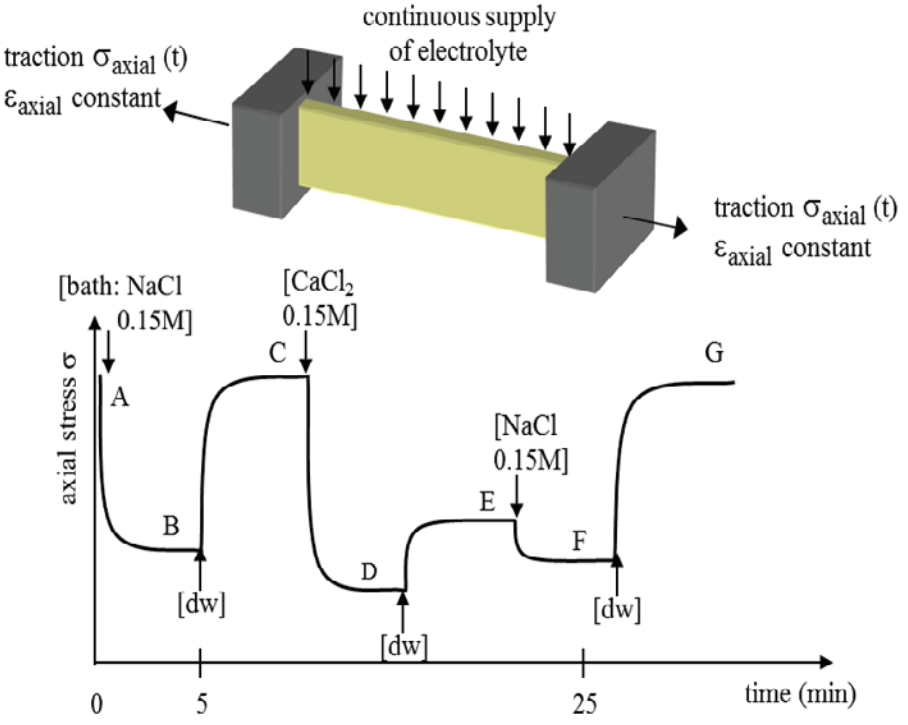

Fig. 13.10.4: Uniaxial traction experiment on bovine articular cartilage by Owens et al. [1991], redrawn with permission from Loret et al. [2004]a. At a given axial strain of 5% counted from the isotropic free swelling configuration, the chemical composition of the bath is modified instantaneously at times A, B, C, D, E and F. Sufficient time is left however for equilibrium to be reached before the next modification. Note that the stress of point A is recovered only after calcium chloride is substituted by sodium chloride.

13.10.2.5 The effects of pH in articular cartilage and corneal stroma

As pH decreases, the hydrogen ions H^+ fix onto the proteoglycans and decrease their electrical charge. At given ionic concentration, the electrical repulsion between PGs decreases and therefore so does the macroscopic chemical pressure, Fig. 13.10.9(a). However the picture is complicated by the fact that, at low and high pH, the collagen molecules become charged, while at physiological pH they display nearly equal numbers of amino and carboxyl groups, NH_3^+ and COO^-, respectively, and hence their net charge is virtually nil.

The corneal stroma consists mainly of a collagen fiber network and intermingled proteoglycans like articular cartilages. The presence of a fixed charge implies qualitatively similar electro-chemomechanical couplings. Still, the intensity of the charge is much less and the structural arrangements of these two components are quite apart. In the stroma, the collagen fibers run in alternate directions in adjacent lamellae presumably to maximize the transparency. The stroma has an innate tendency to swell without limit because the crosslinks between lamellae are not strong enough to oppose the chemical pressure unlike in cartilage. However a too large hydration would tend to generate an inhomogeneous repartition of the absorbed water and to form 'lakes' that would decrease the transparency. The latter is ensured by endothelial pumps that drive bicarbonate ions HCO_3^+ out of the cornea, thus maintaining ionic strength and hydration to acceptable levels.

The variation of the swelling properties of corneal stroma with pH provides another illustration of the electromechanical coupling. At neutral pH, collagen is almost neutral. At high pH, amino-groups loose their positive charge, and the collagen molecules become negatively charged. Conversely, at low pH, the negatively charged carboxyl groups become neutral, and the collagen molecules become positively charged. As a consequence of the electrical repulsion between proteoglycans and collagen fibrils, macroscopic swelling is observed as the pH of the tissue electrolyte departs from the isoelectric point. This strongly pH-dependent swelling is illustrated by the change of hydration sketched in Fig. 13.10.9(b).

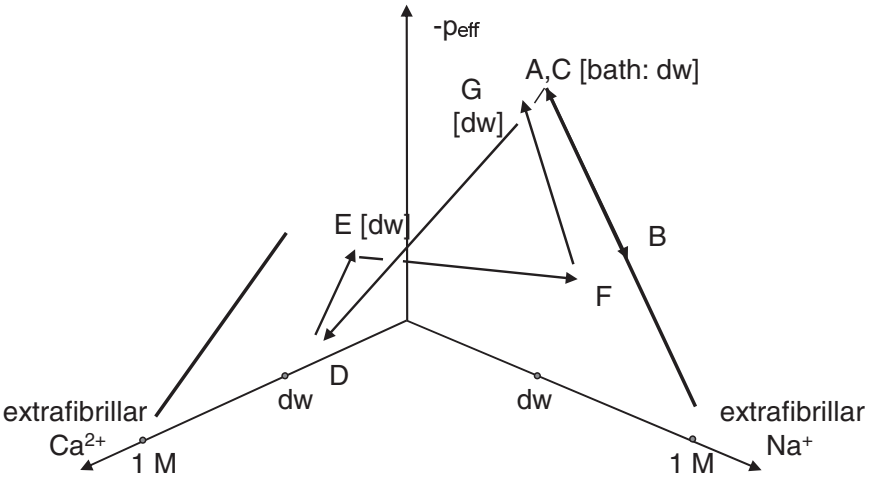

Fig. 13.10.5: Interpretation via the effective pressure p_{eff} of the test by Owens et al. [1991] at fixed axial strain of 5% shown in Fig. 13.10.4, reproduced with permission from Loret and Simões [2005]a. The basic assumption is the notion of effective stress, to be developed in Chapter 14: the stress-strain relation links the strain to this effective stress $\boldsymbol{\sigma} + p_{\text{eff}}\,\mathbf{I}$. Indeed, the presence of proteoglycans in the cartilage gives rise to a chemical pressure p_{eff}. For the strain of interest, the chemical pressure p_{eff} is maximum (in absolute value) for a fresh bath and decreases as ionic strength increases. The collagen fibers resist the external load $\boldsymbol{\sigma}$ and the pressure p_{eff} by stretching. Since the strain is prescribed (in fact in the axial direction only), decrease of p_{eff} implies the external load to decrease as well. The reverse phenomenon occurs when the water of the bath is refreshed. The difference in response to the two salts can be traced to the fact that the chemical pressure induced by calcium ions is smaller than by sodium ions.

13.11 The heart muscle and cell electrophysiology

The human heart beats about 60 to 80 times per minute at rest. Functionally, each beat involves a passive stage (intake of blood) and an active stage (expulsion of blood). For the organ itself, the process involves the following steps:

- step 1: *electrical conduction*: the sino-atrial node, which has a larger eigenfrequency than the other parts of the heart, is the cardiac pacemaker. It sends a signal that travels through a dedicated net: the signal reaches first the atria and next, through the His bundle and the Purkinje net, it circulates the ventricles, from the endocardium to the epicardium: the epicardium has received the electrical impulsion after about 200 ms;
- step 2: *action potential and calcium release*: the electrical signal induces a depolarizing current across the membrane of the cardiac cell (the myocyte) which gives rise to the action potential: the resting potential difference of -90 mV increases temporarily, a small amount of plasmic ions Na^+ enters the cell through dedicated channels, and this intake in turn produces a considerable modification of the internal repartition of ions Ca^2+, the latter being temporarily released from the sarcoplasmic reticulum;
- step 3: *establishment of cross-bridges and force development*: calcium is used immediately. Binding to the low affinity site of Troponin C, calcium induces a change of conformation of the tropomyosin that makes possible myosin heads to establish a *bond* with actin sites: the relative sliding of the myosin and actin filaments is the vehicle that develops a force.

Cell electrophysiology models aim at describing the many currents and cytoplasmic fluxes that develop, Fig. 13.11.1. Some of these currents and fluxes are driven by ionic pumps that require energy. The biological energy unit ATP is produced by the metabolism. In fact, the proportion of energy used by ionic pumps is small with respect to that necessary to ensure the bond of the myosin head on the actin sites for force development. Many models of muscle behavior use the *cross-bridge theory* of Huxley as a basic ingredient.

It is important to highlight that this description corresponds to

- an electrochemical coupling, i.e., the electrical current induces a change of ionic concentrations in the cardiomyocytes, followed by
- a chemomechanical coupling, i.e., the temporary increase of calcium concentration allows a relative motion of the myosin and actin filaments that implies force development.

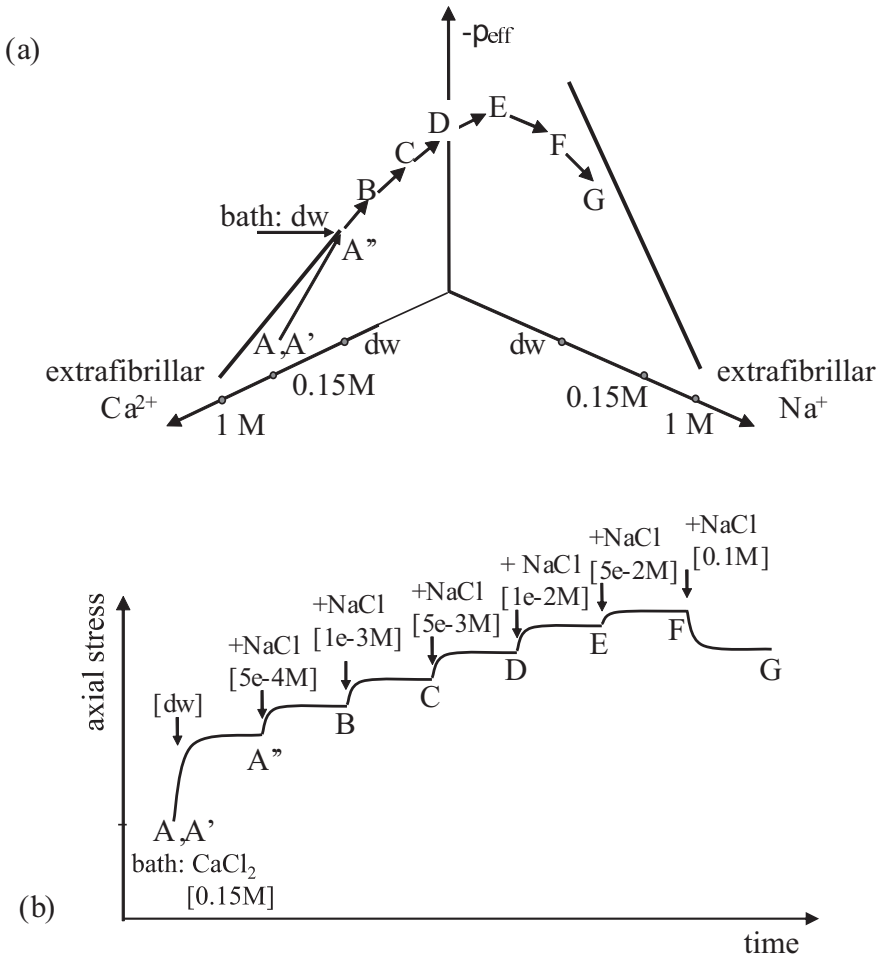

Fig. 13.10.6: Interpretation of a second test by Owens et al. [1991] via the effective pressure, reproduced with permission from Loret and Simões [2005]a. At a given axial strain of 10% counted from the isotropic free swelling configuration, the bath composition is changed periodically as indicated by the sketch (b). Sufficient time is left however for equilibrium to be reached before the subsequent modification. Initially, the bath contains only calcium cations, but the extrafibrillar water may also contain sodium cations: that is why point A has been located at short distance from the Ca-plane. The experiment starts by refreshing the bath to quasi-distilled water.

The concentration of sodium cations in the bath is next increased and, when equilibrium is reached, the water of the bath is refreshed. This sequence is repeated several times with increasing sodium concentrations.

As explained in the caption of Fig. 13.10.5, for this strain, the pressure $-p_{\text{eff}}$ is zero at maximal ionic strength and increases as ionic strength decreases. This dependence is indicated in the sketch (a) by the thick lines on the vertical planes. The quantitative variation of p_{eff} depends on the cations, and it is assumed to be larger for sodium cations than for calcium cations. The overall picture is due to the competition of two phenomena. Indeed, as the concentration of sodium ions increases, they overweigh the influence of calcium ions (-p_{eff} increases). However, by the same token, electrical shielding begins to be significant, and the pressure -p_{eff} finally decreases.

It is worth to recall that the effective pressure p_{eff} does not depend directly on the bath composition but on the extrafibrillar electrolyte. Still, the change of chemical composition of the bath indicated in sketch (b) is guessed to induce the qualitative path shown in sketch (a) and the associated change in tension shown in sketch (b).

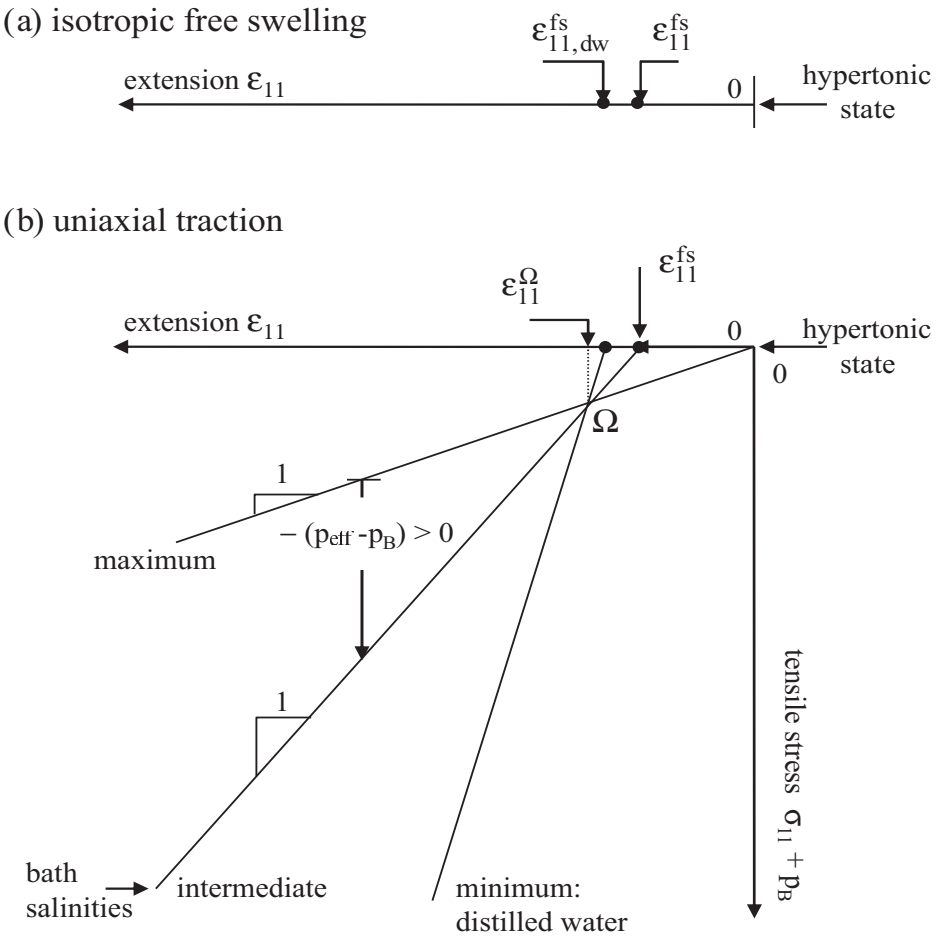

Fig. 13.10.7: Qualitative understanding of basic mechanical and chemical tests in uniaxial tension, reproduced with permission from Loret and Simões [2005]a. Specimens are in equilibrium with a bath of controlled ionic strength and pressure p_B. The presence of sodium or calcium cations in the extrafibrillar water shields the repulsive forces due to negatively charged proteoglycans, and, at given strain, modifies the total stress.

(a) Isotropic free swelling consists in decreasing the ionic strength of the bath starting from the hypertonic state with a zero external traction. The fresher the bath, the larger the free swelling strain: it vanishes in the hypertonic state, and it is maximal for distilled water (denoted by dw).

(b) At small strains, uniaxial traction shows that the stress varies nonlinearly with the strain, e.g., Kempson et al. [1968], [1973]. This nonlinearity is not shown here to simplify the understanding of the chemomechanical coupling phenomenon. The apparent moduli decrease with the ionic strength. Isotropic free-swelling strains are then obtained by extrapolation to zero axial stress (a). The sketch is in qualitative agreement with the experimental data shown in Fig. 4 of Akizuki et al. [1986]: in particular, there exists a balance strain, indicated here with the superimposed index Ω, which separates opposite effects associated with chemomechanical coupling. Above this balance strain, decreasing the ionic strength of the bath makes $p_{eff} - p_B$ more negative and thus induces a larger stress. The opposite phenomenon occurs below the balance strain.

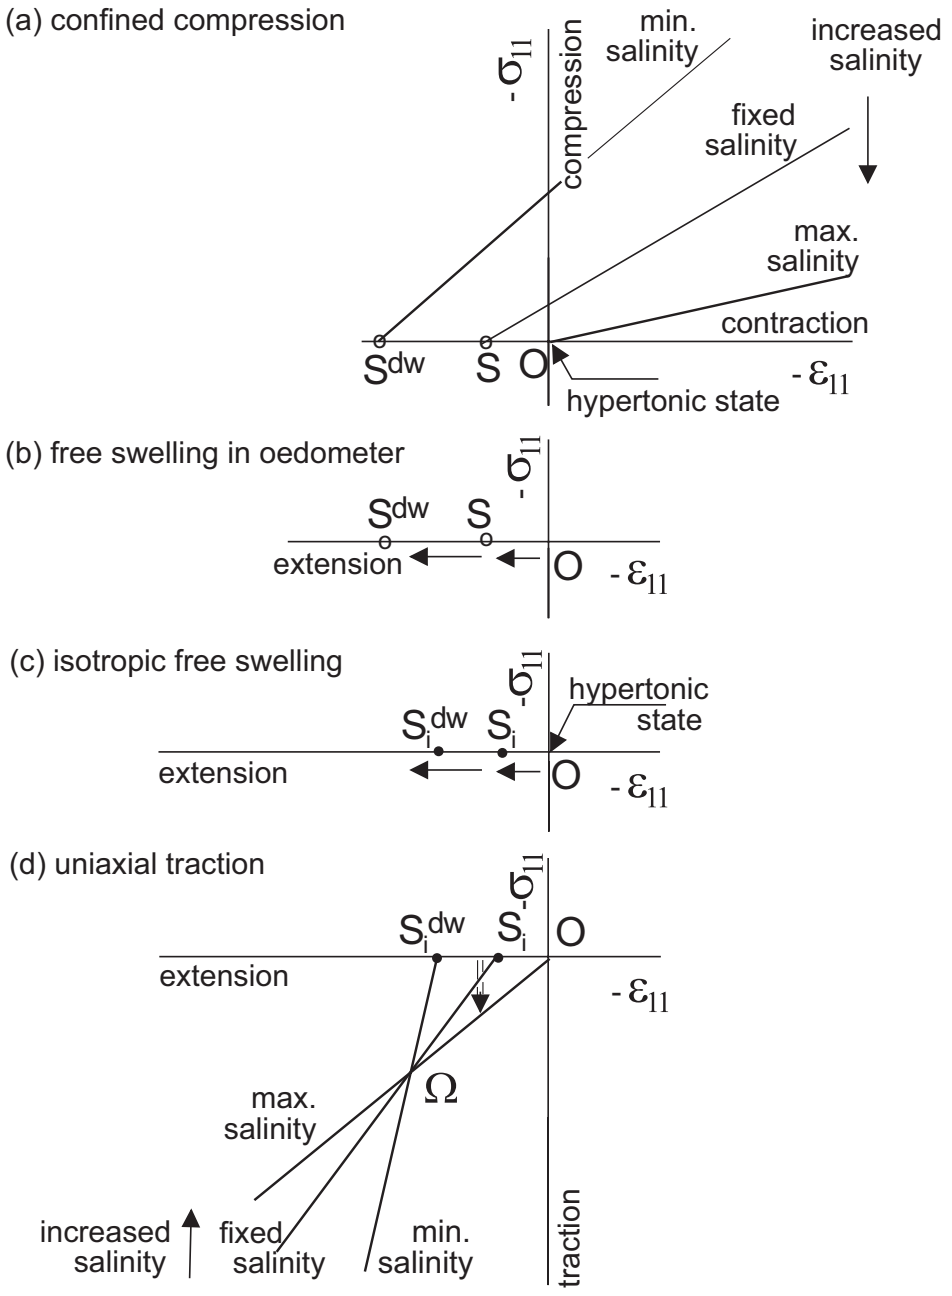

Fig. 13.10.8: Qualitative understanding of basic mechanical and chemical tests in confined compression, oedometric free swelling, isotropic free swelling and uniaxial traction, reproduced with permission from Loret and Simões [2004].

Specimens are in equilibrium with a bath of fixed ionic strength and pressure p_B taken as reference. Confined compression tests show apparent linear elasticity with modulus decreasing with the ionic strength (a). Oedometric free-swelling strains are then obtained by extrapolation to zero axial stress (b). Isotropic free-swelling with all stress components vanishing induces smaller strain components, which are equal only if the material behavior is isotropic (c). If starting from the hypertonic state, isotropic free-swelling is followed by uniaxial traction, the in-axis apparent moduli are observed to be larger than for confined compression at the same ionic strength of the bath, and to decrease with ionic strength of the bath due to the shielding effect.

The presence of sodium cations in extrafibrillar water shields the repulsive forces due to negatively charged proteoglycans and reduces the absolute value of the axial stress.

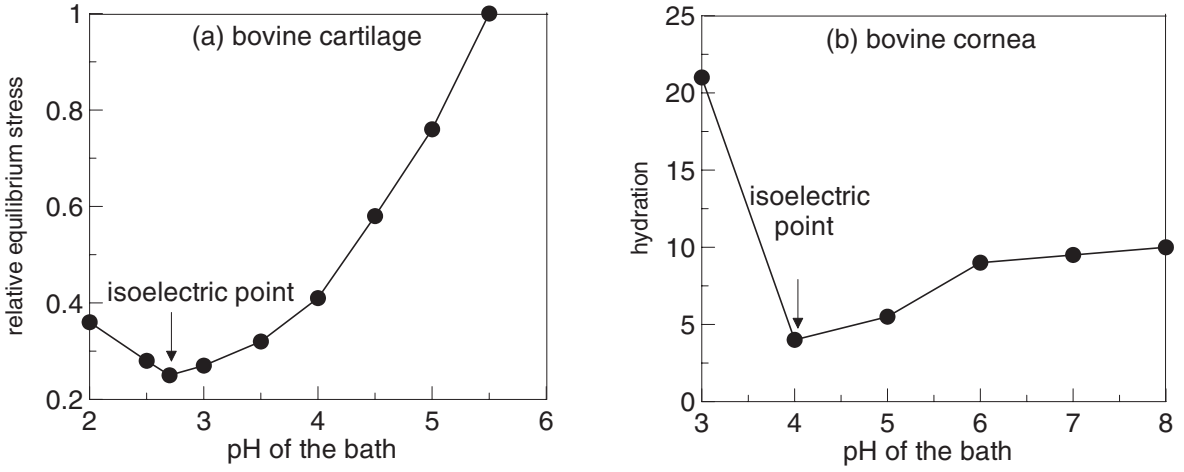

Fig. 13.10.9: pH affects the electrical charge, and therefore the electrostatic repulsion. At the isoelectric point, where the electrical charge vanishes, the repulsion is at its minimum. (a): axial stress relative to its value in distilled water in a uniaxial traction test at given axial strain, data on bovine articular cartilage redrawn from Grodzinsky et al. [1981]; (b): relative hydration (≡ wet weight/dry weight - 1) at low ionic strength of sodium chloride (30 mM) and under zero stress, data on bovine cornea from Huang and Meek [1999]. Reproduced with permission from Loret et al. [2004]a.

But none of these two steps involves a priori a feedback, that is

- neither a mechanochemical effect, i.e., the force developed by the muscle does not influence the chemical intra- or extracellular concentrations,
- nor a chemoelectrical feedback, that is the electrical current created by the ions moving in and out of the cells does not modify the electric signal originated from the sino-atrial node.

However, due to some physiological observations, e.g., commotio cordis, there has been recently a renewed interest in so-called stretch-activated ionic channels through which mechanics impacts directly on ionic currents. Along another avenue, in view of mechanical tests on muscle fibers, we will come to implicate rate-effects in the mechanochemical feedback.

13.12 Reverse couplings

The above examples address essentially the effects of the chemical composition on the mechanical properties. Conversely, the mechanical environment may influence the time course of the chemical composition. However, significant reverse mechanochemical effects are much more seldom considered than the direct chemomechanical effects. Besides stretch-dependent ionic currents, one may cite,

- the influence of confinement on the breakthrough time of a diffusion process;
- the influence of the intraocular pressure on the fixed charge density in the stroma, Section 19.11.4;
- the fact that the kinetics of some enzymes, like the matrix metalloproteinases that affect collagen degradation, are sometimes suggested to be strain-dependent.

13.12.1 Mechanoelectric feedback in the heart muscle

13.12.1.1 Commotio cordis and stretch-gated ionic channels

Stretch-activated ionic channels located on the membrane of cardiac cells (SACs) are still subject to debate because they have not been cloned in adult mammalian myocytes but observed in cultured cells and in young cells. Interest in these channels has been renewed due to their link to *commotio cordis* which is observed in young adults, because they may originate arrhythmia and fibrillation. The Oxford group has contributed to suggest models and to stress the physiological importance of the phenomemon, Kohl and Sachs [2001]. Commotio cordis is associated with the impact of a projectile on the chest leading to sudden cardiac death, but without creating material damage. In fact,

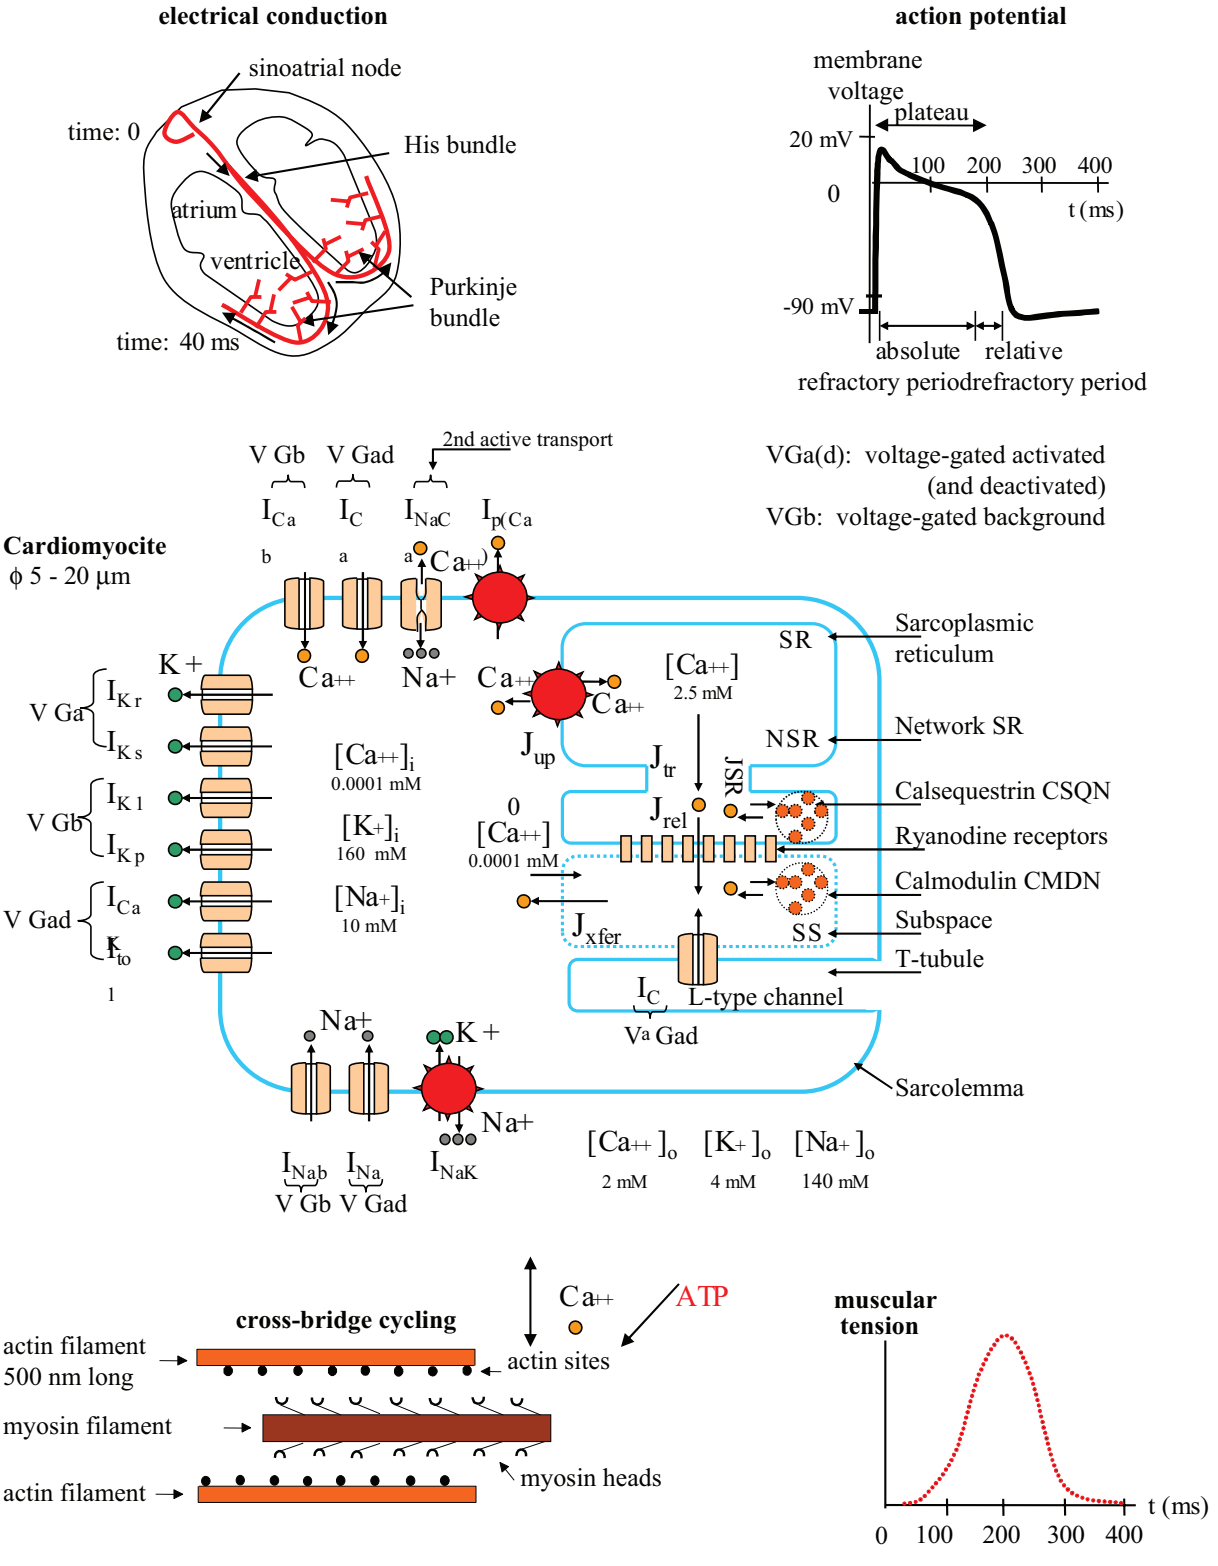

Fig. 13.11.1: Sketch of the successive steps of a cardiac period. The signal starts from the sinoatrial node and reaches quickly the endocardium and next the pericardium. It gives rise to a potential difference across the cell membrane, which in turn triggers complex currents between the cytoplasm and the extracellular milieu as well as intracellular fluxes. The main effect is a temporary release of calcium which is necessary to ensure cross-bridge cycling and force development. The central sketch illustrates the membrane currents and intracellular fluxes in the cardiomyocyte electrophysiology model of Winslow et al. [1999]. Redrawn with permission from Loret et al. [2004]a.

the potential danger of such impacts depends much on the precise time during the heart beat at which they occur: they are much more dangerous if applied during diastole.

Quite generally, SACs are thought to contribute to depolarize cell membrane, essentially during diastole, alter/prolongate action potential, raise the rest potential, increase the active force and induce premature ventricular excitations and arrhythmias.

In practice, SACs just create another additional current I to be added to the list of membrane currents. They are controlled by some representative of the stretch of the muscle fibers. Stretch λ, or increase of sarcomere length SL, is believed to increase the electric conductance. Several models, ion-*in*sensitive or ion-sensitive, have been proposed. A general expression has the form $I = g(\lambda)\,(V - E_r)$ where E_r is the reverse potential. For $V < E_r$, this model indicates an inward/depolarizing current, while the opposite applies for $V > E_r$. That is, the maximum potential is lowered while the rest potential is increased and the descending branch of the voltage is modified/raised if the reverse potential is sufficiently high.

Stretch-activated channels participate to the mechanoelectric feedback. However, there has been doubt that stretch itself is the sole agent responsible for phenomena that can be traced to belong to this kind of effect. Indeed, strain rate or tension are other candidates to enter the game.

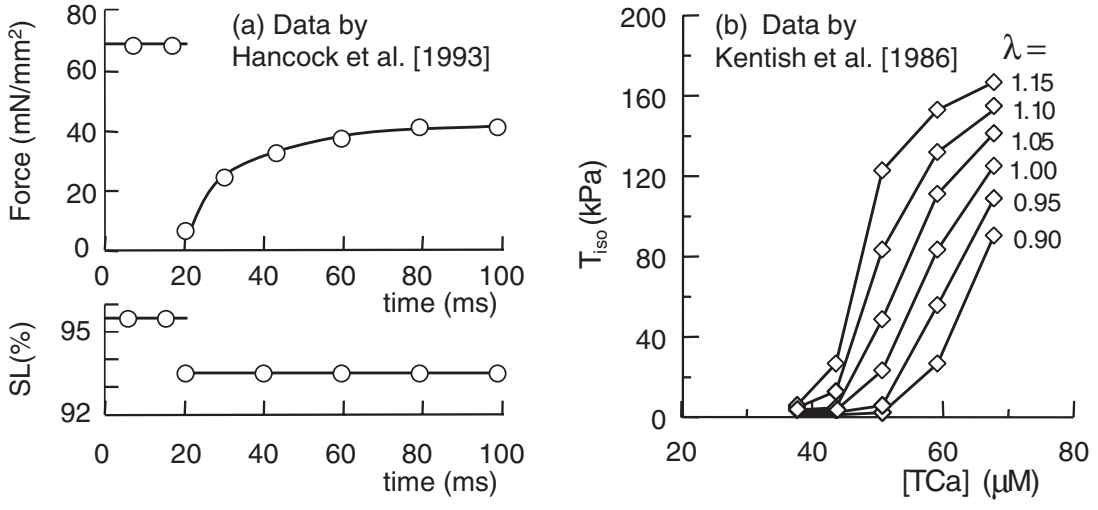

Fig. 13.12.1: (a) Upon rapid muscle shortening, the tension is suddenly reduced but it does not recover its value after transients are wiped off, even if the elastic correction is applied. (b) The increase of the isometric tension with the concentration of calcium bound to Troponin C is 'length-modulated'. Redrawn with permission from Loret et al. [2004]a.

13.12.1.2 Rate-dependent cell electrophysiology

Upon rapid shortening the isometric tension $T_{\rm iso}$ of muscle fibers decreases and, after the transient effects have been wiped off, it returns to a lower value, Fig. 13.12.1(a). This *force deficit* phenomenon is attributed to an increased (rate of) Ca-detachment from Troponin C. This force deficit is too large to be due only to an elastic parallel contribution. That elastic component is on the other hand sufficient to define the force at its steady state for instantaneous (re-)stretching. Therefore a *force recovery* phenomenon does not exist during (re-)stretching.

One way to describe the force deficit phenomenon is to consider a cell-electrophysiology model that depends on the rate of stretch or on the tension transients represented by the ratio $T/T_{\rm iso}$ of the tension over its isometric value. Hunter et al. [1998] modify the kinetics of the Ca^{2+} binded to Troponin C,

$$\frac{d[\mathrm{TCa}]}{dt} = k_{+1}\,[\mathrm{Ca}^{2+}]_i\Big([\mathrm{TCa}]_{\max} - [\mathrm{TCa}]\Big) - k_{-1}\,[\mathrm{TCa}], \tag{13.12.1}$$

with $[Ca^{2+}]_i$ the cytoplasmic calcium concentration, k_{+1} and k_{-1} the rates of attachment and detachment of calcium on Troponin C. The rate of detachment $k_{-1} = k^0_{-1}\left(1-(T/T_{\rm iso})/\gamma\right)$, with $\gamma > 0$, increases as the tension T decreases, so that a lower concentration [TCa] of Ca^{2+} binded to Troponin C induces a lower isometric tension, Fig. 13.12.1(b).

13.12.2 Mechanobiology and engineered cartilages

Immature articular cartilage contains vessels that circulate nutrients. On the other hand, adult articular cartilage is aneural, avascular and alymphatic. Nutrients from the synovial joint are transported by the extracellular fluid through diffusion and convection. Therefore the self-healing capacities of adult articular cartilage are practically nil. An introduction to tissue engineering is presented in Chapter 20.

Although experiments tend to quantify the variations in the rates of stimulation and inhibition of cartilage synthesis, the numbers should be taken with care. Indeed, the depth-distribution of strain in a cartilage layer submitted to compression at its top surface is highly inhomogeneous. Strains are much larger near the surface and thus the percentage of tissue undergoing mechanical stimuli strongly depends on the layer thickness. These heterogeneities on the other hand may imply that there are optimal geometries for the loaded cultures. The biological environment should also be controlled, e.g., hypoxic conditions are also known to stimulate regeneration of cartilage.

Special bioreactors have been developed to apply unconfined compression on cartilage cultures. The following points have been highlighted, Buschmann et al. [1992] [1995], Mauck et al. [2000]:

- static (prolongated) compression has a detrimental influence on the synthesis of the ECM;
- dynamic (time variable) compression on the other hand contributes to matrix synthesis. The actual efficiency of dynamic compression depends on the frequency and on the details of the loading program (amplitude, mean value, etc.).

Unconfined compression, which is accompanied by lateral extension, is thought to represent correctly the *in vivo* state of stress. On the other hand, the loading programs are highly arbitrary and in particular the pros and cons of strain- over stress-controlled loadings are not elucidated. Therefore, there are plenty of degrees of freedom for optimization.

Mauck et al. [2000] loaded dynamically disks about 1 mm thick with a strain amplitude of 10%, at a frequency of 1 Hz, 3 times 1 hour on, 1 hour off, 5 days a week during 4 weeks. At the end of this period, the elastic modulus is increased sixfold over unloaded disks. They also observed an increase in glycosaminoglycans (GAGs) and hydroxyproline (measurements use [^{35}S]sulfate and [^{3}H]proline radiolabel incorporation). However, the GAG content showed a peak at week 3, and further studies showed that it is later substantially reduced. On the other hand, Buschmann et al. [1992] observed, on agarose-seeded calf chondrocytes, an increase of GAGs until day 70. Another conclusion of the studies of Mauck et al. [2000] is that agarose gels are more prone than alginate gels to improve the mechanical properties and matrix proliferation.

Whether mechanics and metabolism cooperate or compete in the growth and resorption of cartilage is an open question which probably does not have a global answer. The intensity and mode of application of the mechanical load and the respective concentrations of macromolecules are key factors. One possible way in which mechanics stimulates biological synthesis is by generation of *advective flow* that particularly enhances the transport of large soluble molecules (e.g., growth factors) that are thus more accessible to the chondrocytes and their immediate neighborhood, Garcia et al. [1996]. A second mode in which mechanics acts is by *altering the metabolism*. Deforming the chondrocytes and their organelles modifies intracellular signaling and communication between cells.

The effects of shear-stress have also been tested. M.S. Lee et al. [2002] observe that a fluid-induced shear-stress (1.64 Pa) on human chondrocytes during periods of 2 to 24 hours increases more than twofold the production of nitric oxide (NO), an intra- and extracellular messenger present at increased levels in osteoarthritis, and inhibits aggrecan and type II collagen mRNA levels by about a third. These observations confirm the alternative point of view that cartilage degeneration and ossification are stimulated by shear stress but inhibited by dynamic compression, Carter and Wong [1990].

13.13 A partially coupled chemo-poroelastic model

Interactions between chemical content and mechanics are introduced in the chemo-poroelastic model below due to Myers et al. [1984]: the basic motivation is that increase of the concentration of the solute at constant stress implies contraction of the porous medium by expulsion of water. The underlying physical phenomena are investigated in detail in relation with articular cartilages in Chapter 14.

13.13.1 The chemo-poroelastic field and constitutive equations

The constituents being incompressible, the following field equations should be satisfied pointwise,

$$\begin{array}{ll} \text{Balance of mass of the porous medium} & \operatorname{div}\,(n^{\mathrm{s}}\,\mathbf{v}_{\mathrm{s}} + n^{\mathrm{w}}\,\mathbf{v}_{\mathrm{w}}) = 0, \\ \text{Balance of mass of the chemical} & \dfrac{\partial C}{\partial t} + \operatorname{div}\mathbf{J} = 0, \\ \text{Balance of momentum of solid phase} & \operatorname{div}\,\boldsymbol{\sigma}^{\mathrm{s}} + k_{\mathrm{Sd}}(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) - p_{\mathrm{w}}\boldsymbol{\nabla} n^{\mathrm{w}} = \mathbf{0}\,, \\ \text{Balance of momentum of fluid phase} & \operatorname{div}\,\boldsymbol{\sigma}^{\mathrm{w}} - k_{\mathrm{Sd}}(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) + p_{\mathrm{w}}\boldsymbol{\nabla} n^{\mathrm{w}} = \mathbf{0}\,, \end{array} \tag{13.13.1}$$

where $\mathbf{v}_k$, $k = \mathrm{s}, \mathrm{w}$, denotes the velocity of phase k. The partial stresses in the solid and fluid phases sum up to the total stress, $\boldsymbol{\sigma} = \boldsymbol{\sigma}^{\mathrm{s}} + \boldsymbol{\sigma}^{\mathrm{w}}$. The partial stress in the fluid is equal to $\boldsymbol{\sigma}^{\mathrm{w}} = -n^{\mathrm{w}}\,p_{\mathrm{w}}\,\mathbf{I}$, p_{w} being the intrinsic fluid pressure. The volume fractions n^k, $k = \mathrm{s}, \mathrm{w}$, are implicitly assumed to remain fixed. The concentration of the chemical $C = C(x,t)$ [unit : mole/m^3] obeys a diffusion equation, that is controlled by the coefficient of molecular diffusion (or chemical diffusivity) D [unit : m^2/s]. Indeed, the diffusion phenomenon is governed by Fick's law $\mathbf{J} = -D\,\boldsymbol{\nabla} C$ that relates the flux $\mathbf{J} = C\,(\mathbf{v}_c - \mathbf{v}_{\mathrm{w}})$, where $\mathbf{v}_c$ is the absolute velocity of the chemical, to the gradient of concentration $\boldsymbol{\nabla} C$, leading to the decoupled equation of mass balance of the chemical,

$$\frac{\partial C}{\partial t} - D\,\frac{\partial^2 C}{\partial x^2} = 0\,. \tag{13.13.2}$$

The chemomechanical constitutive equation,

$$\text{Chemo} - \text{poroelastic equation} \quad \boldsymbol{\sigma}' = \lambda\,\mathrm{tr}\;\boldsymbol{\epsilon}'\,\mathbf{I} + 2\,\mu\,\boldsymbol{\epsilon}'\,, \tag{13.13.3}$$

involves the poroelastic *effective* stress $\boldsymbol{\sigma}'$, that accounts for poroelastic effects, and the chemoelastic *effective* strain $\boldsymbol{\epsilon}'$, that accounts for chemical effects.

$$\boldsymbol{\sigma}' = \boldsymbol{\sigma} + p_{\mathrm{w}}\,\mathbf{I}\,, \quad \boldsymbol{\epsilon}' = \boldsymbol{\epsilon} + \alpha_c\,C\,\mathbf{I}\,. \tag{13.13.4}$$

The poroelastic equation is phrased in terms of the Lamé moduli of the drained solid skeleton, or matrix, namely λ and μ, or equivalently in terms of its drained Young's modulus E and Poisson's ratio ν.

By convention, $C = 0$ for a fresh solution (quasi-distilled water). At zero effective stress, the effective strain vanishes as well and the total strain $\boldsymbol{\epsilon}$ is equal to $-\alpha_c\,C\,\mathbf{I}$: increase of the chemical concentration C from a fresh solution leads to contraction. The coefficient of chemical contraction $\alpha_c \geq 0$ [unit : m^3/mole] plays a role similar to the coefficient $c_{\mathrm{T}} > 0$ of thermal expansion: the thermoelastic strain associated with a change of temperature ΔT would be $\boldsymbol{\epsilon}' = \boldsymbol{\epsilon} - c_{\mathrm{T}}\,\Delta T\,\mathbf{I}$.

The two balances of momentum are equivalent to

$$\begin{array}{ll} \text{Balance of momentum of porous medium} & \operatorname{div}\,\boldsymbol{\sigma} = \mathbf{0}\,, \\ \text{Darcy's law} & n^{\mathrm{w}}\,(\mathbf{v}_{\mathrm{w}} - \mathbf{v}_{\mathrm{s}}) = -k_{\mathrm{H}}\,\boldsymbol{\nabla} p_{\mathrm{w}}, \end{array} \tag{13.13.5}$$

where the hydraulic permeability $k_{\mathrm{H}} = (n^{\mathrm{w}})^2/k_{\mathrm{Sd}}$ [unit : m^2/Pa/s] is equal to the intrinsic permeability [unit : m^2] of the porous medium divided by the viscosity [unit : Pa×s].

13.13.2 Uniaxial deformation under chemical loading

Myers et al. [1984] consider a strip of cartilage of sizes $L_1 \times L_2 \times L_3$ with $L_1 << L_2 << L_3$. At time $t = 0$, the strip is bathed in a solution of given concentration C_0. It is maintained between two grips that prevent deformation along the main direction of the strip. Close to the mid-height in the intermediate direction, the strain is mainly unidirectional along the thin direction of thickness $2\,l = L_1$.

The assumption of a unidirectional solid displacement $u_{\mathrm{s}} = u_{\mathrm{s}}(x)$, for $x \in [-l, l]$, is adopted subject to the initial conditions,

$$(\mathrm{IC})_u \quad u_{\mathrm{s}}(x, t = 0) = 0\,, \tag{13.13.6}$$

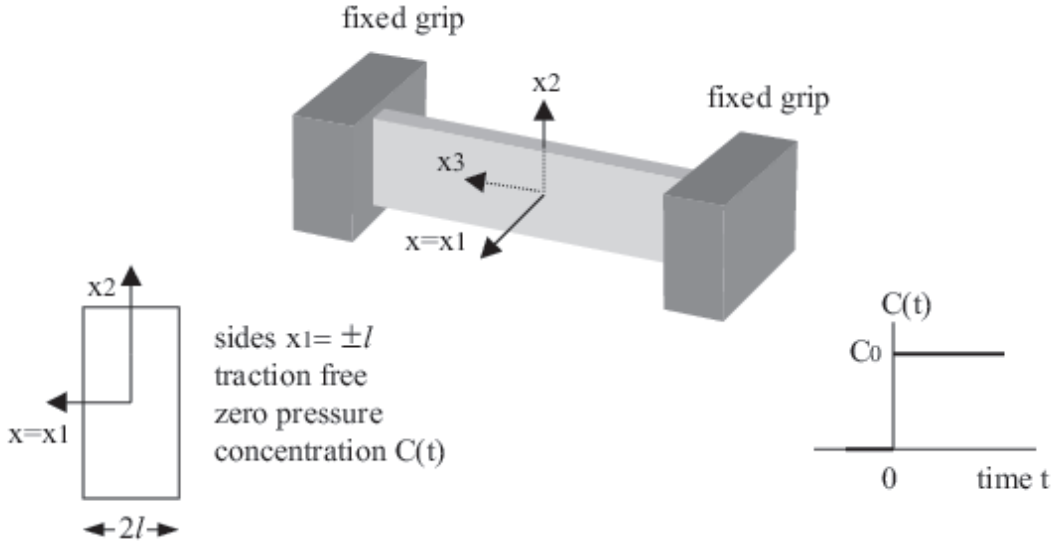

Fig. 13.13.1: A cartilage strip is maintained by two grips. In the central part, only the lateral deformation along x_1 can be considered to be nonzero. At time $t = 0$, the tissue is put in contact with a solution of controlled chemical composition.

and boundary conditions for the displacement and total (and effective) traction,

$$(\mathrm{BC})_u : \quad u_{\mathrm{s}}(x=0,t)=0; \quad (\mathrm{BC})_{\sigma_x} : \quad \sigma'_{xx}(x=\pm l,t) = (H\,\frac{\partial u_{\mathrm{s}}}{\partial x} + 3\,K\,\alpha_c\,C)(x=\pm l,t) = 0\,, \tag{13.13.7}$$

where H and K are respectively the confined compression modulus and the drained bulk modulus,

$$H = \lambda + 2\,\mu = 2\,\mu\,\frac{1-\nu}{1-2\,\nu}, \quad K = \lambda + \frac{2}{3}\,\mu = \frac{2}{3}\,\mu\,\frac{1+\nu}{1-2\,\nu}\,. \tag{13.13.8}$$

The second condition (13.13.7) results from the fact that both the normal stress and pore pressure vanish on the sides of the strip,

$$(\mathrm{BC})_{p_{\mathrm{w}}} : \quad p_{\mathrm{w}}(x=\pm l,t) = 0\,, \tag{13.13.9}$$

and accounts for symmetry with respect to the axis $x = 0$. The balance of mass $(13.13.1)_1$ can be integrated in space with help of the symmetry conditions,

$$n^{\mathrm{w}}\,v_{\mathrm{w}} = -n^{\mathrm{s}}\,\frac{\partial u_{\mathrm{s}}}{\partial t}\,. \tag{13.13.10}$$

Therefore Darcy's law $(13.13.5)_2$ yields the gradient of fluid pressure in terms of the solid velocity,

$$k_{\mathrm{H}}\,\frac{\partial p_{\mathrm{w}}}{\partial x} = \frac{\partial u_{\mathrm{s}}}{\partial t}\,. \tag{13.13.11}$$

Introduction of the elastic equation (13.13.3) in the field equation $(13.13.5)_1$ and use of (13.13.11) yields the field equation satisfied by the displacement,

$$(\mathrm{FE})_u \quad \frac{\partial^2 u_{\mathrm{s}}}{\partial x^2} - \frac{1}{H\,k_{\mathrm{H}}}\,\frac{\partial u_{\mathrm{s}}}{\partial t} + 3\,\alpha_c\frac{K}{H}\,\frac{\partial C}{\partial x} = 0\,. \tag{13.13.12}$$

Elimination of the solid velocity between (13.13.11) and (13.13.12) and integration in space, accounting for the vanishing of pore pressure on the boundaries $\pm l$, provides the pore pressure,

$$p_{\mathrm{w}}(x,t) = H\left(\frac{\partial u_{\mathrm{s}}}{\partial x}(x,t) - \frac{\partial u_{\mathrm{s}}}{\partial x}(l,t)\right) + 3\,\alpha_c\,K\left(C(x,t) - C(l,t)\right). \tag{13.13.13}$$

The diffusion of the chemical uncouples from deformation,

$$\begin{aligned} &(\mathrm{FE})_C \quad \frac{\partial C}{\partial t} - D\,\frac{\partial^2 C}{\partial x^2} = 0, \\ &(\mathrm{IC})_C \quad C(x,t=0) = 0, \\ &(\mathrm{BC})_C : \quad C(\pm l,t) = C_0\,\mathcal{H}(t)\,. \end{aligned} \tag{13.13.14}$$

The chemical loading is the sole loading source. Diffusing through the medium, the chemical will be shown to give rise to shrinking, due to chemomechanical coupling, and to an accompanying axial tensile force.

13.13.3 Diffusion of the chemical

In order to solve the diffusion equation for the concentration C, both a change of spatial variable $x \to y = x + l$, and a change of unknown $C(x,t) \to \tilde{C}(y,t) = C(y,t) - C_0$ are defined.

Elementary solutions are sought in separable form $\tilde{C}(y,t) = Y(y)\,T(t)$, so that $Y''/Y = T'/(D\,T)$ has to be a negative constant, say $-a^2$, so as to ensure that the solution does not grow unboundedly in time. Thus $T(t) \sim \exp(-a^2 D\,t)$, and $Y(y) = b\cos(ay) + c\sin(ay)$. Requiring the boundary conditions to be satisfied yields $b = 0$, $a = n\,\pi/(2\,l)$, with n an arbitrary integer. Thus the elementary solutions,

$$\tilde{C}_n(y,t) = c_n\,\sin(n\,\pi\,\frac{y}{2l})\,\exp(-n^2\,\frac{\pi^2}{(2l)^2}\,D\,t)\,, \tag{13.13.15}$$

satisfy the field and boundary conditions for any c_n. The latter coefficients are obtained by imposing the initial condition $\tilde{C}(y,0) = -C_0$. For that purpose, the odd function, equal to C_0 over $[-2\,l, 0[$, and to $-C_0$ over $]0, 2\,l]$, is defined. Its Fourier series involves only terms of the form (13.13.15). The coefficients c_n are obtained as $c_n = (1/l)\,\int_0^{2\,l}(-C_0)\,\sin(n\,\pi\,y/(2\,l))\,dy$, namely $c_{2n} = 0$, $c_{2n+1} = -2\,C_0/X_n$ with $X_n = (n+1/2)\,\pi$ for $n \geq 0$. Consequently the concentration has the following analytical expression,

$$\frac{C(x,t)}{C_0} = 1 - 2\,R(\frac{x}{l}, \frac{t}{t_{\rm C}})\,, \tag{13.13.16}$$

where, for $t_{\rm X} = t_{\rm C},\, t_{\rm H}$,

$$R(\frac{x}{l}, \frac{t}{t_{\rm X}}) = \sum_{n=0}^{\infty} \frac{(-1)^n}{X_n}\,\cos\left(X_n\,\frac{x}{l}\right)\,e^{-X_n^2\,t/t_{\rm X}}\,. \tag{13.13.17}$$

The characteristic time of chemical diffusion,

$$t_{\rm C} = \frac{l^2}{D}\,, \tag{13.13.18}$$

is to be compared with the characteristic time of seepage,

$$t_{\rm H} = \frac{l^2}{H\,k_{\rm H}}\,. \tag{13.13.19}$$

This initial and boundary value problem for the chemical can also be solved through the Laplace transform technique, e.g., Mei [1995], p. 267.

13.13.4 The solution for the displacement

13.13.4.1 The solution in the Laplace domain

If the displacement is measured from time $t = 0$, namely $u_{\rm s}(x,0) = 0$, the Laplace transform $\overline{u}_{\rm s}(x,s)$ of $u_{\rm s}(x,t)$ satisfies the non homogeneous differential equation,

$$\frac{\partial^2 \overline{u}_{\rm s}}{\partial x^2} - \frac{\overline{u}_{\rm s}}{b^2} = \overline{F}(x,s)\,, \tag{13.13.20}$$

with $b = \sqrt{H\,k_{\rm H}/s}$. The rhs $\overline{F}$ can be read from (13.13.12). The solution is sought in the form,

$$\overline{u}_{\rm s}(x,s) = A(x,s)\,\cosh\frac{x}{b} + B(x,s)\,\sinh\frac{x}{b}\,, \tag{13.13.21}$$

where the functions $A(x,s)$ and $B(x,s)$ are required to satisfy the constraint,

$$\frac{dA(x,s)}{dx}\,\cosh\frac{x}{b} + \frac{dB(x,s)}{dx}\,\sinh\frac{x}{b} = 0\,. \tag{13.13.22}$$

Backsubstitution of (13.13.21) and (13.13.22), and its derivative wrt x in (13.13.20), results in the system

$$\left[\begin{array}{cc} \cosh(x/b) & \sinh(x/b) \\ \sinh(x/b) & \cosh(x/b) \end{array}\right]\left[\begin{array}{c} dA/dx \\ dB/dx \end{array}\right] = \left[\begin{array}{c} 0 \\ b\,\overline{F} \end{array}\right] \Longrightarrow \left[\begin{array}{c} dA/dx \\ dB/dx \end{array}\right] = b\,\overline{F}\left[\begin{array}{c} -\sinh(x/b) \\ \cosh(x/b) \end{array}\right]\,. \tag{13.13.23}$$

Since $\overline{F} = -3\,\alpha_c\,K/H\,\partial\overline{C}/\partial x$,

$$A(x,s) = A_0(s) + 3\,b\,\alpha_c\,\frac{K}{H}\int_0^x \frac{\partial\overline{C}}{\partial x}\,\sinh\frac{x}{b}\,dx, \quad B(x,s) = B_0(s) - 3\,b\,\alpha_c\,\frac{K}{H}\int_0^x \frac{\partial\overline{C}}{\partial x}\,\cosh\frac{x}{b}\,dx\,. \tag{13.13.24}$$

The standard algebraic relations below will be used,

$$\begin{aligned}\int_0^x \sin(\alpha\,y)\,\sinh(\beta\,y)\,dy &= \frac{\beta\,\sin(\alpha\,x)\,\cosh(\beta\,x) - \alpha\,\cos(\alpha\,x)\,\sinh(\beta\,x)}{\alpha^2+\beta^2},\\ \int_0^x \sin(\alpha\,y)\,\cosh(\beta\,y)\,dy &= \frac{-\alpha\,\cos(\alpha\,x)\,\cosh(\beta\,x) + \beta\,\sin(\alpha\,x)\,\sinh(\beta\,x)}{\alpha^2+\beta^2}\,.\end{aligned} \tag{13.13.25}$$

From (13.13.16),

$$\frac{\partial\overline{C}}{\partial x}(x,s) = \frac{2\,C_0}{l}\sum_{n=0}^{\infty}(-1)^n\,\frac{\sin(X_n\,x/l)}{s + X_n^2/t_{\rm C}}\,. \tag{13.13.26}$$

Thus with $\beta = 1/b$,

$$\begin{aligned}A(x,s) &= A_0(s) + 6\,C_0\,\alpha_c\,b\,k_{\rm H}\,\frac{K}{l}\sum_{n=0}^{\infty}(-1)^n\,\frac{\beta\,\sin(X_n\,x/l)\,\cosh(\beta\,x) - X_n/l\,\cos(X_n\,x/l)\,\sinh(\beta\,x)}{(s+X_n^2/t_{\rm C})\,(s+X_n^2/t_{\rm H})},\\ B(x,s) &= B_0(s) - 6\,C_0\,\alpha_c\,b\,k_{\rm H}\,\frac{K}{l}\sum_{n=0}^{\infty}(-1)^n\,\frac{-X_n/l\,\cos(X_n\,x/l)\,\cosh(\beta\,x) + \beta\,\sin(X_n\,x/l)\,\sinh(\beta\,x)}{(s+X_n^2/t_{\rm C})\,(s+X_n^2/t_{\rm H})}\,.\end{aligned} \tag{13.13.27}$$

Insertion of these expressions in (13.13.21) yields

$$\overline{u}_{\rm s}(x,s) = A_0(s)\,\cosh(\beta\,x) + B_0(s)\,\sinh(\beta\,x) + 6\,C_0\,\alpha_c\,k_{\rm H}\,\frac{K}{l}\sum_{n=0}^{\infty}\frac{(-1)^n\,\sin(X_n\,x/l)}{(s+X_n^2/t_{\rm C})\,(s+X_n^2/t_{\rm H})}\,. \tag{13.13.28}$$

The constants $A_0(s)$ and $B_0(s)$ are obtained via the boundary conditions (13.13.7). The Laplace transform of the displacement finally simplifies to,

$$\overline{u}_{\rm s}(x,s) = -3\,C_0\,\alpha_c\,\frac{K}{H}\,\frac{b}{s}\,\frac{\sinh(\beta\,x)}{\cosh(\beta\,l)} + 6\,C_0\,\alpha_c\,k_{\rm H}\,\frac{K}{l}\sum_{n=0}^{\infty}\frac{(-1)^n\,\sin(X_n\,x/l)}{(s+X_n^2/t_{\rm C})\,(s+X_n^2/t_{\rm H})}\,. \tag{13.13.29}$$

13.13.4.2 The solution in the time domain

Using the retardation formula, and decomposing the denominator in the sum of two terms, the inverse transform of the second part of the solution is simply

$$6\,C_0\,\alpha_c\,\frac{K}{H}\,\frac{l}{t_{\rm H}/t_{\rm C}-1}\left(S(\frac{x}{l},\frac{t}{t_{\rm H}}) - S(\frac{x}{l},\frac{t}{t_{\rm C}})\right), \tag{13.13.30}$$

where generically, for $t_{\rm X} = t_{\rm C},\,t_{\rm H}$,

$$S(\frac{x}{l},\frac{t}{t_{\rm X}}) = \sum_{n=0}^{\infty}\frac{(-1)^n}{X_n^2}\,\sin(X_n\,\frac{x}{l})\,e^{-X_n^2\,t/t_{\rm X}}\,. \tag{13.13.31}$$

The first part of displacement can be inverted through integration in the complex domain. Note first that the functions in the complex domain of the Laplace variable s are uniform, due to the parity of the function sinh and the definition $b = 1/\beta = \sqrt{H\,k_{\rm H}/s}$, so that

$$\frac{l}{b} = \pi\,\sqrt{t_{\rm H}\,s}\,. \tag{13.13.32}$$

The roots of the denominator are all simple, namely $s = 0$ and $\sqrt{t_{\rm H}\,s_n} = i\,(n+1/2)$, that is $s_n = -(n+1/2)^2/t_{\rm H}$, $n \geq 0$. The contribution of each root is calculated as indicated in (7.5.38), yielding

$$-\,3\,C_0\,\alpha_c\,\frac{K}{H}\,x + 6\,C_0\,\alpha_c\,\frac{K}{H}\,l\,S(\frac{x}{l},\frac{t}{t_{\rm H}})\,. \tag{13.13.33}$$

From the displacement,

$$\frac{1}{C_0\,\alpha_c}\,\frac{u_{\rm s}(x,t)}{l} = -3\,\frac{K}{H}\,\frac{x}{l} + 6\,\frac{K}{H}\,\frac{1}{t_{\rm H}-t_{\rm C}}\left(t_{\rm H}\,S(\frac{x}{l},\frac{t}{t_{\rm H}}) - t_{\rm C}\,S(\frac{x}{l},\frac{t}{t_{\rm C}})\right), \tag{13.13.34}$$

follows the strain,

$$\frac{1}{C_0\,\alpha_c}\,\frac{\partial u_{\rm s}}{\partial x}(x,t) = -3\,\frac{K}{H} + 6\,\frac{K}{H}\,\frac{1}{t_{\rm H}-t_{\rm C}}\left(t_{\rm H}\,R(\frac{x}{l},\frac{t}{t_{\rm H}}) - t_{\rm C}\,R(\frac{x}{l},\frac{t}{t_{\rm C}})\right), \tag{13.13.35}$$

with R defined by (13.13.17). Thus the strain at the boundaries $\pm l$ takes instantaneously the final value, to which all points of the strip will ultimately converge, namely

$$\frac{\partial u_{\rm s}}{\partial x}(\pm l,t) = -3\,C_0\,\alpha_c\,\frac{K}{H}\,. \tag{13.13.36}$$

This value agrees with a vanishing normal stress and a vanishing pore pressure, as indicated by (13.13.7).

13.13.5 The solution for the pore pressure

The pressure (13.13.13) is now deduced from (13.13.16) and (13.13.35), namely

$$\frac{1}{C_0\,\alpha_c}\,\frac{p_{\rm w}(x,t)}{H} = 6\,\frac{K}{H}\,\frac{t_{\rm H}}{t_{\rm H}-t_{\rm C}}\left(R(\frac{x}{l},\frac{t}{t_{\rm H}}) - R(\frac{x}{l},\frac{t}{t_{\rm C}})\right). \tag{13.13.37}$$

The fluid flux $J_{\rm w} = n^{\rm w}\,(v_{\rm w}-v_{\rm s})$ results as

$$\frac{1}{C_0\,\alpha_c}\,\frac{J_{\rm w}}{l/t_{\rm H}} = 6\,\frac{K}{H}\,\frac{t_{\rm H}}{t_{\rm H}-t_{\rm C}}\,\sum_{n=0}^{\infty}(-1)^n\,\sin(X_n\,\frac{x}{l})\left(e^{-X_n^2\,t/t_{\rm H}} - e^{-X_n^2\,t/t_{\rm C}}\right). \tag{13.13.38}$$

Other entities follow from the above expressions, like the effective axial strain $\epsilon'_{xx} = \epsilon_{xx} + C\,\alpha_c$, the effective axial stress $\sigma'_{xx} = H\,\epsilon_{xx} + 3\,K\,C\,\alpha_c$ or $\sigma'_{xx} = H\,\epsilon'_{xx} + (3\,K-H)\,C\,\alpha_c$. In fact, the total axial stress $\sigma_{xx} = \sigma'_{xx} - p_{\rm w}$ vanishes everywhere for the 1D problem.

13.13.6 The axial force

The fact that the strains are prevented along the axis 3 gives rise to a reaction over the section of area $L_1 \times L_2$,

$$F(t) = L_2\,\int_{-l}^{l}\sigma^{\rm s}_{33}(x,t)\,dx\,. \tag{13.13.39}$$

The force is transmitted only by the solid phase, on the ground that the material is actually in tension along the axial direction. The stress-strain relation implies,

$$\sigma^{\rm s}_{33} = \lambda\,\frac{\partial u_{\rm s}}{\partial x} + 3\,K\,\alpha_c\,C - n^{\rm s}\,p_{\rm w}\,. \tag{13.13.40}$$

The following intermediate quantities are needed:

$$\begin{aligned}
&u_{\rm s}(l,t) - u_{\rm s}(-l,t) = 6\,C_0\,\alpha_c\,\frac{K}{H}\,\frac{l}{t_{\rm H}-t_{\rm C}}\left(-t_{\rm H}\,Q(\frac{t}{t_{\rm H}}) + t_{\rm C}\,Q(\frac{t}{t_{\rm C}})\right),\\
&\int_{-l}^{l}C(x,t)\,dx = 2\,C_0\,l\,Q(\frac{t}{t_{\rm C}}),\\
&\int_{-l}^{l}p_{\rm w}(x,t)\,dx = 6\,C_0\,\alpha_c\,K\,l\left(-Q(\frac{t}{t_{\rm H}}) + Q(\frac{t}{t_{\rm C}})\right)\frac{t_{\rm H}}{t_{\rm H}-t_{\rm C}}\,,
\end{aligned} \tag{13.13.41}$$

where

$$Q(\frac{t}{t_{\rm X}}) = 1 - 2\,S(1,\frac{t}{t_{\rm X}}) = 1 - 2\,\sum_{n=0}^{\infty}\frac{e^{-X_n^2\,t/t_{\rm X}}}{X_n^2}\,. \tag{13.13.42}$$

Note that $Q(0) = 0$ because $\sum_{n=0}^{\infty}1/(n+1/2)^2 = \pi^2/2$, and $Q(\infty) = 1$. The force can then be expressed in the format,

$$\frac{F(t)}{F_\infty} = (1 - \frac{H}{2\,\mu}\,n^{\rm w})\,\frac{t_{\rm H}}{t_{\rm H}-t_{\rm C}}\,Q(\frac{t}{t_{\rm H}}) - (\frac{t_{\rm C}}{t_{\rm H}} - \frac{H}{2\,\mu}\,n^{\rm w})\,\frac{t_{\rm H}}{t_{\rm H}-t_{\rm C}}\,Q(\frac{t}{t_{\rm C}})\,, \tag{13.13.43}$$

with F_∞ the value at large times,

$$F_\infty = 6\,\mu\,L_1\,L_2\,C_0\,\alpha_c\,\frac{K}{H}\,. \tag{13.13.44}$$

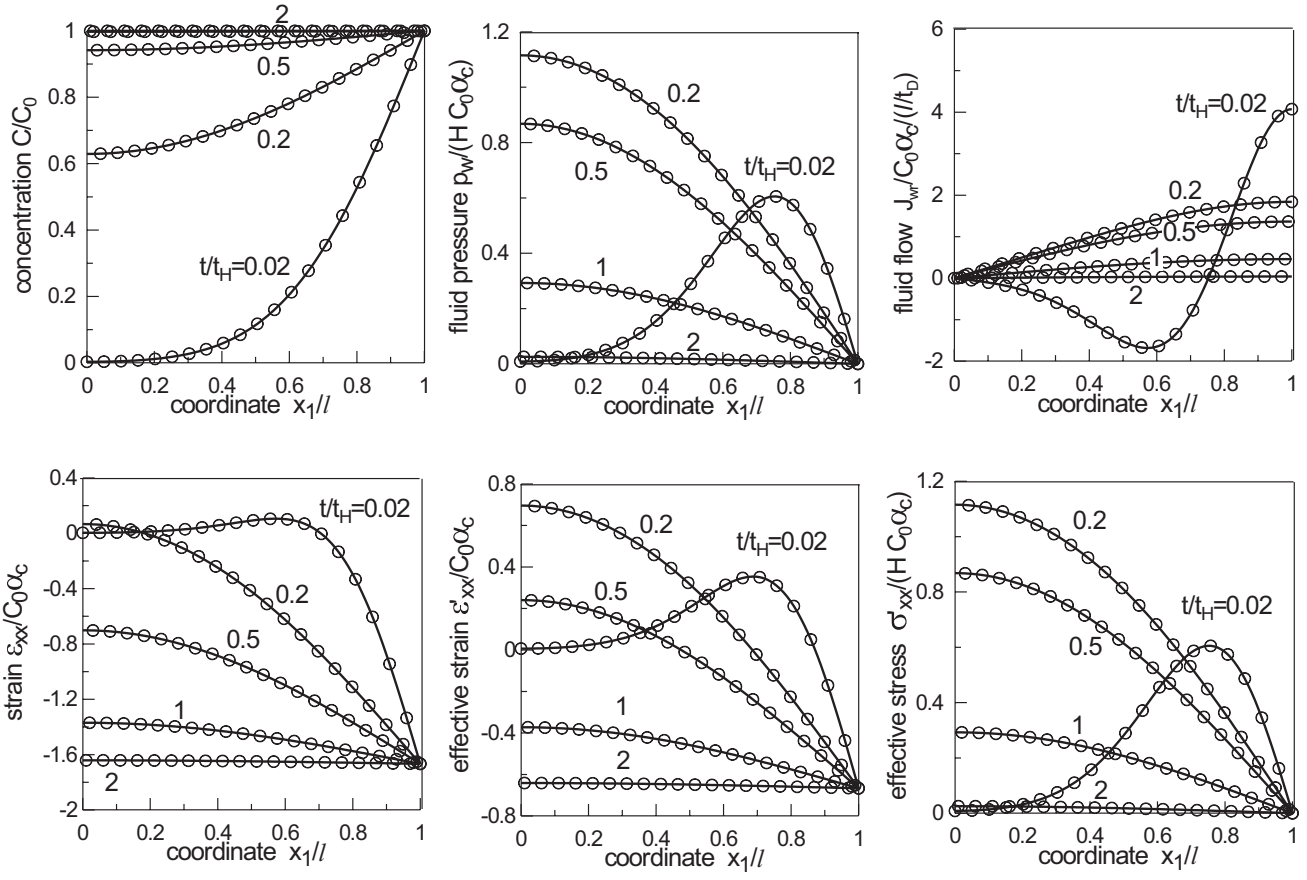

Fig. 13.13.2: Strip of cartilage submitted to step chemical loading along the boundary $x_1/l = 1$. Spatial profiles at several times.

13.13.7 Simulations of chemical loadings

Simulations using the values shown in Table 13.13.1, which are typical of articular cartilages, are displayed in Figs. 13.13.2 and 13.13.3. The associated seepage time is $t_{\rm H} = 10\,{\rm s}$ and the minimum time for chemical diffusion is $t_{\rm C} = 4\,{\rm s}$.

The profiles of various entities displayed in Fig. 13.13.2 correspond to the ratio $t_{\rm H}/t_{\rm C} = 2.5$. Consequently, the trend towards equilibrium of the concentration which is governed solely by Fick's time is faster than for the other entities whose transient behavior depends on both seepage and chemical diffusion.

In other words, chemical diffusion takes place first and the chemical penetrates the tissue progressively. Chemo-mechanical coupling implies contraction and increase of the pore fluid pressure. Since the latter is maintained to zero at the boundary, the transient pressure profile displays a maximum which enters the tissue progressively. This non monotonous profile leads to a temporary divergent flow process associated with Darcy's law.

Since the total stress is permanently zero, and the pore pressure ultimately vanishes, so does the effective stress. On the other hand, the steady states of the effective strain and total strain are contractile, in agreement with the expressions shown at the end of Section 13.13.5 since $3\,K - H > 0$.

The time profile of the force shown in Fig. 13.13.3 depends much on the ratio of the characteristic times. If $t_{\rm H}/t_{\rm C}$ is small, i.e., seepage is fast, the force is monotonous, corresponding to the progressive penetration of the chemical into the strip. The situation is more complex when the seepage is slow, and the force displays a maximum if $t_{\rm H}/t_{\rm C}$ is larger than about 0.5. In fact when this ratio is large, only the second term of (13.13.43) contributes to the force at times much larger than $t_{\rm C}$ but much smaller than $t_{\rm H}$. Since $Q(0) = 0$ and $Q(\infty) = 1$, the maximum is bounded by $n^{\rm w}\,H/2\,\mu$. Myers et al. [1984] observe that a ratio $t_{\rm H}/t_{\rm C} = 2.5$ and a Poisson's ratio $\nu = 0.44$ describes best their experimental time profiles.

Table 13.13.1: Constitutive parameters used in the simulations, Myers et al. [1984].

Entity	Symbol	Value	Unit
Fluid volume fraction	n^{w}	0.80	-
Drained Poisson's ratio	ν	0.25	-
Elastic shear modulus	μ	333	kPa
Hydraulic permeability	k_{H}	10^{-15}	$\mathrm{m}^2/\mathrm{Pa/s}$
Coefficient of chemical diffusion	D	$0.5\text{-}25 \times 10^{-10}$	m^2/s
Coefficient of chemical contraction	α_c	0.093	liter/mole
Initial chemical concentration	C_0	0.15	mole/liter
Dimensions of specimen	$L_1 = 2\,l$	2×10^{-4}	m
	L_2	17×10^{-4}	m

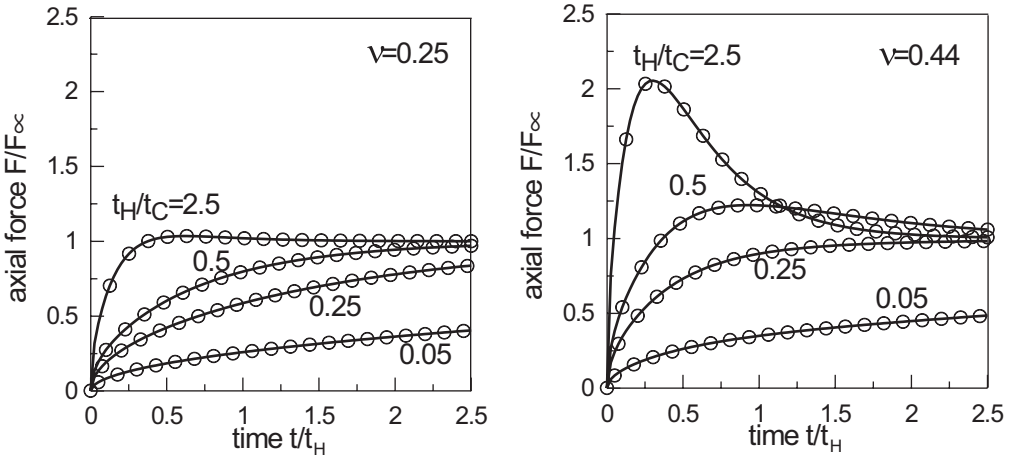

Fig. 13.13.3: Axial force along the direction 3, as indicated in Fig. 13.13.1, due to the increase of concentration of the bath, the cartilage is put in contact with at time $t = 0$. The relative values of the characteristic times for seepage and chemical diffusion and Poisson's ratio are key parameters affecting the transient profile of the force.

Exercises on Chapter 13

Exercise 13.1 Single diffuse double layer

The spatial repartition of a fixed electrical charge bathed in an electrolyte has been for long idealized, at the nanoscale, by a linear fixed attractor, charged negatively at neutral pH, adjacent to a diffuse layer of mobile ions: due to the presence of the two parallel charge distributions, the model has been called single diffuse double layer theory.

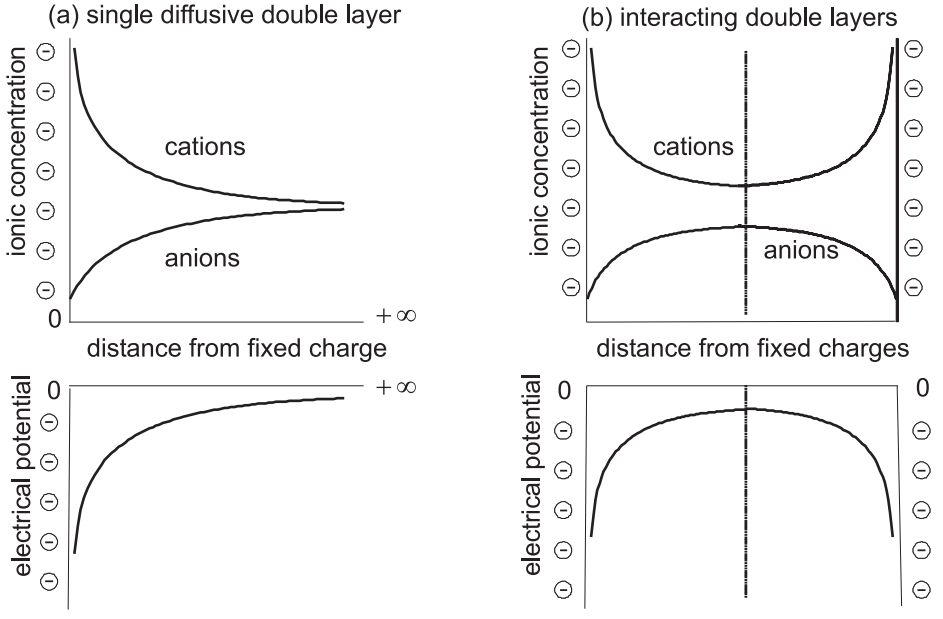

Fig. 13.E.1: Spatial profiles of the ionic concentrations and electrical potentials across (a) a single diffuse double layer and (b) interacting double layers in presence of a negative fixed charge.

A more elaborated configuration considers two parallel and identical attractors separated by a symmetric diffuse layer of electrolyte, so called interacting double layers, Fig. 13.E.1. Mitchell [1993], p. 111 et seq., contains a compact summary of developments in the area, as well as references to the subject.

Here we consider only a single diffuse double layer theory.

Assumptions:

A1. Electroneutrality is satisfied globally, not locally. Indeed, it is not satisfied pointwise in the diffuse layer, but the sum of all charges in the diffuse layer and in the attractor vanishes. On the other hand, pointwise electroneutrality is satisfied far from the attractor at $z = \infty$.

A2. Electrochemical equilibrium holds pointwise;

A3. The ionic strength $I(\infty)$ and electrical potential $\phi(\infty)$ are known far from the attractor.

The electrical potential $\phi(0)$ at the surface of the attractor $z = 0$ is obtained as a result of the analysis, if the charge of the attractor is given, and conversely: the issue is addressed in Exercise 13.2.

1. Prove the Boltzmann relation linking the molar fraction x, or concentration c, to the electrical potential ϕ,

$$\frac{x(z)}{x_\infty} = \frac{c(z)}{c_\infty} = \exp\Big(-\frac{\mathrm{F}\zeta}{RT}[\phi](z)\Big), \quad [\phi](z) \equiv \phi(z) - \phi(\infty)\,. \tag{13.E.1}$$

Hint: Electrochemical equilibrium of a species with valence ζ implies its electrochemical potential $g^{\mathrm{ec}} = RT\,\mathrm{Ln}\,x + \zeta\,\mathrm{F}\phi$ to be spatially uniform, in particular equal to its value at $z = +\infty$. Whence the Boltzmann relation.

2. Assume two species of valences ζ_+ and ζ_- to be present so that their respective electrical densities are $I_{\mathrm{e}}^+ = \mathrm{F}\,(\zeta\,c)_+$ and $I_{\mathrm{e}}^- = \mathrm{F}\,(\zeta\,c)_-$. Show that the electric density expresses in terms of the electrical potential as

$$\begin{aligned} I_{\mathrm{e}} &= I_{\mathrm{e}}^+ + I_{\mathrm{e}}^- \\ &= I_{\mathrm{e}}^+(\infty)\Big(\exp\Big(-\frac{\mathrm{F}\zeta_+}{RT}\,[\phi]\Big) - \exp\Big(-\frac{\mathrm{F}\zeta_-}{RT}\,[\phi]\Big)\Big)\,. \end{aligned} \tag{13.E.2}$$

Hint: Use of the relations (13.E.1) applied to both species, namely

$$\frac{c_\pm}{c_\pm(\infty)} = \exp\Big(-\frac{\mathrm{F}\zeta_\pm}{RT}\,[\phi]\Big)\,, \tag{13.E.3}$$

and of the electroneutrality condition far from the attractor,

$$I_\mathrm{e}(\infty) = I_\mathrm{e}^+(\infty) + I_\mathrm{e}^-(\infty) = 0\,, \tag{13.E.4}$$

provides (13.E.2).

3. Applying Poisson's equation (13.6.4),

$$\frac{d^2\phi}{d^2z} = -\frac{I_\mathrm{e}}{\epsilon}\,, \tag{13.E.5}$$

obtain the Poisson-Boltzmann differential equation for the sole electrical potential,

$$\frac{d^2\phi}{d^2z} = -\frac{I_\mathrm{e}^+(\infty)}{\epsilon}\Big(\exp\Big(-\frac{\mathrm{F}\zeta_+}{RT}\,[\phi]\Big) - \exp\Big(-\frac{\mathrm{F}\zeta_-}{RT}\,[\phi]\Big)\Big)\,. \tag{13.E.6}$$

Here ϵ [unit : F/m] is the permittivity of the medium.
Hint: Use relation (13.E.2) in the Poisson's equation.

4. Assuming a small variation of the electrical potential, so that the exponentials can be approximated by a first order Taylor expansion, show that the electrical potential decreases exponentially from the attractor to infinity with a length constant $1/\kappa$ called the Debye length,

$$\frac{\phi(z)-\phi(\infty)}{\phi(0)-\phi(\infty)} = \exp(-\kappa\, z), \quad \frac{1}{\kappa} = \sqrt{\frac{RT\,\epsilon}{2\,I(\infty)}}\,\frac{1}{\mathrm{F}}\,, \tag{13.E.7}$$

where I is the *ionic strength* of the solution [unit : mole/m^3] (replace I by $1000\,I$ if I is expressed in mole/liter),

$$I = \frac{1}{2}(\zeta_+^2\, c_+ \;+\; \zeta_-^2\, c_-)\,. \tag{13.E.8}$$

Note that the Debye length does not depend on the charge σ_e of the attractor.
Hint: Linearization of the Poisson-Boltzmann differential equation yields

$$\frac{d^2\phi}{d(\kappa\, z)^2} = [\phi]\,. \tag{13.E.9}$$

The integration constants are readily obtained from the condition at the surface of the attractor $z = 0$ and at infinity. The ionic strength comes into picture by use of the electroneutrality condition (13.E.4).

The Debye length represents the range of influence of the attractor. It decreases as the ionic strength at infinity increases: the mobile ions in the electrolyte are said to shield the influence of the attractor.

The influence of the solvent is present through its dielectric constant $\epsilon_r = \epsilon/\epsilon_0$. Clearly the larger ϵ_r, the longer the Debye length.

A multivalent cation is also seen to shield more efficiently the attractor. For sodium chloride and calcium chloride, the ionic strength at infinity is $2\,I = 6\,c_\mathrm{Ca}$ and $2\,I = 2\,c_\mathrm{Na}$ respectively. Hence, the Debye length for calcium chloride is $1/\sqrt{3}$ smaller than the Debye length for sodium chloride at equal cationic concentration $c_\mathrm{Ca} = c_\mathrm{Na}$ at infinity.

At a macroscopic level, increase of ionic strength will imply a reduced Debye length, corresponding to closer PGs, and therefore to overall contraction.

Once the potential ϕ is known, the spatial variations of the concentrations of the two species are read from (13.E.3). The density of counterions, endowed with a charge opposite to the attractor, is expected to decrease from the attractor surface $z = 0$ to infinity where it is given. By contrast, the density of co-ions, of charge of the same sign as the attractor, is expected to be small close to the attractor and to increase to the prescribed value at infinity.

5. Calculate the Debye length as a function of the concentration (or ionic strength) $c^+(\infty) = I_\mathrm{e}^+(\infty)/\mathrm{F}$ for a binary symmetric electrolyte $\zeta_+ = -\zeta_- = \zeta$.
Answer: With the constants given in Chapter 25, and with $c^+(\infty)$ in mole/liter,

$$\frac{1}{\kappa} = \frac{3.044}{\zeta\sqrt{c^+(\infty)}} \quad [\text{unit : Å}]\,. \tag{13.E.10}$$

6. Restricting now the analysis to symmetric binary electrolytes, $\zeta_+ = -\zeta_- = \zeta$, reconsider determining the electrical potential without linearization. Show that the Debye length (13.E.7) remains unchanged and that the solution $[\tilde\phi](z) = (\zeta\,\mathrm{F}/RT)\,(\phi(z)-\phi(\infty))$ is given in the format,

$$[\tilde\phi](z) = 2\,\mathrm{Ln}\,\frac{1+\exp(-\kappa\, z)\,\tanh([\tilde\phi(0)]/4)}{1-\exp(-\kappa\, z)\,\tanh([\tilde\phi(0)]/4)}, \quad \frac{1}{\kappa} = \sqrt{\frac{RT\,\epsilon}{2\,c^+(\infty)}}\,\frac{1}{\zeta\,\mathrm{F}}\,. \tag{13.E.11}$$

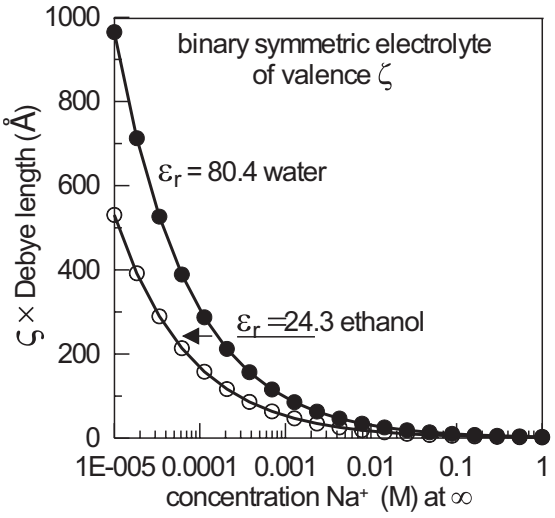

Fig. 13.E.2: Debye length times the valence of a binary symmetric electrolyte as a function of the concentration far from the attractor. The diffuse layer is larger when the solvent is water, rather than ethanol.

Fig. 13.E.2 displays typical ranges for the Debye length as a function of the concentration.

Proof:

Eqn (13.E.6) becomes

$$\frac{d^2[\tilde{\phi}]}{d(\kappa z)^2} = \sinh[\tilde{\phi}]\,. \tag{13.E.12}$$

Accounting for the flattening of the electrical potential at infinity, the expression below can be checked to satisfy the second order differential equation above,

$$\frac{d(\frac{1}{2}\tilde{\phi})}{d(\kappa z)} = -\sinh\left(\frac{1}{2}[\tilde{\phi}]\right). \tag{13.E.13}$$

The remaining integration

$$\frac{d(\frac{1}{2}\tilde{\phi})}{\sinh\left(\frac{1}{2}[\tilde{\phi}]\right)} = -d(\kappa z)\,, \tag{13.E.14}$$

is performed through the change of variable $[\tilde{\phi}]/2 \to \exp([\tilde{\phi}]/2)$, and the boundary condition at $z = 0$.

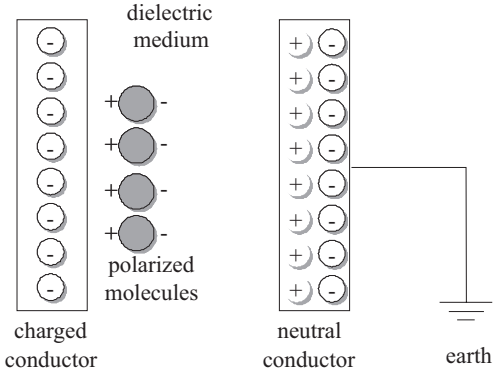

Fig. 13.E.3: Sketch of a typical capacitor device.

Exercise 13.2 The constant capacitance model

1. Basic definitions of capacitors

A capacitor can be represented by two conductor plates separated by an insulating dielectric medium in which the molecules can be polarized to form electric dipoles. One plate has a fixed charge, while the second charge is often neutralized through an earth connection, Fig. 13.E.3. The capacitance G_e [unit : F=C/V] is equal to the charge Q required to increase the potential ϕ by one volt, $G_e = Q/\phi$. It depends only on the geometry of the capacitor and on the dielectric constant of the medium.

The energy of a capacitor is equal to the work done in charging it, namely $\int_0^Q \phi\, dQ = \frac{1}{2}\, G_e\, \phi^2$, or $\frac{1}{2}\, Q^2/G_e$.

Connected in parallel (same potential but individual charges), the capacitance of two capacitors is equal to the sum of the individual capacitances. Conversely, connected in series (same charge but individual potentials), the inverse capacitance of set is equal to the sum of the inverses of the individual capacitances.

Consider a capacitor consisting of two parallel plates of area S separated by a distance d and with respective charges $(0, Q)$ and $(-Q, +Q)$. According to Gauss's law (13.6.3), the difference of potentials between the two plates ϕ and the charge Q are linked by the relation $\epsilon\,(\phi/d)\,S = Q$: hence the capacitance of the two parallel plates is equal to $G_e = \epsilon\,S/d$, where ϵ [unit : F/m] is the permittivity.

An isolated sphere of radius r_0 can be seen as the inner part of a capacitor whose external neutralized part is a sphere whose radius is large with respect to r_0. With help of (13.6.5), its capacitance has the expression,

$$G_e = \frac{Q}{\phi} = 4\,\pi\,\epsilon\,r_0\,. \tag{13.E.15}$$

The diffuse double layer can be seen as a (half) capacitor. Indeed, consider an attractor of surface charge σ_e [unit : C/m^2] and the adjacent diffuse layer extending from the attractor $z = 0$ to infinity. As indicated in the assumptions of Exercise 13.1, the sum of all charges vanishes,

$$\sigma_e + \int_0^\infty I_e\,dz = 0\,. \tag{13.E.16}$$

The electrical charge may be eliminated through the Poisson's relation (13.E.5),

$$\sigma_e = \int_0^\infty \epsilon\,\frac{d^2\phi}{dz^2}\,dz = -\epsilon\,\frac{d\phi}{dz}(0)\,, \tag{13.E.17}$$

where the fact that the electrical potential flattens at infinity has been used, Eqn (13.E.7). The second relation above has also assumed the permittivity ϵ to be spatially uniform. This spatial property holds if the permittivity is seen as a property of the solvent only. It is more questionable if ϵ is interpreted as a property of the electrolyte, since the spatial repartition of the ions is not uniform.

2. If the linearization of exponentials, as in Exercise 13.1, is accurate enough, show that the diffuse double layer can be seen as a capacitor of areal capacitance $\kappa\,\epsilon$ [unit : F/m^2], namely

$$\phi(0) - \phi(\infty) = \frac{\sigma_e}{\kappa\,\epsilon}\,. \tag{13.E.18}$$

Hence, if the attractor is negatively (respectively positively) charged, the potential is lower than at infinity (respectively higher): it attracts cations (respectively anions) and plays the role of a cathode (respectively anode).

Proof: The derivative of the potential can be estimated by Eqn (13.E.7), namely $d\phi/dz(z=0) = -\kappa\,(\phi(0) - \phi(\infty))$, whence the relation (13.E.18).

3. Reconsider the above problem without linearization and show that

$$[\tilde{\phi}](0) \equiv \frac{\zeta\,\mathrm{F}}{RT}\,\big(\phi(0) - \phi(\infty)\big) = 2\,\mathrm{Ln}\,\big(X + \sqrt{X^2+1}\big)\,, \quad X \equiv \frac{\sigma_e}{\sqrt{8\,RT\,\epsilon\,c^+(\infty)}}\,. \tag{13.E.19}$$

Proof: Insertion of (13.E.13) into (13.E.17) yields

$$\sigma_e = \sqrt{8\,RT\,\epsilon\,c^+(\infty)}\,\sinh\Big(\frac{1}{2}\,[\tilde{\phi}](0)\Big)\,. \tag{13.E.20}$$

Solving (13.E.20) for the potential $\phi(0)$ yields the announced result.

The spatial profiles of the electrical potential and ionic concentrations away from the fixed charge are displayed in Fig. 13.E.4 for the fixed charge $\sigma_e = -0.125\,\mathrm{C/m^2}$.

Exercise 13.3 Triple layer theory

Various degrees of refinement can be developed for the spatial variation of the electrical potential in the neighborhood of an attractor A endowed with fixed charge σ_0, Sposito [1984], Stumm [1992], Petrangeli Papini and Majone [2002]. Three models are sketched in Fig. 13.E.5.

In the layers where the charges are located along discrete planes, the electrical potential varies linearly according to Poisson's equation. The constant capacitance model involves a single constant to be obtained by optimization of some nanometric or macroscopic entities. The triple layer model requires a second capacitance. For the diffuse layer model and the triple layer model, where mobile charges are distributed in the outer layer, the spatial variation of the electrical potential in this layer is the one defined in Exercise 13.1.

The fixed charge σ_0 of the attractor is due to broken bonds, e.g., pH-sensitive terminations A-OH, A-OH-H$^+$, A-O$^-$. For the triple layer model, the plane β gathers the charge σ_β of adsorbed ions, e.g., Cl$^-$ and Na$^+$.

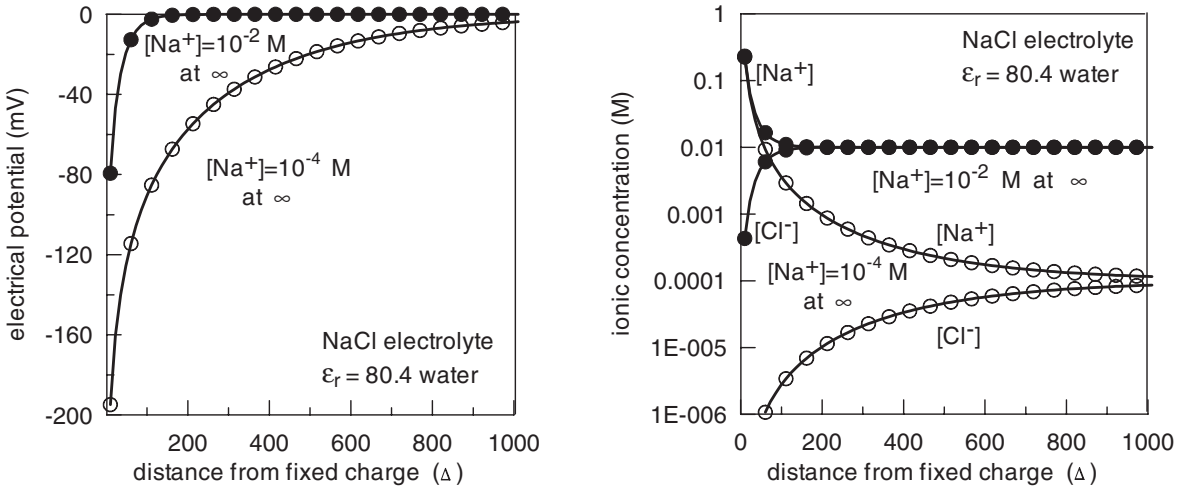

Fig. 13.E.4: Diffuse double layer. Spatial variation of the electrical potential and ionic concentration for sodium chloride and a negative fixed electrical charge $\sigma_e = -0.125\,\mathrm{C/m^2}$.

What are the potentials on the planes of interest?

Answer: The difference of electrical potentials between the layers is linked to the fixed or adsorbed charge through the capacitances, namely for the constant capacitance model,

$$\phi_0 - \phi_\infty = \frac{\sigma_0}{G_{e0}}\,, \tag{13.E.21}$$

for the triple layer model,

$$\phi_0 - \phi_\beta = \frac{\sigma_0}{G_{e0}}, \quad \phi_\beta - \phi_s = \frac{\sigma_0 + \sigma_\beta}{G_{es}}\,, \tag{13.E.22}$$

and for the outer layers where ions are solvated,

$$\phi_s - \phi_\infty \text{ given by (13.}E\text{.18) or (13.}E\text{.19) with } \sigma_e = -\sigma_s\,. \tag{13.E.23}$$

Exercise 13.4 Osmotic pressure in the diffuse double layer model

Show that the osmotic pressure, at low ionic strength $I = I(\infty)$, is equal to

$$\pi = p(0) - p(\infty) = \frac{(\mathrm{F}\,[\phi])^2}{RT}\,I(\infty)\,. \tag{13.E.24}$$

Proof:

The local osmotic pressure is equal to $p = RT\,(c_+ + c_-)$. Therefore the relation (13.E.3) yields

$$\frac{1}{RT\,c_+(\infty)}\Big(p(0) - p(\infty)\Big) = \exp\Big(-\frac{\mathrm{F}\zeta_+}{RT}\,[\phi]\Big) - 1 - \frac{\zeta_+}{\zeta_-}\Big(\exp\Big(-\frac{\mathrm{F}\zeta_-}{RT}\,[\phi]\Big) - 1\Big)\,. \tag{13.E.25}$$

The result is obtained by linearization to second order of the exponentials, and use of electroneutrality at infinity (13.E.4), with the ionic strength defined by (13.E.8).

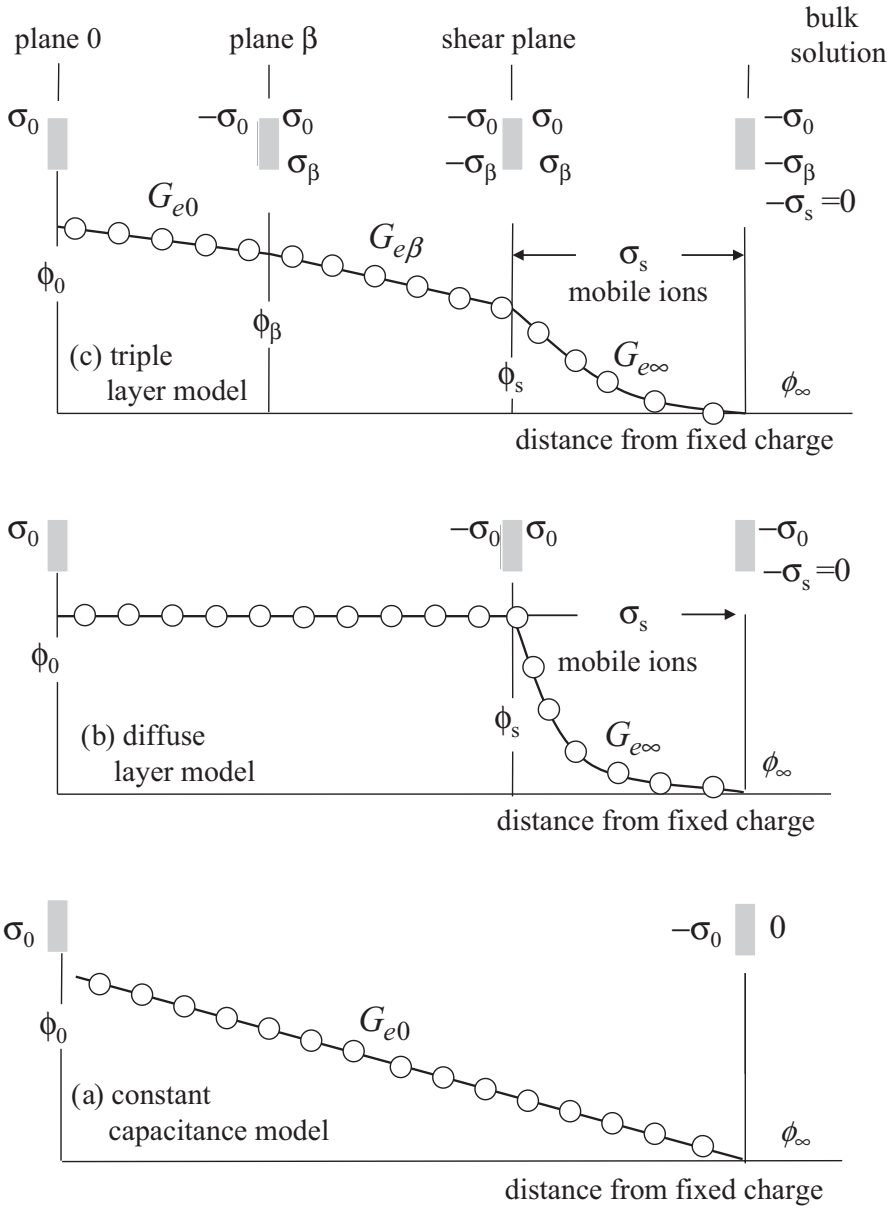

Fig. 13.E.5: Three models of spatial variation of the electrical potential in the neighborhood of the fixed charge, Sposito [1984], Stumm [1992], Petrangeli Papini and Majone [2002].

Chapter 14

Chemomechanical couplings in articular cartilages

14.1 Overview

Articular cartilage is a porous medium, structured by collagen fibers and saturated by an electrolyte, with water as solvent and metallic ions as solutes. Charged macromolecules, the proteoglycans, intermingled with collagen fibers, give rise to electro-chemomechanical couplings that allow moderate deformation to take place, and ensure an optimal adaption of the tissue to physiological loads.

The mechanical significance of the partition of tissue water in intrafibrillar (IF) and extrafibrillar compartments (EF) has been advocated by Maroudas and co-workers. The intrafibrillar compartment is defined as the volume between the collagen fibrils. The presence of ions in the intrafibrillar compartment is constrained by steric considerations : the size of a collagen molecule is 15 Å, and the distance between molecules 5 Å. Thus water molecules of size 3.6 Å, chloride ions Cl^-, sodium cations Na^+, and calcium cations Ca^{2+} with respective non hydrated diameters equal to 3.6 Å, 2 Å and 2.2 Å, can penetrate the intrafibrillar compartment while larger molecules, like PGs, cannot, Torzilli [1985]. Proteoglycans (PGs) belong to the extrafibrillar compartment. Experimentally, the partition between intrafibrillar and extrafibrillar water is measured by injecting serum albumin whose size (hydrodynamic radius 35 Å) is large with respect to the intrafibrillar characteristic dimension.

Hydrated PGs induce collagen fibers in tension: a mechanical model would consist of two parallel systems, the pressure induced by PGs being resisted by the applied mechanical load *and* collagen in tension, Maroudas et al. [1991], Lai et al. [1991], Basser et al. [1998]. For unloaded cartilage under physiological salinity, intrafibrillar water represents up to 25% of total water, the extrafibrillar water furnishing the complement. The latter can be moved by mechanical loading and osmosis with water external to the cartilage (synovial fluid). The intrafibrillar water is in contact with the extrafibrillar compartment only and it is moved essentially by changes of the chemical composition of the latter. Still, a mechanical loading modifies the relative chemical composition of water, e.g., water being expelled, the concentration of proteoglycans increases and, therefore, indirectly induces a transfer of water between the intrafibrillar and extrafibrillar compartments.

The two-compartment idea is adopted in a hierarchical multi-phase multi-species context. In line with the idea of Maroudas, collagen fibrils behave as a semipermeable membrane, impermeable to macromolecules of molar mass larger than about 4000 gm and permeable to dissolved metallic ions and water, Li and Katz [1976]. They are viewed as separating the two fluid phases.

Experiments of Eisenberg and Grodzinsky [1985] consider a cartilage specimen in equilibrium with a bath of controlled chemical composition. The stresses and strains induced by changes of the bath composition and of the applied mechanical loads are simulated in Loret and Simões [2004]. The latter reference assumes that only dissolved sodium chloride NaCl is present in the cartilage. In Loret and Simões [2005]a, attention is paid to the mechanical interactions between ions, specifically sodium Na^+ and calcium Ca^{2+}, and simulations of ionic replacements intertwined with mechanical loadings are performed.

The electro-chemomechanical model exposed in this chapter is restricted to mechanical and chemical equilibria. In other words, the chemical and mechanical loadings are performed with characteristic times much larger than

the times characterizing the material response. Moreover the electro-chemomechanical constitutive equations are assumed here as time-independent. Therefore time is elusive. The extension to transient loadings where time comes explicitly into picture due to generalized diffusion and mass transfer is exposed in Chapter 16.

The constitutive equations developed here use a thermodynamic framework, that in fact may embody not only purely mechanical aspects but also transfers of masses between the two fluid phases, flow of water through the solid skeleton and diffusion of ions through the extrafibrillar phase, Section 14.7. Still, as just pointed out, diffusion phenomena are not addressed in this chapter. The complete framework is used in Chapter 18 to solve, via the finite element method, initial and boundary value problems in order to simulate mechanical and transport phenomena in laboratory specimens submitted to transient mechanical and chemical loading processes.

14.2 Histological aspects of articular cartilages

14.2.1 The three major types of cartilage in the human body

Cartilage exists in three major types in the body, Fig. 14.2.1:

- elastic cartilage in the epiglottis and Eustachian tube;
- hyaline cartilage in the foetal skeleton and in the growing bones of young animals and humans as well as in diarthroidal joints covering long bones;
- fibrocartilage in the intervertebral disks of the spine and in the meniscus of the knee.

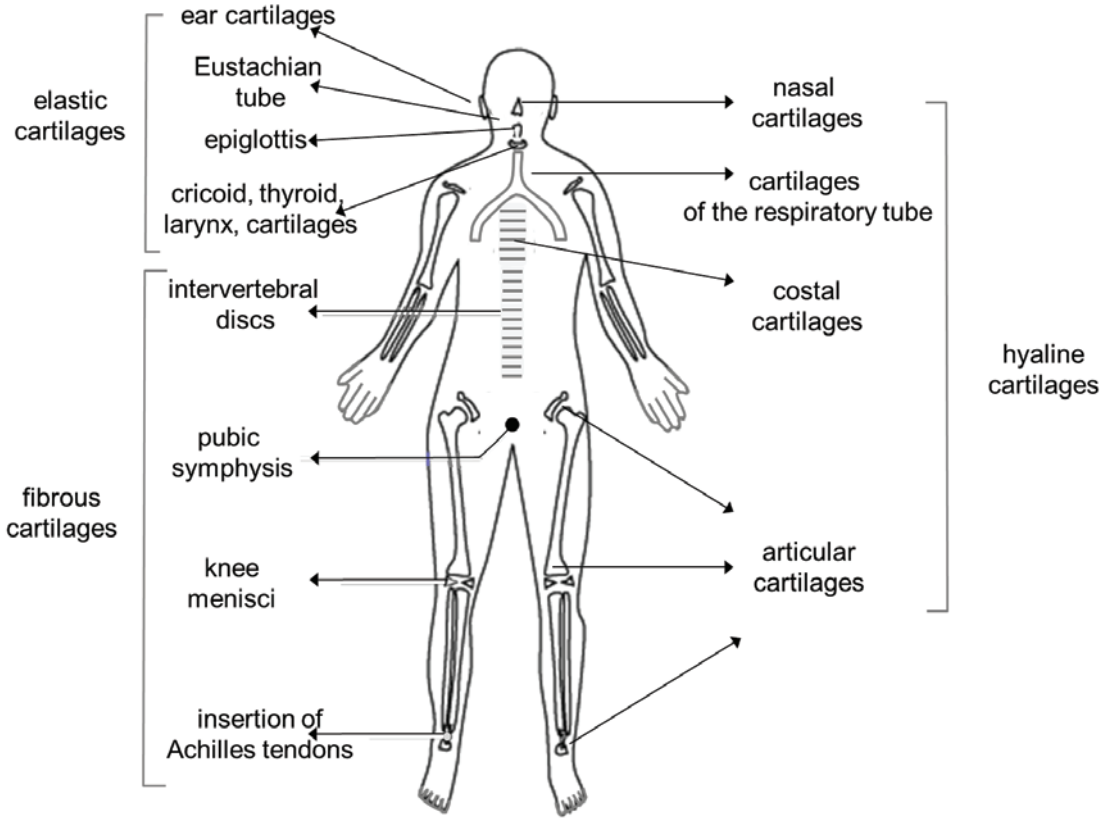

Fig. 14.2.1: Three main types of cartilage exist in the human body: hyaline cartilages, elastic cartilages and fibrous cartilages. The sketch of the human body has been modified from the site https://www.unifr.ch/anatomy/assets/files/elearning/fr/stuetzgewebe/knorpel/faser/f-faser.php (last visit 2015/11/20)

Hyaline, elastic and fibrous cartilages differ by the relative proportions of their constituents and by the types of collagen they contain, Table 14.2.1.

Table 14.2.1: Composition of various cartilages (percentage in weight).

Tissue	Collagen (% dry weight)	Proteoglycans (% dry weight)	Water (% wet weight)
Articular cartilage	50-73	15-30	58-78
Meniscus	75-80	2-6	70
Intervertebral disc-Nucleus Pulposus	15-25	50	70-90
Intervertebral disc-Annulus Fibrosus	50-70	10-20	60-70

Articular cartilage is a soft hyaline tissue that minimizes friction between diarthroidal joints covering long bones. The thickness of a diarthroidal joint varies typically from 2 to 4 mm, Fig. 14.2.2. Cartilage from adult animals and humans is avascular, aneural and alymphatic. Nutrients are transported from the synovial fluid towards the cells by convection, water diffusing through the articular surface and extracellular matrix. The cells in foetus and young subjects, called chondroblasts, are very active and they produce the extracellular matrix (ECM) composed essentially of fibrillar proteins (elastin, fibronectin and mainly collagen) and highly negatively charged proteoglycans. In adults, the chondroblasts become almost inactive; they are then called chondrocytes and their volume decreases, Stevens and Lowe [1993], p. 52. Mature chondrocytes occupy only 2% of the volume, Fig. 14.2.3. In that respect, cartilage is the opposite extreme of a syncitium, like the heart muscle or onion tissue, where the intercellular space and extracellular matrix are absent, cells occupy most of the volume and are linked together by gap junctions.

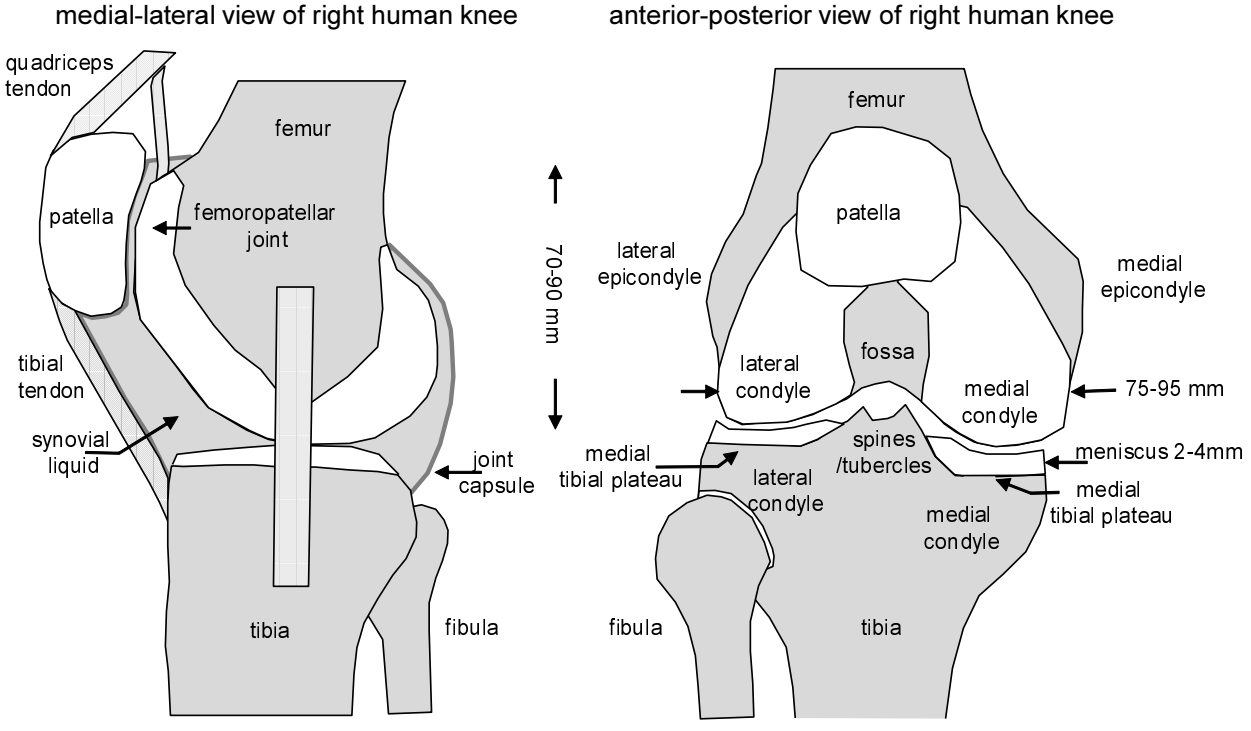

Fig. 14.2.2: Schematic of the human knee anatomy with cartilage surface in white color.

The negatively charged proteoglycans are hydrated. For normal cartilage, the negative fixed charge density ranges from 0.1 to 0.2 mole/liter of water[14.1]. The matrix is circulated by an electrolyte, namely water containing dissolved ionic species, essentially NaCl. These ions ensure electroneutrality, they move in water closeby to the fixed charge and neither Na^+ nor Cl^- bind to the charged groups.

[14.1] C.C.B. Wang et al. [2002] have developed a non-invasive technique based on video microscopy to determine the stiffness and charge density of articular cartilages.

Absorbed water within the intrafibrillar space of collagen can represent as much as 20 to 30% of the mass of the cartilage. Absorbed (intrafibrillar) water and free (extrafibrillar) water represent together 70 to 80% of the mass in articular cartilage and a little bit less in meniscus. Absorption of water results in *swelling* of the cartilage. The amount of swelling depends on the concentration of proteoglycans and on the tensile stiffness of collagen.

At physiological pH, in contrast with PGs, collagen has almost no net charge.

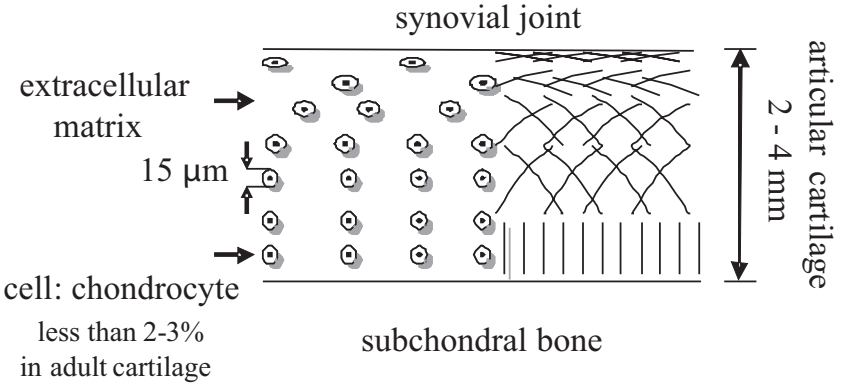

Fig. 14.2.3: Articular cartilage is formed by the interweaving of collagen fibers and proteoglycans (PGs). The spatial orientation of the collagen network aims at optimizing its mechanical role: normal to the subchondral bone to anchor the cartilage into the bone and parallel to the synovial joint to resist tangential tensile stress induced by friction. Reproduced with permission from Loret et al. [2004]a.

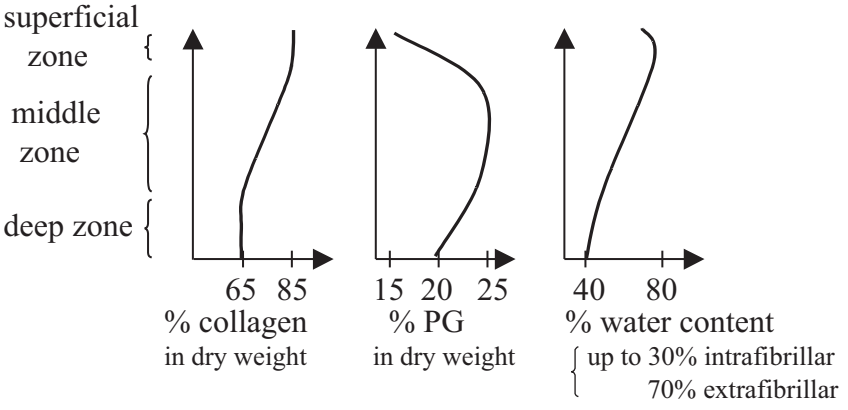

Fig. 14.2.4: The cartilage layer is formed by three main sub-layers (zones) and the content of the various components varies along the depth, presumably so as to optimize the physiological function of the organ. The mass distribution along the depth of human knee cartilage is documented in Muir et al. [1970] and Brocklehurst et al. [1984]. The sketch above redrawn from Mow and Guo [2002] summarizes data for bovine knee cartilage. The depth variation of the intervertebral disc is different from articular cartilage : the collagen content increases with depth while the content of PGs decreases, Muir [1978]. Reproduced with permission from Loret et al. [2004]a.

14.2.2 A layered structure

In the cornea and in the intervertebral disc, collagen fibers are arranged in layers in which they run parallel and along a specific pattern: two adjacent layers are rotated one with respect to the other, Chapter 19. In these two organs, the seemingly similar spatial organizations in rotated layers serve clearly distinct purposes, which are induced by additional features like the presence or absence of crosslinks. The directional distribution of collagen fibers in articular cartilages varies with depth, Fig. 14.2.3. Data are reported in Hiltner et al. [1985], their Fig. 12.

The density of PGs varies depending on the specific joint : it is larger in the femoral head than in the femoral condyle, Maroudas [1975], Fig. 2. Within a joint, it usually is minimal at the surface, maximal on the subsurface and decreases again in the depth, Maroudas [1976], Maroudas et al. [1980], as indicated in Fig. 14.2.4. The depth density

of collagen varies as well. This heterogeneity in the concentrations of collagen and PGs carries over to their ratio which seems to correlate with some mechanical properties: the tensile modulus is shown to decrease with depth, see Fig. 2 in Kempson et al. [1973], and Fig. 7 in Akizuki et al. [1986]. On the other hand, strong increase of compressive modulus with depth is reported by A.C. Chen et al. [2001] and S.S. Chen et al. [2001].

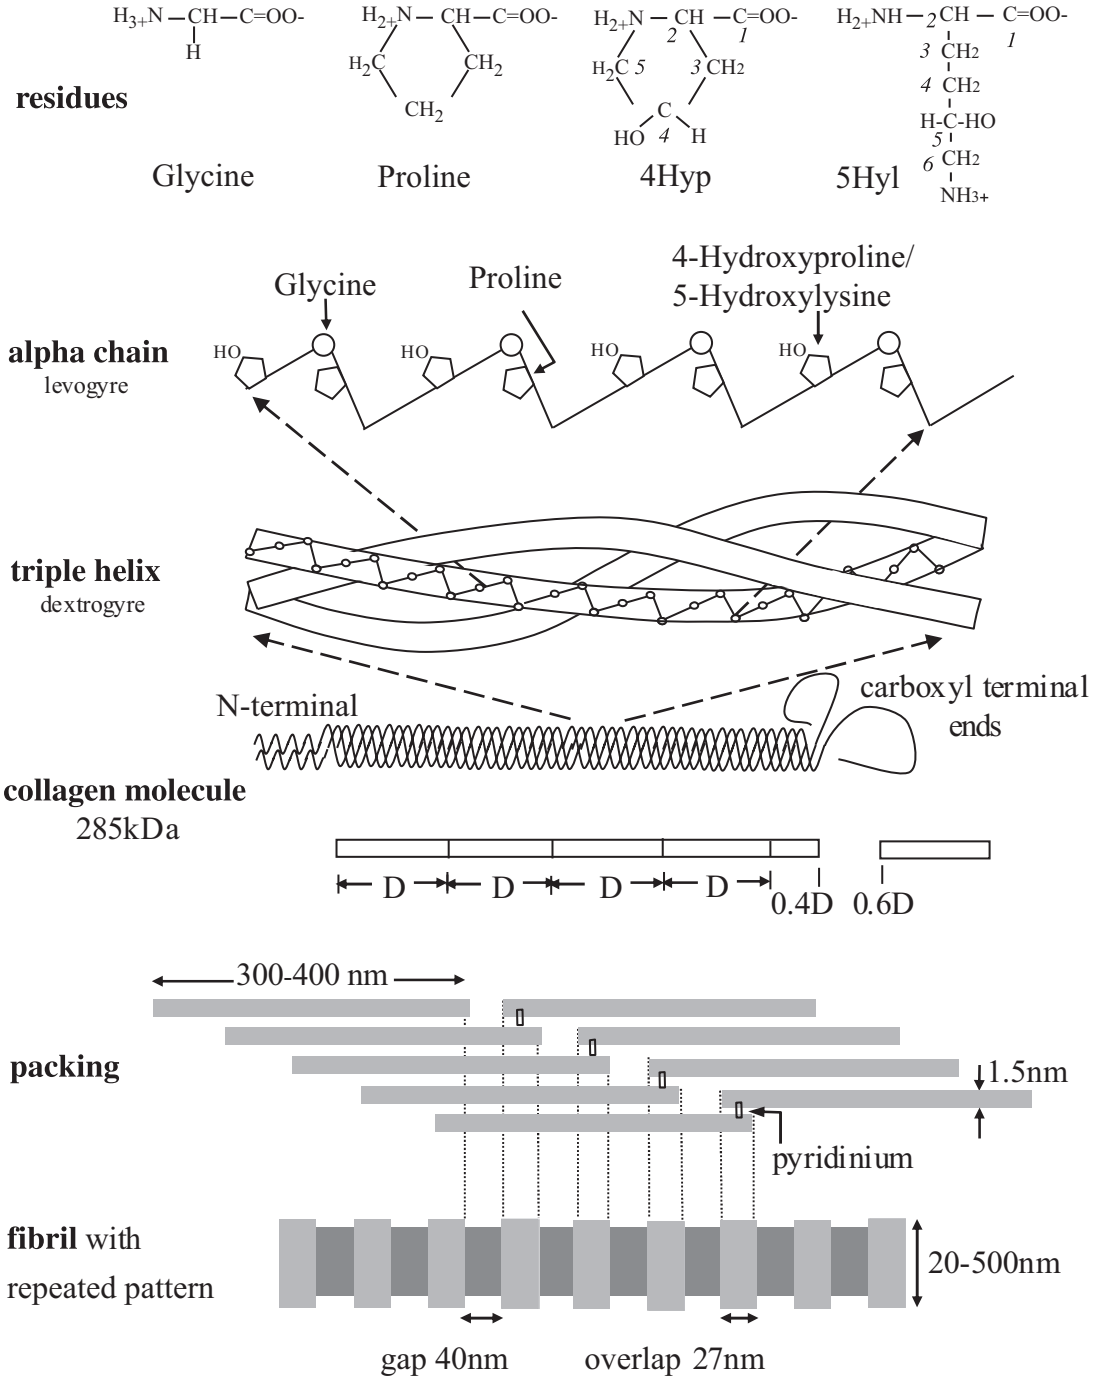

Fig. 14.2.5: Structure of collagen at various scales. The diameter of the collagen molecules depends on the type, e.g., 290 nm for collagen type I. Cartilages and cornea are endowed with fibrils of small diameters, e.g., 30-40 nm for corneal stroma. Collagen fibrils are formed by staggered collagen molecules, shifted by 67 nm and interconnected by pyridinium crosslinks (pyridinoline): the crosslink density increases with maturation.

14.2.3 Composition of collagen

Collagen is the most abundant protein, representing around 25% of proteins in the human body. There are more than twenty types of collagen in vertebrates which are classified into three super families. Some types form cylindrical fibrils (among them types I and II), others form networks, fibril surfaces and transmembrane proteins.

The tissues where the three main types of collagen are found are listed in Table 14.2.2. Adult articular cartilage, human or bovine, and the vitreous humor of the eye[14.2] contain predominantly hyaline collagen of type II (approximately 96% in mass). Fibrocartilage of the meniscus involves collagen of types I and II. Skin, bones, tendons and cornea contain primarily collagen of type I. The inner part of intervertebral discs, called nucleus pulposus, contains collagen of type II, while the outer part, called annulus fibrosus, involves collagen of type I. Blood vessels and skin contain collagen of types I and III. Actually, the inner layer of arteries (intima) changes with age from collagen of type IV to collagen of type III while the outer layer contains collagen of type I. In fact, while collagen types I and II are the most widespread, the presence of other types even in minor amount is important to ensure the fibrillar structure and packing. Collagen of articular cartilages and tendons establishes strong links with proteoglycans.

Table 14.2.2: The main collagen types in some tissues.

Type I	Skin, blood vessel, annulus fibrosus, bone, tendon, cornea
Type II	Nucleus pulposus, articular cartilage, vitreous humor
Type III	Blood vessel

14.2.3.1 The structure at various scales

The collagen molecule is elongated, about 1.5 nm in diameter and 300 to 400 nm in length, Fig. 14.2.5. It is formed by three chains of polypeptides[14.3] which are arranged in a dextrogyre triple helix.

The collagen molecule of type I consists of two $\alpha_1(I)$ chains and one α_2(I) chain, which contains more hydrophobic residues. Collagen types II and III consist of three identical α_1(II) chains and α_1(III) chains respectively.

Each chain bears a polypeptide sequence whose sense of rotation is levogyre. The inverse sense of rotation of the three chains and of the polypeptide sequences in each chain is presumed to oppose unpacking of the molecule through lateral contraction under axial traction, Voet and Voet [1998], p. 159. This remarkable structural arrangement may be compared with other fibrillar organizations. Hollow cylinders can be reinforced by winding consecutively in alternative directions, Rogers [1984]: there, the alternative winding takes place at a single level of the structure. As another example, ropes are built by successive layers of alternate handedness. At variance, the alternate handedness in the collagen molecule takes place at distinct structural levels (polypeptide sequence/triple helix).

The polypeptide of each chain is formed by the repeat of the sequence -Gly-X-Y, where Gly is the amino acid glycine, X is often the amino acid proline (Pro) or alanine, arginine$^+$, glutamine, while Y is the 4- or 3-hydroxyproline[14.4] (4Hyp, 3Hyp), the 5-hydroxylysine (5Hyl), arginine$^+$, or glutamine. Having the hydrogen H as a side chain, glycine is the smallest amino acid. Glycine constitutes 33% of the amino acids, proline and hydroxyproline counting for 10%. The polypeptide sequence is shifted by one unit, from one chain to the other.

For each chain, the sequence of the amino acid residues depends on the collagen type and on the tissue. Mutations may lead to severe diseases. In osteogenesis imperfecta, known as brittle bone disease, a glycine of one of the type I collagen chains is substituted by another amino acid. Ehlers-Danlos syndrome, which affects blood vessels, is due to a mutation in type III collagen.

[14.2] The vitreous humor is a gel formed by collagen (1% in weight) and hyaluronic acid (1% in weight) with a high hydration (98% of water).

[14.3] A *polypeptide* is a macromolecule composed of amino acids linked by covalent peptide bonds. A peptide bond, or amide bond, is a bond between the carboxyl group and the amino group of two amino acids. This bond is obtained by a reaction of condensation, as described in Section 20.2.1, that releases a water molecule, the oxygen coming from the carboxyl group and the two hydrogen molecules coming from the amino group,

$$\mathrm{C{=}OO^-{-}\underset{R1}{\overset{H}{C}}H{-}NH_3^+} \;+\; \mathrm{C{=}OO^-{-}\underset{R2}{\overset{H}{C}}H{-}NH_3^+} \;\rightarrow\; \mathrm{C{=}OO^-{-}\underset{R1}{\overset{H}{C}}H{-}NH{-}C{=}O{-}\underset{R2}{\overset{H}{C}}H{-}NH_3^+} \;+\; H_2O\,. \qquad (14.2.1)$$

A *protein* is a macromolecule of molar mass larger than 5000 g containing one or several polypeptide chain(s).

[14.4] Hydroxyproline is typically used to estimate the collagen content, based on a mass ratio of 7.25-7.30, Herbage et al. [1977].

Each chain is split in four blocks, of equal size D, and one fifth block of size 0.4 D. Each D-block contains 234 amino acids, so that, together with the non structured telopeptide ends, the total number of amino acids per collagen chain is about 1050 and, therefore, 3150 per collagen molecule.

The amino acid sequence is clustered in polar and hydrophobic domains. Besides the alternate handedness of the polypeptide sequences and of the triple helix, the thermal and mechanical stability of the collagen packing is ensured by several chemical bonds. In the highly polar domains, the positively and negatively charged amino acids alternate. Hydroxylation (introduction of the hydroxyl group -OH^-) of the proline and lysine residues provides crosslinks between the chains: these crosslinks are observed in adult tissues only and they serve as a marker of maturation in cartilages and bones. Conversely, their release in blood is viewed as a testimony of metastatic bone tumor. Since these crosslinks stiffen the tissue, it is not unexpected that they are not observed in skin.

Each chain is formed by the assembly of amino acids through covalent bonds (peptide bonds). The three chains are held together by weaker bonds, as just mentioned. Heat denaturation breaks these bonds, but leaves intact peptide bonds.

14.2.3.2 Amino acids and the electrical charge of collagen

Amino acids are composed of the elements carbon, hydrogen, oxygen, nitrogen and sulfur (C H O N S). They contain at least two ionizable groups (or termini). Their structure is organized around a central carbon and consists of a basic amino terminus NH_3^+, a carboxylic acid, or acidic carboxyl terminus COO^-, a hydrogen atom, and a side chain R. The central carbon and the amino and carboxyl termini are usually referred to as α carbon, α amino and α carboxyl termini. There exist 20 side chains R corresponding to the 20 amino acids, the simpler where the chain R is reduced to hydrogen H being glycine.

Such molecules, with a positive charge and a negative charge, are called zwitterions. Their charge depends on pH :

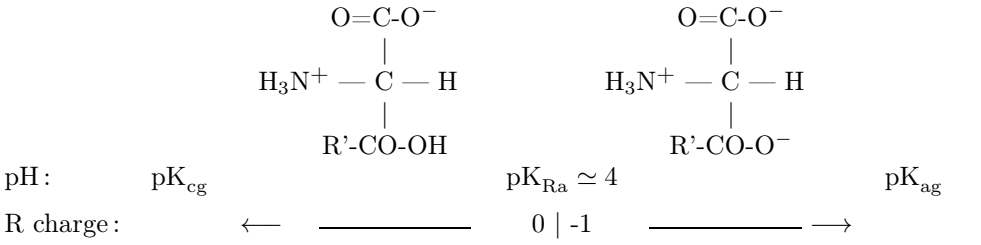
$$
\begin{array}{ccccc}
\mathrm{O{=}C\text{-}OH} & & \mathrm{O{=}C\text{-}O^-} & & \mathrm{O{=}C\text{-}O^-} \\
| & & | & & | \\
\mathrm{H_3N^+ - C - H} & & \mathrm{H_3N^+ - C - H} & & \mathrm{H_2N - C - H} \\
| & & | & & | \\
\mathrm{R} & & \mathrm{R} & & \mathrm{R} \\
\mathrm{pH:} & & \mathrm{pK_{cg} \simeq 3.2} & & \mathrm{pK_{ag} \simeq 9.2} \\
\mathrm{charge:} \quad \longleftarrow & & +1 \mid 0 & \text{———} & 0 \mid -1 \quad \longrightarrow
\end{array}
\tag{14.2.2}
$$

The carboxyl group COO^- becomes protonated at pH lower than $pK_{cg} \simeq 3.2$. The amino group NH_3^+ becomes neutral at pH higher than $pK_{ag} \simeq 9.2$. At physiological pH, the carboxyl group bears a negative charge, while the amino group bears a positive charge. Therefore, the charge due to carboxyl and amino groups is positive at low pH, zero in a wide interval of pH between 4 to 8, and negative at higher pH.

The above description sketched in (14.2.2) holds if the side chains R remain neutral. However, some side chains are ionizable. Their position in the peptide sequence may be visualized by staining by heavy metal salts. In fact, the D-blocks are divided in 12 bands, whose striation is observed upon staining, due to the reaction of anions on the positively charged amino acids. For collagen of type I, bands e1, e2, a1, a2 are in the gap region, band a3 is at gap/overlap boundary, and bands a4, b1, b2, c1, c2, c3 are in the overlap region, Meek and Quantock [2001]. Negative staining corresponds to zones of stain penetration or exclusion. Positive staining reveals the sites of charged amino acid residues.

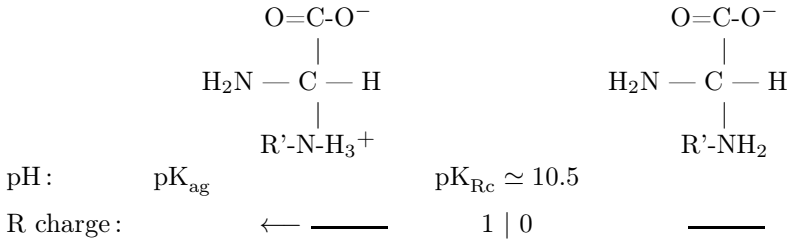
Besides, some amino acids can be considered hydrophobic: turned inside the protein, they participate to intramolecular crosslinks. The hydrophilic amino acids are exposed at the surface, Voet and Voet [1998], p. 166 et seq. The percentage of charged amino acids at the surface (termed *exposed* amino acids) is expected to be larger than within the molecule, since water is a polar substance. Still, not all exposed amino acids are charged and not all charged amino acids are at the surface.

Some of these amino acid residues, namely aspartic acid and glutamic acid, are acidic, with a pK about 4:



(14.2.3)

Others, namely lysine, hydroxylysine and hydroxyproline, are basic, with a pK about 10.5 :



(14.2.4)

and a pK of about 12.5 for arginine. At physiological pH, the side chains of aspartic and glutamic acids are negatively charged, the side chains of lysine, hydroxylysine and arginine are positively charged and the side chain of hydroxyproline is neutral.

The carboxyl and amino termini are engaged in covalent peptide bonds and their charge is therefore not available for ionic interactions. On the other hand, available data at physiological pH indicate that about 17% of the carboxyl groups of acidic residues are negatively charged and about the same percentage of amino groups of basic residues are protonated. In fact, collagen has often nearly equal numbers of acidic and basic residues and hence has almost no net charge at physiological pH. In articular cartilages which contain mainly collagen of type II, the number of positively charged residues per collagen molecule is 273 and the number of negatively charged groups is 264, Wachtel and Maroudas [1998]. These numbers fit with the estimate of 17% of charged residues: 273+264=537 versus 17%×3150 = 535.5. Only a dozen of lysine groups per molecule are not exposed to the surface of the molecule. Consequently, at physiological pH, the numbers of functionally active positive and negative charged residues are 261=273-12 and 264, respectively. On the other hand, departure from electroneutrality is more definite in other tissues due to an excess of negative charges, Table 14.2.3.

Table 14.2.3: Number of positively (+) and negatively (-) charged amino acid residues at physiological pH per (tropo-)collagen molecule (3150 residues).

Tissue	Collagen Type (% in mass)	+	-	Ref.
Articular cartilages	Type II (96%)	273	264	Wachtel and Maroudas [1998]
Rat tail tendon	Type I	264	350	Grodzinsky and Melcher [1976]
Human skin	Type I (80%) type III(15%)	268	362	Seehra and Silver [2006]
Bovine corneal stroma	Type I (75%) type V(15%)	281	394	Panjwani and Harding [1978]

Collagen molecules form fibrils, Fig. 14.2.5, bathed in (extrafibrillar) water and containing as well a significant amount of (intrafibrillar) water. The charges, namely carboxyl groups, amino groups and exposed charged residues are partitioned into a part in direct, or close, contact with the extrafibrillar water, and a part in contact with the intrafibrillar water. The charges in contact with the extrafibrillar water are considered to participate directly to the swelling and transport properties of the tissues: they interact with other mobile and fixed charges located in the extrafibrillar water. The intrafibrillar compartment can be viewed as introducing a second porosity associated with a delayed response to mechanical stimuli and it may also have a significant role in chemomechanical interactions.

14.2.3.3 Collagen development, fibrillogenesis

Cells secrete soluble substances that are fibrillated outside the cell. Single or small groups of fibrils transfer from the perinuclear region and Golgi apparatus to the extracellular space via tubules. More complex structures at

higher length scales are formed outside the cell by crosslinking that is responsible for their resistance to dissolution, Jackson [1958]. After secretion, collagen molecules and intermediates first extend in length, by linear end-to-end aggregation, and next laterally. End-to-end aggregation is possible once the N- and C-termini have been removed by proteinases. The heterogeneity of structures, marked by e.g., fibril diameter, increases during development. Extracellular linear aggregation is thought to contribute to the tensile strength of the collagen assembly. Extension of a collagen tissue is believed to be due to the viscous sliding between units in the fetal stage and, later, to the elastic deformation of the collagen molecules. The ultimate energy $\int_0^l \tau\, x\, dx = \tau\, l^2/2$ required by the relative parallel sliding of two units of length l undergoing a uniform shear stress τ is therefore proportional to the square of the length of the units. The actual length is limited by the axial strength of the units themselves. Typical tensile strengths vary from a few MPa's in the chick embryo to 50-60 MPa at a month. Measurements indicate that fibril length, rather than fibril diameter, is the key parameter in the elastic properties of collagen.

Many tissues involve heterotypic collagen, e.g., type I and type III in tendons. In a number of tissues, e.g., cartilages and tendons, strong links are established with proteoglycans during the early steps of development.

These structures are expected to depend on the mechanical conditions of the ECM. The fibers are secreted by the cells (fibroblasts) consistently with the existing state of the ECM. Girton et al. [2002] report that muscle cell morphology and fiber orientation evolve according to the stress and/or strain eigendirections. In fact, the fibroblasts are roughly aligned with the fibers and they secrete collagen molecules along their own morphology. Fibers provide guidance to adherent cells whose activity is regulated in particular by the mechanical stimuli of the fibers and ECM.

14.2.3.4 Suprafibrillar architecture of collagen units is function-dependent

The spatial organization of collagen fibrils presumably adapts to the physiological functions of the organs, Fratzl [2003]. In tendons, the fibrils are grouped in successive units of increasing diameters, which are aligned along the traction direction,

$$\underbrace{\text{molecule}}_{\phi\ 1.5\,\text{nm}} \longrightarrow \underbrace{\text{fibril}}_{\phi\ 50-500\,\text{nm}} \longrightarrow \underbrace{\text{fascicle}}_{\phi\ 50-300\,\mu\text{m}} \longrightarrow \underbrace{\text{fiber/tendon}}_{\phi\ 100-500\,\mu\text{m}} \tag{14.2.5}$$

Another terminology is used as well, namely molecule, microfibril, subfibril, fibril, fiber and tendon,

$$\underbrace{\text{molecule}}_{\phi\ 1.5\,\text{nm}} \longrightarrow \underbrace{\text{microfibril}}_{\phi\ 3.5\,\text{nm}} \longrightarrow \underbrace{\text{subfibril}}_{\phi\ 10-20\,\text{nm}} \longrightarrow \underbrace{\text{fibril}}_{\phi\ 50-500\,\text{nm}} \longrightarrow \underbrace{\text{fiber}}_{\phi\ 50-300\,\mu\text{m}} \longrightarrow \underbrace{\text{tendon}}_{\phi\ 100-500\,\mu\text{m}} \tag{14.2.6}$$

This hierarchical structure is generally thought to improve the mechanical properties, e.g., stiffnesses at low or high strains and tensile strength. Miyazaki and Hayashi [1999] report considerable increase of the stiffness from fibrils to fascicles and to tendons[14.5]. This situation is in line with that of composite materials where a matrix is reinforced by fibers. In the hierarchical sequence (14.2.5), the geometrical arrangement of the collagen units induces strong interactions and mechanical properties correlate with size.

Still, much remains to be explored, given that the strains are not identical at the different scales. The properties of the units themselves matter: Christiansen et al. [2000] suggest that lateral fusion of small subunits onto the fibrils increases the elastic modulus at low strain while longitudinal fusion increases the modulus at high strain.

At rest, tendons are observed to display waviness or crimp, with a wave-length of 10 to 100 µm, perhaps due to contraction imposed by the ground substance. They uncrimp progressively on extension.

To explain the more compliant mechanical behavior of skin with respect to tendon, Silver et al. [2001] point out to some differences in composition and geometrical arrangement:

- collagen of type III is present in skin in combination with collagen of type I while tendon contains only collagen of type I;
- the length of the collagen fibril is an order of magnitude smaller in skin;
- the D period of 67 nm in tendon is associated with a tilt angle of 7° while the D period of 65 nm in skin requires a larger tilt angle of 16°: this larger default of orientation with respect to the traction axis is expected to decrease significantly the stiffness.

Quite similar spatial organizations sometimes serve different purposes. For example, the annulus fibrosus, which forms the external part of vertebral discs and the cornea are both constituted by thin lamellae: in each of them, collagen fibrils are all aligned but the alignment directions between two successive layers is alternate. This organization in the annulus fibrosus limits the radial extension of the nucleus pulposus, the central part of the disc. In the cornea, the target to be optimized is thought to be transparency.

[14.5] Typical stiffness of fibrils: 0.4 GPa for Sasaki and Odajima [1996], 0.5-1 GPa for Fung [1993].

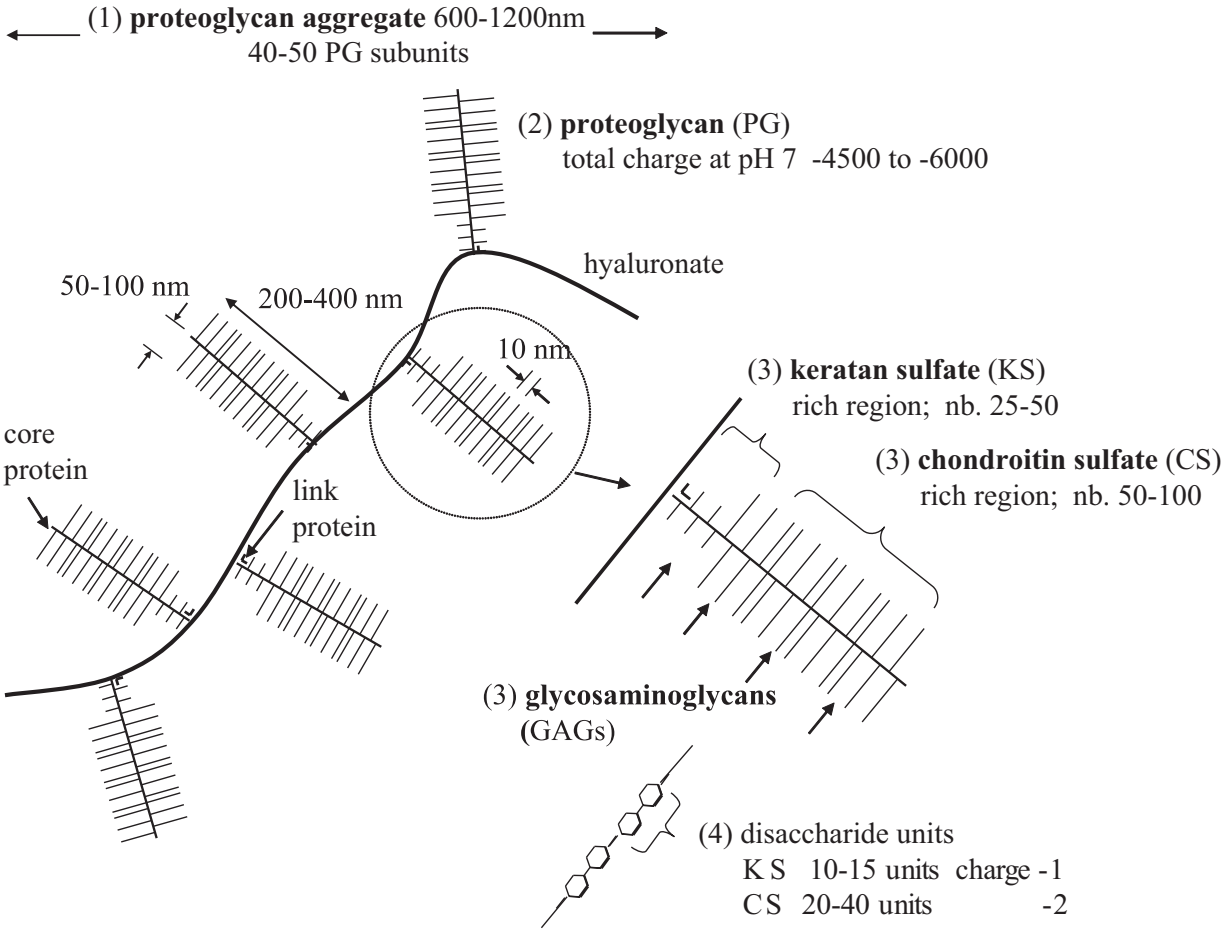


Fig. 14.2.6: Hierarchical organization of the multimolecular units composing proteoglycans. (1) an aggrecan is formed by the gathering of proteoglycans along a hyaluronate; (2) proteoglycan monomer (PG) of molar mass about 2000×10^3 gm; (3) glycosaminoglycans (GAGs), essentially chondroitin sulfates (CS), and keratan sulfates (KS); (4) disaccharide units. The negative charge of proteoglycans gives rise to electrical repulsion at various structural levels, which in turn provides compressive stiffness at the macroscopic level.

14.2.4 Composition and structure of proteoglycans

Proteoglycan aggregates are long molecular structures developing along an axis formed by a hyaluronic acid, a polysaccharide, as sketched in Fig. 14.2.6. On that axis are attached, like leaves, proteoglycan monomers structured around their own axis. Along this axis are attached in turn groups of amino acids called glycosaminoglycans (GAGs). The basic structure of GAGs is composed by disaccharide units containing a uronic acid and an aminoglycan. The uronic acid displays a negatively charged carboxyl group COO^- and the aminoglycan displays at least one sulfonic group SO_3^-. The two main types of GAGs in articular cartilages are chondroitin sulfates (CS) and keratan sulfates (KS), Table 14.2.4. Keratan sulfates are shorter than chondroitin sulfates, and contain about half of the number of disaccharide units, Muir [1978]. They possess no uronic acid (carboxyl group), so that their charge is -1, while chondroitin sulfates have a charge equal to -2. The ratio of chondroitin to keratan sulfates decreases significantly with age. On the other hand, it is much larger in osteoarthritic cartilage than in normal cartilage. The disaccharide units of chondroitin sulfates consist of glucuronic acid and N-acetylgalactosamine, while the disaccharide units of keratan sulfates feature a galactose and an N-acetylglucosamine, Fig. 14.2.7. The ratio of galactosamine over glucosamine is used to obtain the relative content of chondroitin over keratan sulfates.

Proteoglycans, which are negatively charged, are hydrated: the water molecule being an electric dipole, the hydrogen branches are attracted by the negative charges, the oxygen pointing outwards the crowned negative charges.

Wether or not proteoglycans can fix/bind other ions which would act as inhibitors of the hydration process is an issue. Na^+ and Cl^- are known not to bind to charged groups of the extracellular matrix of articular cartilages: this

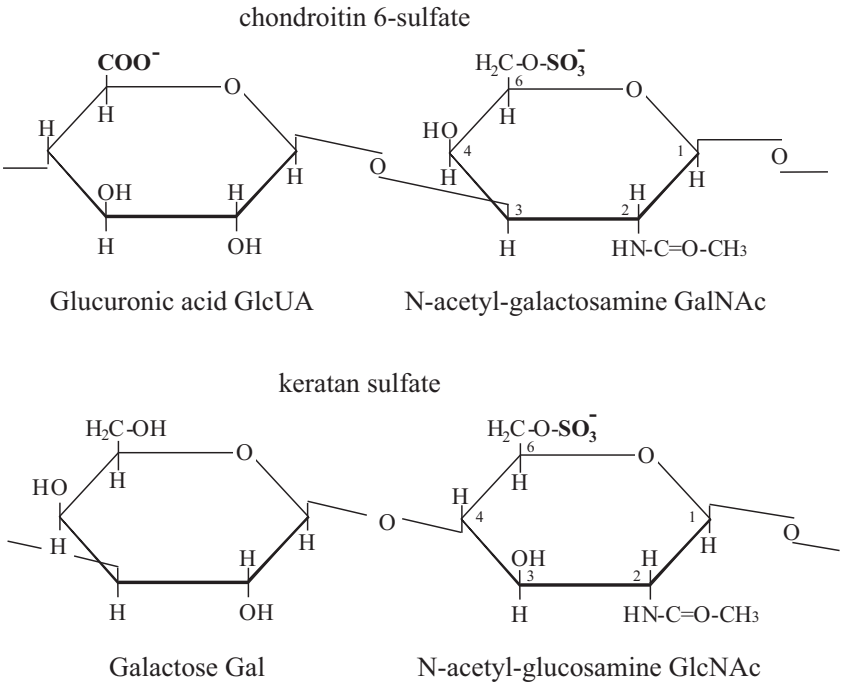

Fig. 14.2.7: The two main disaccharide units in articular cartilages are chondroitin sulfates and keratan sulfates. The fact that they are electrically charged is a key to the mechanical behavior of cartilages. Chondroitin 4-sulfate and 6-sulfate are sulfated at carbons 4 and 6, respectively.

Table 14.2.4: Average composition of proteoglycans of articular cartilage (% weight).

	GAGs		Proteins
85-92%	Chondroitin sulfate (charge -2)	80%	8-15%
	Keratan sulfate (charge -1)	20%	

property has been verified through macroscopic experiments by e.g., Frank and Grodzinsky [1987], p. 621. It does not hold in every tissue, Stevens and Lowe [1993], p. 42. Calcium cations bind reversibly onto the carboxyl groups and irreversibly onto the sulfonic groups, Chapter 17. In the corneal stroma, chloride anions bind reversibly to ligands associated with collagen molecules, Chapter 19.

In summary, sodium and chloride ions do not bind to the proteoglycans of articular cartilages: they may diffuse in the extrafibrillar fluid phase, even if a certain number of cations surround the negative charges so as to satisfy the electroneutrality condition.

14.2.5 Physical properties

The molar mass $\widehat{m}_{\text{PG}}$ of a proteoglycan monomer is approximately equal to 2×10^6 gm. The main charged glycosaminoglycans of proteoglycans are keratan sulfates (KS) and chondroitin sulfates (CS). The disaccharide units of keratan sulfates have molar mass $\widehat{m}^{\text{du}}_{\text{KS}} = 464\,\text{gm}$ and valence $\zeta_{\text{KS}} = -1$ resulting from the negatively charged sulfonic group. The disaccharide units of chondroitin sulfates have molar mass $\widehat{m}^{\text{du}}_{\text{CS}} = 513\,\text{gm}$ and valence $\zeta_{\text{CS}} = -2$, resulting from the negatively charged carboxyl and sulfonic groups, Urban et al. [1979]. Typical cartilage consists of 80% of CS and 20% of KS, Table 14.2.4. Proteoglycans are composed of GAGs and proteins, and the relative mass of all GAGs wrt to PGs is around 85% according to Sweet et al. [1977], from 85 to 90% according to Muir [1978] and around 92% according to Basser et al. [1998].

The valence ζ_{PG} of PGs can be obtained from

- the relative number of moles of disaccharide units in KS and CS namely $N^{\text{KS}}_{\text{du}} N_{\text{KS}}$ over $N^{\text{CS}}_{\text{du}} N_{\text{CS}}$,
- the relative mass $M_{\text{GAG}}/M_{\text{PG}}$ of GAGs with respect to PGs.

Indeed, the fixed charge in a reference volume of cartilage has the format,

$$\zeta_{\rm KS}\, N_{\rm KS} + \zeta_{\rm CS}\, N_{\rm CS} = \zeta_{\rm PG}\, N_{\rm PG}, \tag{14.2.7}$$

while the mass of GAGs is equal to,

$$M_{\rm GAG} = \widehat{m}^{\rm du}_{\rm KS}\, N^{\rm KS}_{\rm du}\, N_{\rm KS} + \widehat{m}^{\rm du}_{\rm CS}\, N^{\rm CS}_{\rm du}\, N_{\rm CS}\,. \tag{14.2.8}$$

Then

$$\zeta_{\rm PG} = \widehat{m}_{\rm PG}\, \frac{\zeta_{\rm KS}\, N^{\rm KS}_{\rm du}\, N_{\rm KS} + \zeta_{\rm CS}\, N^{\rm CS}_{\rm du}\, N_{\rm CS}}{\widehat{m}^{\rm du}_{\rm KS}\, N^{\rm KS}_{\rm du}\, N_{\rm KS} + \widehat{m}^{\rm du}_{\rm CS}\, N^{\rm CS}_{\rm du}\, N_{\rm CS}}\, \frac{M_{\rm GAG}}{M_{\rm PG}}\,. \tag{14.2.9}$$

The lower algebraic value is reached for a CS-proteoglycan cartilage and the upper algebraic value for a KS-proteoglycan cartilage.

With the above data, the valence results in $\zeta_{\rm PG} \sim -6080$ for the mass ratio of Sweet et al. [1977], and in $\zeta_{\rm PG} \sim -6580$ for the mass ratio of Basser et al. [1998]. Since proteoglycans are macromolecules their concentration is necessarily much smaller than those of ions, their valence is much larger and it depends strongly on pH. Electroneutrality will introduce the notion of *effective* concentration.

Table 14.2.5: Representative physical properties of constituents of articular cartilage.

Species	Molar Mass (gm)	Molar Volume cm^3	Density (gm/cm^3)	Valence * at pH=7
CS	18×10^3			-50*
KS	9×10^3			-13*
PGs	2000×10^3	1.1×10^6	1.8	- 6000 *
Collagen	285×10^3	2×10^5	1.4	$\sim$0 *
H_2O	18	18	1	0
Na^+	23	2.4-6.2		+1
Ca^{2+}	40.1			+2
Cl^-	35.5	14.9		-1

Table 14.2.5 shows the representative values of the molar mass, molar volume, density and valence of the constituents of articular cartilage. Calculating the volume of a mole of cation Na^+ and anion Cl^- using their non-hydrated radius posted in Table 13.5.1, yields $\widehat{v}_{\rm Na} = 2.37\,{\rm cm}^3$, $\widehat{v}_{\rm Cl} = 14.9\,{\rm cm}^3$, resulting in a density $\rho_{\rm s} = 3.6\,{\rm gm/cm}^3$ and molar volume $\widehat{v}_{\rm s} = 17.3\,{\rm cm}^3$ of dissolved salt NaCl. Molar volumes vary with concentration as displayed in Fig. 13.2.2 : the above values correspond to physiological concentration.

The density of collagen $\rho_{\rm c}$ is equal to $1/0.7 \sim 1.4\,{\rm gm/cm}^3$, and hence its molar volume $\widehat{v}_{\rm c}$ to $2\times10^5\,{\rm cm}^3$, Basser et al. [1998], Table I. The specific volume of GAGs and proteins that compose PGs are equal to 0.54 and $0.74\,{\rm cm}^3/{\rm gm}$ respectively, Basser et al. [1998], Table I, and therefore the specific volume of PGs is equal to $0.92\times0.54 + 0.08\times 0.74$=$0.556\,{\rm cm}^3/{\rm gm}$, i.e. $\rho_{\rm PG}$=$1.8\,{\rm gm/cm}^3$, and therefore $\widehat{v}_{\rm PG} = 1.1\times10^6\,{\rm cm}^3$.

The difference of density between constituents is used for separation through density gradient centrifugation, larger and denser particles pelleting at smaller centrifugal forces, Muir [1978].

14.2.6 Electroneutrality in the two compartment context

Most macroscopic studies consider a single condition of electroneutrality for the cartilage as a whole. At variance, Li and Katz [1976] assume electroneutrality of the intrafibrillar compartment, that is, of collagen fibrils plus the species in that compartment. Then a second electroneutrality condition applies to the extrafibrillar compartment. This way of thinking is adopted in the constitutive model of articular cartilage developed in this work. As a preliminary requirement, the electrical charges of collagen under non physiological pHs are partitioned between the intra- and extrafibrillar fluid phases. These charges are considered to be electrically and mechanically active in the phases they are in contact with.

14.2.7 Methods of measurement of the fixed charge

The tracer cation method, Maroudas and Thomas [1973], is the standard method used for the determination of the fixed charge density in articular cartilages and intervertebral discs. When a cartilage sample is equilibrated in a dilute electrolyte solution, typically a 0.015 M NaCl solution, the sole ions that remain in the cartilage are the cations that balance the negative fixed charge of PGs. Their charge is the negative of the total fixed charge of the cartilage, that is, of the PGs at neutral pH. The concentration of these neutralizing cations is obtained by transferring the sample into a radio-labelled 0.015 M NaCl solution. The latter solution is stirred for a long period under low temperature, typically 4°C, to avoid autolysis. The sample is finally dried and the radioactive isotopes Na^{22} are counted by a γ-radiation scintillation detector.

In fact, the spread of the cation tracer method is hampered by the presence of radio-active ions which is subject to regulatory approval. Therefore, other destructive and non destructive methods have been developed.

In the conductivity technique developed by Jackson et al. [2009], the FCD of the nucleus pulposus is accessed by measuring the electrical conductivity. In general, the swelling pressure generated by the fixed charge is sustained by the collagen network in tension. However, the collagen tension is small in the nucleus pulposus. Then the outward flux due to an increase of pressure applied to the sample can be related to the FCD. This property has been used by Sivan et al. [2013] in developing a needle micro-osmometer technique to measure the FCD of excised human nucleus pulposus.

While the cation tracer and the dimethyl methylene blue techniques are destructive, i.e. they require that the tissue should be sacrificed, the micro-osmometer technique might possibly be applied *in vivo*. Magnetic resonance imaging (MRI) has also been used to assess the fixed charge of intervertebral discs and articular cartilages but with moderate success. Key issues with *in vivo* techniques such as MRI, Nuclear Magnetic Resonance imaging, or micro-computed tomography, are the availability and cost of the equipment.

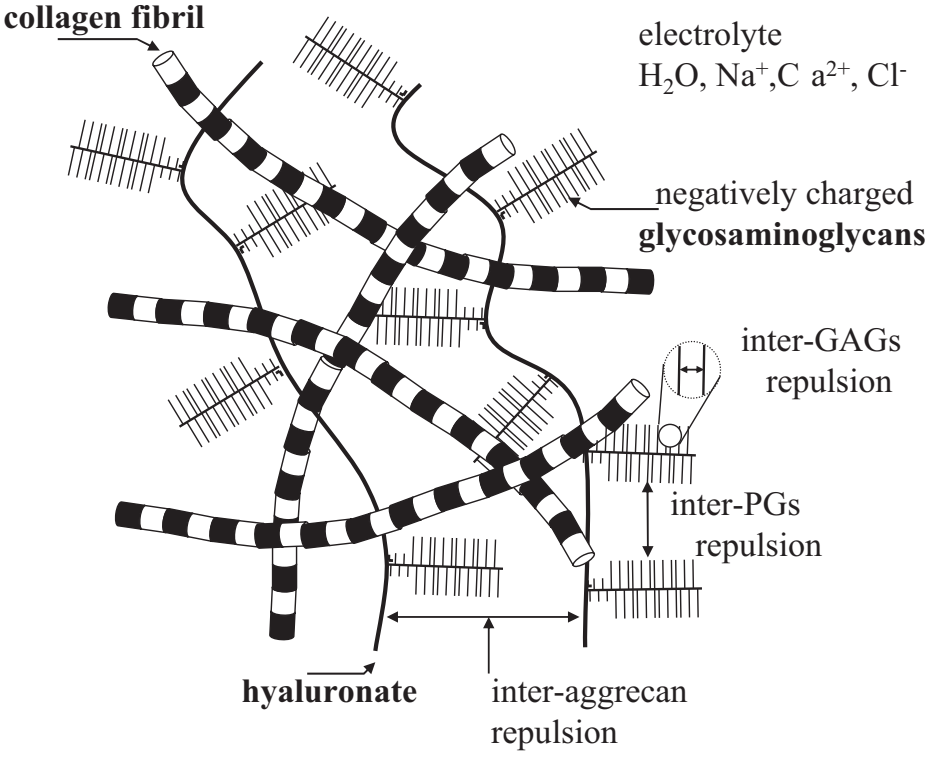

Fig. 14.2.8: Main components of articular cartilages, adapted from Loret and Simões [2004] :
- collagen fibers resist external tensile loads and chemical pressure;
- negatively charged proteoglycans (PGs) provide compressive stiffness;
- these proteins are bathed in an electrolytic solution, consisting of sodium chloride NaCl and calcium chloride $CaCl_2$ dissolved in water.

14.2.8 Mechanical properties

Articular cartilage undergoes repetitive high stresses ranging from 3 to 18 MPa as many as 1 million times a year.

As indicated by Figs. 14.2.3 and 14.2.4, the collagen content increases and the fibers become more and more aligned with the articular surface from the cancellous bone to the articular surface. Close to the bone, the fibers are almost orthogonal to the separating surface. The water content decreases from the surface to be minimal at the subchondral bone. Therefore, as a consequence of this heterogeneous composition, the mechanical properties of articular cartilage vary from point to point and, mainly in the deep and superficial zones, display anisotropy.

Collagen fibers endow cartilage with high *tensile* properties in the fiber directions, Fig. 14.2.8. Tensile stiffness may be 5-10 times higher than compressive stiffness. This difference of mechanical response in tension and compression endows the tissue with a conewise constitutive elasticity. This concept and the concept of anisotropy are, at least a priori, quite distinct.

On the other hand, the *compressive* properties are provided by the proteoglycans who resist compression because GAGs repel each other due to their negative charges. The presence of cations Na^+ *shields* the negative charges of the PGs and the mutual repulsive forces decrease with increasing sodium concentration, Section 13.9. Shielding implies decreasing macroscopic compressive and tensile moduli when the salt content increases, Eisenberg and Grodzinsky [1985], Akizuki et al. [1986][1987]. Correlatively, at higher salt content, a smaller confinement is necessary to expel water, as shown by Fig. 10 in Maroudas [1975] sketched in Fig. 18.5.1.

14.2.9 Typical laboratory experiments

Typical chemomechanical experiments are performed on specimens taken from post mortem or injured bodies[14.6]. Maroudas [1975] uses full-depth plugs of the hip, of diameter $2\,L$ about 6 mm. The hydraulic permeability $k_{\rm H}$ decreases from 5 to about $1 \times 10^{-15}\,\mathrm{m^2/Pa/s}$ as the fixed charge density increases from 0.1 to 0.25 M, her Fig. 7. Adopting the drained confined compression modulus $H = 1$ MPa of Armstrong et al. [1984] results in a diffusivity $D_{\rm H} = H\,k_{\rm H}$ from 1 to $5 \times 10^{-9}\,\mathrm{m^2/s}$. The consolidation time $L^2/D_{\rm H}$ ranges from 30 mn to 2 1/2 hours, in agreement with the experimental data shown in her Fig. 10.

To minimize the consolidation time, current practice is to slice thin strips parallel to the cartilage layer, of the order of 500 µm. Another motivation to test thin strips is to avoid the heterogeneous deformations (curling) due to the depth-dependent composition of the cartilage layer.

14.2.10 Cell density and spatial organization

Cell density is measured in cell number per wet weight or in cell number per tissue volume. It is estimated via the mass of DNA with a conversion factor of 7.7 pg per cell, Kim et al. [1988]. The order of magnitude of DNA per wet weight is 1 mg/g, Williamson et al. [2003], so that the order of magnitude of the cell density is 100×10^6 cells per gram of wet weight, or 120×10^6 cells per ml of tissue.

For immature articular cartilage, the chondrocyte diameter is typically equal to 10 µm and the cell density 200×10^6 cells per ml of tissue, Wong et al. [1997], so that the volume fraction of the cells is significant, namely 0.12, and it can influence, actually weaken, the mechanical properties of the tissue since the typical modulus of cells is three orders of magnitude smaller than the modulus of the extracellular matrix. The size of the chondrocytes correlates inversely with the cell density, increasing with age. The range of variation is moderate, the diameter being multiplied at maximum by 1.5, Stockwell [1979].

The size of chondrocytes is generally reported to be larger in the middle zone of the cartilage layer, although this observation might be an artefact due to the fact that the chondrocytes loose their spherical shape to become flattened in the lower zone and spindle-shaped near the upper zone.

The earlier the tissue is analyzed the higher the cell density, e.g., 450×10^6 cells/ml in the 2nd trimester of gestation against 290×10^6 cells/ml in the 3rd trimester for the upper zone of bovine distal articular cartilage, Jadin et al. [2007]. Collected data by Stockwell [1979] indicate that the cell density in human femoral condyle decreases from 110×10^6 cells/ml at birth to 25×10^6 cells/ml at year 10 to 15×10^6 cells/ml at year 25.

The cell density decreases with depth in fetal and calf cartilage from 180×10^6 cells/ml in surface to 80×10^6 cells/ml below a depth of 0.5 mm, Klein et al. [2007]. The decrease with depth is stronger according to Stock-

[14.6] Usually specimens after excision are kept frozen at -20°C and, before handling, they are soaked in physiological saline. This freezing and thawing protocol has been shown to preserve the mechanical properties of tissues.

well [1979], the cell density varying practically inversely with the distance from the synovial joint. In any case, these trends, namely decrease of the cell density from fetal to adult and from the surface to the depth, are confirmed by a number of studies. The decrease of cell density with depth is to be traced to the facts that the source of nutrients is the synovial fluid and that the mode of transport of these nutrients is passive diffusion or convection by the fluid for large molecules. Still, the subchondral bone marrow has also been suggested to act as a nutrient source during maturation. Maroudas [1968] [1975] provides the diffusion coefficients of some ions and macromolecules of interest to articular cartilages. The diffusion of large molecules is known to be slow, as stressed in Section 15.5.

The spatial disposition of cells varies across the depth of the cartilage layer. Cells of mature cartilage align parallel to the synovial joint in the upper zone, and form vertical columns in the deep zone, while the organization in fetal and calf cartilages is more isotropic, Jadin et al. [2007]. The decrease in cell density during growth is thought to deduce mainly from the production of extracellular matrix, but cell death is also suggested. Still, the latter authors report that the distance between next-neighbors does not change with age, which indicates that the spatial reorganization is three-dimensional.

14.2.11 Depth heterogeneities, split-lines and anisotropy

When a whole cartilage layer is bathed in an electrolyte of ionic strength lower than physiological, it deforms non uniformly and undergoes curling, Setton et al. [1998]. The upper zone resists swelling more efficiently than the middle and lower zones. Indeed, close to the surface, collagen fibrils are oriented along the split-lines as indicated by histological analyses. The directional distribution of collagen fibrils is approximately random in the central zone, while the fibrils anchor perpendicularly to the subchondral bone in the lower zone.

A collagen fiber endows tissues with tensile resistance along its direction. When a small circular hole is punched in a collagenous tissue, its shape changes to elliptical, with the principal axis of the ellipse along the direction of larger tension: Fig. 7 of Silver and Bradica [2002] displays the split-lines in a femoral articular cartilage. These lines may be interpreted as orthotropy directions of the elastic properties: the issue is addressed in Section 5.4.

14.2.12 Natural repair and transport of nutrients

Due to the avascular nature of cartilage, renewal of the PGs in adult animals is very slow, 2-5 years for humans. It is even slower for collagen, typically a lifespan for dogs, Maroudas [1975], DiMicco and Sah [2003].

Repair can take place only for deep lesions that affect the subchondral bone, Jackson et al. [2001]. Then, there is the possibility for the bone marrow cells to migrate to the place occupied by the damaged cartilage and proliferate. Such a repair situation may be natural or resulting from operative treatments. However, the produced collagen is principally fibrous of type I, its mechanical and wear characteristics are inferior to collagen of type II and it deteriorates over time.

Transport of nutrients inside the cartilage takes place by diffusion for small molecules. For large molecules whose diffusivity is low, the "pumping" action due to Darcy's law is thought to be the main engine responsible for their transport.

14.2.13 *In vitro* engineered cartilage

Tissue-engineered cartilage has been able to mimic the biochemical appearance of hyaline cartilage but the mechanical properties of the substitutes are inferior. The idea of triggering mechanically the genesis of vessels (angiogenesis) and activity of the cells (chondrocytes) has been around for some time. It is a fact that young animals and humans produce cartilage while fully active. By contrast, it has been observed that prolongated rest was detrimental to the genesis of cartilage and other tissues. Mechanical loading of chondrocyte-seeded agarose gels (scaffolds) is shown to enhance the content of sulfated GAGs and hydroxyproline as well as the compressive modulus, Mauck et al. [2000]. To speed up the period required to produce mechanically improved *in vitro* cartilage, *bioreactors* have been designed in correlation with cyclic loading. The increase of compressive aggregate modulus reported with respect to free swelling agarose and alginate cultured cartilage is up to fourfold. Mauck et al. [2000] however observed that the positive effect of mechanical loading stops for chondrocyte-seeded cartilage cultured over 28 days. Progress is still needed as the aggregate modulus at day 28 has decreased to about one-fourth of the value of natural cartilage.

14.2.14 Interspecies, age and spatial heterogeneity

The magnitude of the representative moduli does not vary much between species as shown in Athanasiou et al. [1991] where a comparison between bovine, human, dog, monkey and rabbit cartilages is presented[14.7]. On the other hand, there are strong differences depending on

- the age of the subject;
- the function and on the location of the cartilage : Chen and Sah [2001] report moduli of aged human femoral head an order of magnitude larger than the ones of aged femoral condyle;
- the location of the sample tissue and on its depth: Akizuki et al. [1986] report tensile moduli from 1 to 15 MPa : moduli from the upper layer and from the low weight bearing zones are higher.

14.3 Pathologies, osteoarthritis, rheumatoid arthritis

Osteoarthritis (OA) is the main pathology that affects articular cartilages, Fig. 14.3.1. In the United States, OA affects 5% of the population and 70% of the population aged over 65, and costs $8 billion annually.

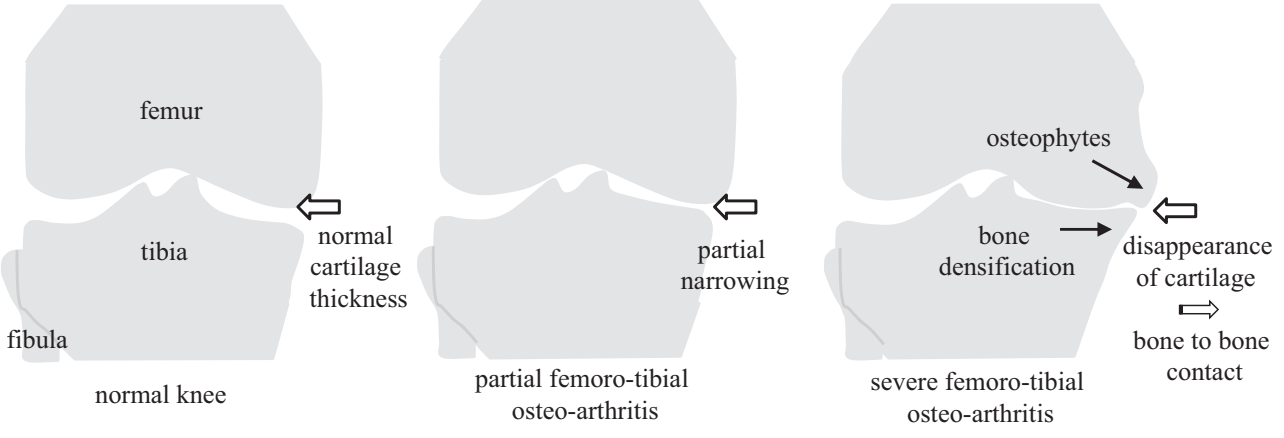

Fig. 14.3.1: Sketches of a normal knee, of a partial internal femoro-tibial osteoarthritis (gonarthrosis) and of a severe pathology. Degeneration of the cartilage layer gives rise to partial contact between femur and tibia, yielding edema and aching. Complete contact leads to a reaction of the bones, in the form of osteophytes resulting in severe pain.

Osteoarthritic cartilage has decreased tensile and compressive stiffness, increased tissue hydration and permeability. The elastic Young's modulus for normal cartilage varies from around 4 MPa in the interior to 8 MPa at the surface of the cartilage layer. These values fall to less than 1 MPa and 1.5 MPa for cartilage undergoing osteoarthritis, Table 14.3.6. Swelling due to proteoglycans is no longer limited by the confinement of collagen which, damaged, loses stiffness. OA is not linked to degradation of the PGs themselves. Since the water content is larger, the density of PGs is smaller and therefore the overall stiffness of the cartilage decreases.

Table 14.3.6: Orders of magnitude of tensile elastic moduli (MPa).

Zone	Normal Cartilage	Osteoarthritic Cartilage
Surface	8	1.5-2
Depth	4	1

One possible cause of OA is traced to the disruption of the crosslinks between collagen fibers. Osteoarthritis is correlated with age because the chondrocytes lose their ability to replace the extracellular matrix (ECM). Martin and Buckwalter [2002] find that senescence of chondrocytes is marked by an increase of β-galactosidase and a decrease in mitotic activity. Therefore, transplantation of chondrocytes in elderly people, to be successful, should also stimulate in place chondrocytes.

[14.7] Isolated moduli should be considered with care. First, it should be made clear whether they are tangent or secant moduli. Besides, the type of experiment (confined compression, traction, etc.) and the strain at which they hold should be known.

Williams et al. [2003] consider that early OA is marked by an increased activity of degradative enzymes and enhanced synthesis of ECM. Clinical treatment of OA includes the use of nonsteroidal anti-inflammatory drugs (NSAIDs): they have unfortunately secondary effects. One of these NSAIDs is the high molar mass hyaluronan, which is present in the synovial fluid, see Section 20.3.3 for more details.

Fernandes et al. [2002] seem to imply that osteoarthritis is not due to a self-degradation of cartilage components, but to proteolytic enzymes[14.8]. These enzymes are generated by the chondrocytes themselves or diffuse into cartilage from an inflamed synovial liquid. Cytokines, interleukin 1 (IL-1) and tumor necrosis factor α (TNF-α) stimulate metalloproteinases gene expression and inhibit the metabolic pathways that generate the receptor antagonists of IL-1 and TNF-α. They suggest that the excess of receptors of IL-1 and TNF-α and lack of receptors of their antagonists may originate overproduction of nitric oxide (NO) in OA tissues. According to Jouzeau et al. [2002], NO mediates most effects of IL-1. Imbalance between pro-inflammatory cytokines such as IL-1 and regulatory or inhibitory systems such as receptors of IL-1 antagonist leads to lesions in cartilage, namely both rheumatoid arthritis (inflammation) and osteoarthritis (disruption of collagen, inhibition of the production of certain components of ECM). Lahiji et al. [2002] mention that the β_1-integrin is associated with the severity of osteoarthritis. A natural target of therapy is thus to increase the levels of antagonists to proteolytic enzymes and of their receptors either by gene therapy or injection.

Electrophysiology of chondrocytes is seldom mentioned but nevertheless interesting. Mechanical stimulation of normal cartilage at 0.33 Hz is reported to induce a membrane hyperpolarization, with secondary activation of Ca^{2+}-activated K-channels, while it produces depolarization in OA cartilage, Salter et al. [2002].

Supra-physiological mechanical loads are also advocated to trigger osteoarthritis. Indeed, clinical and animal studies show that meniscectomy is often followed by osteoarthritic degeneration. W. Wilson et al. [2003] performed an axisymmetric finite element analysis of the knee joint, including part of the subchondral bone, using a biphasic behavior, either isotropic or transversely isotropic. The hydraulic conductivity is assumed to be strain dependent as in (16.4.2). They find that menisectomy increases the stress levels and shear stresses in the articular cartilage. It is in keeping with the role of meniscus which restraints the radial expansion of the cartilage, being itself a transversely isotropic material with a higher stiffness in the circumferential direction. The increase in stress level may lead to damage of either the cartilage or the subchondral bone and finally trigger osteoarthritis. This simulation should however be seen more as a suggestion than as a proof.

Gene therapy is advocated as a promising tool to treat osteoarthritis. Gene therapy is the process by which a protein is produced from a cell whose DNA has been modified. Classical clinical therapy tries to ensure a sufficiently high level of insulin-like growth factor 1 (IGF-I) which is known to improve the metabolism. However the longevity of IGF-I is limited. Gene expression aims at alleviating this problem, Nixon et al. [2000], Grande and Nixon [2000]. One issue concerns the cells to be modified: should they be autologous chondrocytes or chondroprogenitor stem cells ? Another issue concerns the genes to be inserted. The idea is to deliver a therapeutic gene to the cells that would inhibit the production, or the action, of inflammatory cells. For example, stimulation of the level of IL-1 receptor antagonists (IL-1Ra) would result in more IL-1 to be bound to these receptors and prevent them from acting on chondrocytes. To transfer the genes to the cells, the vectors used include recombinant retro-viruses and adenoviruses : Frenkel and di Cesare [1999] provide a list of references.

14.4 A brief review of modeling aspects

14.4.1 Intrafibrillar (IF) and extrafibrillar (EF) compartments

In a series of papers, Maroudas and co-workers [1975]-[1991] have argued that the partition of water in intrafibrillar (IF) and extrafibrillar compartments (EF) has mechanical significance. The intrafibrillar compartment is defined as the volume inside the collagen fibrils or, more exactly, between collagen molecules. Proteoglycans belong to the extrafibrillar compartment. At physiological pH, the slightly positive charge of collagen attracts anions while cations are repelled somehow but they are still present in the intrafibrillar space, possibly to ensure its electroneutrality, Li and Katz [1976]. The presence of chemicals within the intrafibrillar compartment is constrained by steric considerations: the distance between collagen molecules being about 5 Å, Fig. 14.4.1, water molecules and chloride anions

[14.8] For a biochemical description of proteolysis, see APB [1999], pp. 170, 278. Some enzymes degrade proteins into independent amino acids. They are proteases and peptidases. They cut bonds between molecules. Among proteases are serine-proteases 3.4.21.n, metallo-proteases 3.4.24.n, etc. Among serine-proteases are trypsin, chymotrypsin and elastase used to digest components of cartilage.

Cl^- of size 3.6 Å, sodium cations Na^+ and calcium cations Ca^{2+} of size around 2 Å can penetrate the intrafibrillar compartment while large molecules like sucrose or PGs of size comparable to that of the collagen molecule can not. Experimentally, the partition between intrafibrillar and extrafibrillar waters is performed by injecting serum albumin whose size (hydrodynamic radius 35 Å) prevents them to enter the intrafibrillar compartment.

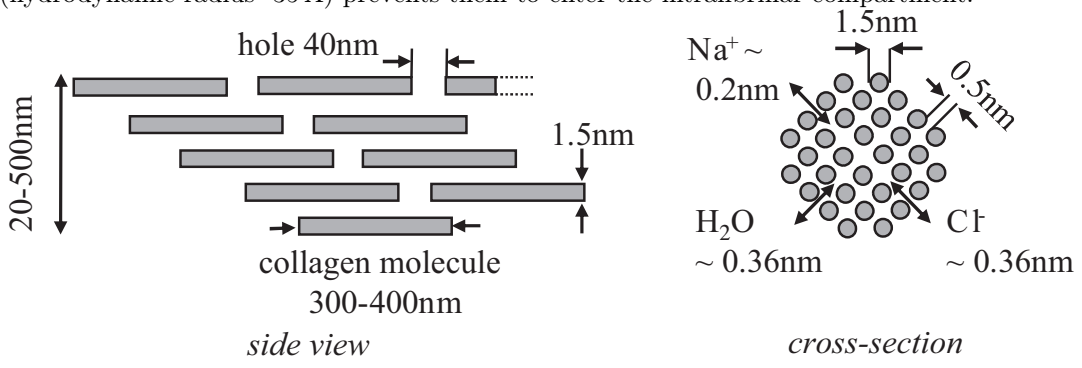

Fig. 14.4.1: Side view and cross-section of a collagen fibril. Collagen fibrils play the role of a semipermeable membrane that allows the transfer, between the intra- and extrafibrillar spaces, of small molecules like water and metallic ions. Macromolecules like proteoglycans are not admitted in the intrafibrillar space. Adapted from Torzilli [1985]. Redrawn with permission from Loret and Simões [2004].

For unloaded cartilage under physiological composition, intrafibrillar water represents up to 25% of total water, the extrafibrillar water furnishing the complement. The latter can be moved by mechanical loading and osmosis with water external to the cartilage (synovial fluid). Since the intrafibrillar water is in contact with the extrafibrillar compartment only, its status with respect to mechanical and chemical loadings is not the same as that of extrafibrillar water. The IF water can be moved by change of chemical composition of the EF compartment. Now a mechanical loading changes the relative chemical composition of the tissue (e.g., water being expelled, the concentration of proteoglycans increases) and therefore indirectly induces a transfer of water from the intrafibrillar compartment. Data are provided by Maroudas et al. [1991] for PG-depleted cartilage. She shows that increase of the concentration in the extrafibrillar compartment depletes the water from the intrafibrillar compartment and so decreases the tension in the collagen. Ultimately, with a large applied compressive load, the fibrils may undergo compression and may buckle, Katz et al. [1986].

Intrafibrillar water and/or hydrated PGs induce collagen fibers in tension, Fig. 14.4.2 : a mechanical model would consist of two parallel systems, collagen and PGs, that resist the applied mechanical load. The tension in the collagen branch is the tensile load carried by the collagen fibers, while the branch of the PGs is compressive, Maroudas et al. [1991], Lai et al. [1991]. The sum of these two components opposes the applied mechanical load, Basser et al. [1998].

The osmotic stress $\boldsymbol{\sigma}_{\rm osm} = -\pi_{\rm osm}\,\mathbf{I}$ due to PGs may be seen as isotropic. It is measured in a solution of proteoglycans at a given fixed charge and therefore at a given volume fraction of water[14.9],

$$\mathrm{FCD} = \frac{|\zeta_{\rm PG}|\,N_{\rm PG}}{M_{\rm w}}\,, \tag{14.4.1}$$

where $\zeta_{\rm PG}$, varying from -6000 to -4000, is the valence of PGs. From the curve displayed in Fig. 3 of Basser et al. [1998] that provides the osmotic pressure $\pi_{\rm osm} = \pi_{\rm osm}(\mathrm{FCD})$ [unit : MPa] as a function of the fixed charge density FCD [unit : mole/kg water],

$$\pi_{\rm osm} = \pi_{\rm osm}(\mathrm{FCD}) = 0.351\,\mathrm{FCD} + 1.93\,\mathrm{FCD}^2\,, \tag{14.4.2}$$

follows the tangent modulus,

$$H_{\rm osm} = -\frac{d\pi_{\rm osm}}{d\mathrm{tr}\,\boldsymbol{\epsilon}} = -\frac{d\pi_{\rm osm}}{d(\Delta V/V_0)} = -\frac{d\pi_{\rm osm}}{d(\Delta V_{\rm w}/V_0)} = \mathrm{FCD}\,\frac{V_0}{V_{\rm w}}\,\frac{d\pi_{\rm osm}}{d\mathrm{FCD}} > 0\,. \tag{14.4.3}$$

The sign of the modulus $H_{\rm osm}$ ensures the stabilization of the osmotic effect. Indeed in Section 14.9.1, the osmotic pressure will be shown to induce tension in the collagen fibers and to lead to an increase of the volume of the tissue. This expansion tends in turn to decrease the osmotic pressure as a consequence of the positive sign of $H_{\rm osm}$ and therefore counteract the effect.

[14.9] The fixed charge density FCD is measured either in mole of PGs per mass of water or in mole of PGs per volume of water. These two definitions differ only by their units. A distinct definition to be introduced later in this chapter refers to the sole volume of the extrafibrillar fluid phase, and not to the total fluid volume.

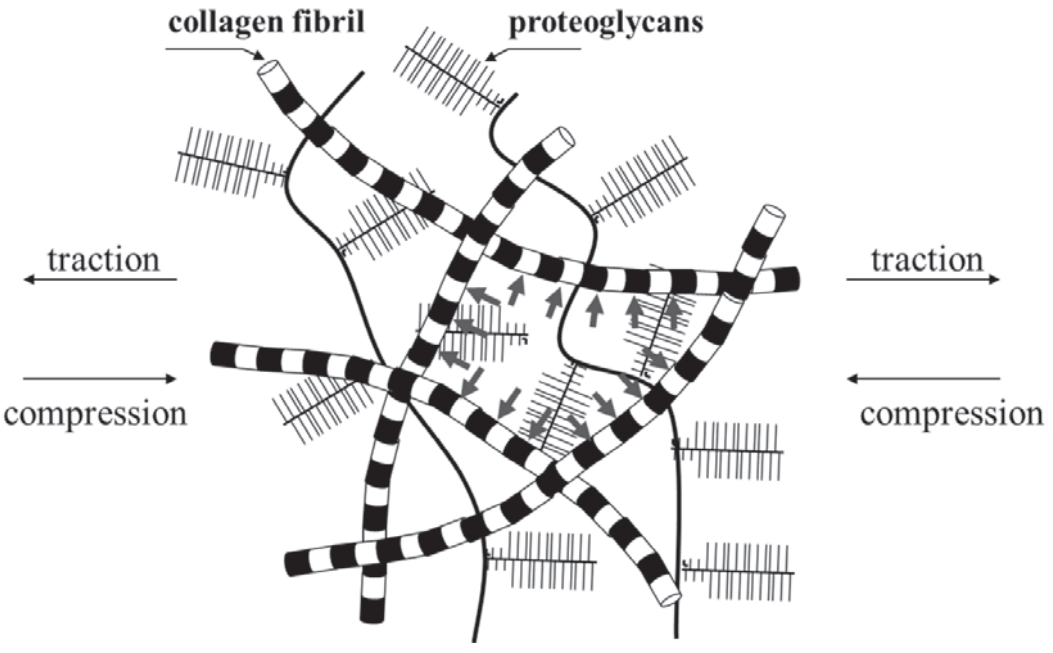

Fig. 14.4.2: The high negative charges of PGs induce repulsive forces at various structural levels. PGs provide compressive stiffness to the cartilage while collagen is put in tension by the water pressure induced by the charged PGs and external loads.

14.4.2 Tensile experiments

Myers et al. [1984] perform tensile tests on bovine articular cartilage on parallelepiped samples of thickness 200 µm bathed in an electrolyte of controlled composition. Under constant axial strain, increase of salt concentration induces a transient tension which is relaxed due to diffusion inside the specimen and perhaps to viscous properties of collagen. The final axial stress is smaller than its initial value. An interpretation of tensile experiments is proposed in the qualitative sketch 13.10.7.

In absence of axial force (isotropic free swelling), increase of salt concentration in the bath implies increased contraction, with in fact a linear dependence of the strain with respect to the salt concentration *in the bath*[14.10]. The latter effects under isotropic free swelling are in agreement with the experiments of Eisenberg and Grodzinsky [1985] and they are due to osmosis which pumps water out of the sample.

Tensile properties of cartilage are mainly due to collagen and in fact to the collagen network. Bader et al. [1981] use an enzyme, the elastase of neutrophil leucocytes, which is known to degrade the non-helical terminal peptides of cartilage collagen molecules and therefore to disrupt the crosslinks between collagen fibrils. In fact this enzyme is present in large quantity in joints affected by rheumatoid arthritis. They show that both tensile stiffness and tensile strength are considerably reduced by leucocyte elastase.

14.4.3 The triphasic model of the Columbia University group

The triphasic model of articular cartilage of Lai et al. [1991] introduces three *phases*, one for the solid that includes collagen and proteoglycans, one for the pore fluid and one for ions, resulting from the dissolution of a single neutral salt, specifically NaCl[14.11]. The chemical potential for the ionic phase is obtained by summation of the individual chemical potentials, i.e.,

$$g_{\rm s} = g_{\rm Na} + g_{\rm Cl} = \widehat{m}_{\rm s}\,\mu_{\rm s} = \widehat{m}_{\rm Na}\,\mu^{\rm ec}_{\rm Na} + \widehat{m}_{\rm Cl}\,\mu^{\rm ec}_{\rm Cl} = \widehat{m}_{\rm Na}\,\mu_{\rm Na} + \widehat{m}_{\rm Cl}\,\mu_{\rm Cl}, \tag{14.4.4}$$

[14.10] The interpretation of this observation requires some care, since the concentrations in the tissue and in the bath are different due to the membrane effect, as explained in Section 14.6.2.

[14.11] The terminology varies with authors. The notion of *phase* used by Lai et al. [1991] and followers and the one defined later in this chapter and used throughout this work are definitely distinct.

where the g's and the μ's are the *mole based* and *mass based* electrochemical potentials respectively, and the $\widehat{m}_k$ the molar masses of the cation for k=Na^+, of the anion for k=Cl^- and of the salt NaCl for $k = s$. The electrochemical potential of the ion involves three contributions, of mechanical, chemical and electrical natures,

$$g_k^{ec} = \widehat{m}_{Na}\,\mu_k = \widehat{v}_{Na}\,p_F + RT\,\mathrm{Ln}\;x_k + \zeta_k\,F\,\phi\,, \tag{14.4.5}$$

where F is Faraday's equivalent charge, ϕ is the electric potential and p_F is the pressure of the pore fluid. Hence the chemical potential of the salt,

$$g_s = \widehat{m}_s\,\mu_s = \widehat{v}_s\,p_F + RT\,\mathrm{Ln}\;x_{Na}\,x_{Cl}\,, \tag{14.4.6}$$

with $\rho_s = \widehat{m}_s/\widehat{v}_s$ the mass density of NaCl, $\widehat{v}_s = \widehat{v}_{Na} + \widehat{v}_{Cl}$ its molar volume and $\widehat{m}_s = \widehat{m}_{Na} + \widehat{m}_{Cl}$ its molar mass.

The chemical potential of water has also the standard form of chemical physics, namely

$$g_w = \widehat{m}_w\,\mu_w = \widehat{v}_w\,p_F + RT\,\mathrm{Ln}\;x_w\,. \tag{14.4.7}$$

The molar fractions involved in the definition of the chemical potentials above are defined with respect to the electrolyte, that involves the fluid and ionic phases,

$$x_k = \frac{N_k}{N_w + N_{Na} + N_{Cl}}, \quad k = w, Na, Cl\,, \tag{14.4.8}$$

where the N's are the mole numbers.

The concentration [unit: mole/l] is the number of moles per unit volume of electrolyte (or per unit volume of fluid only since both are close at low ionic concentration, $V_F = N_w\,\widehat{v}_w + N_s\,\widehat{v}_s \simeq N_w\,\widehat{v}_w$, i.e.

$$c_k = \frac{N_k}{V_F}, \quad k = w, Na, Cl\,. \tag{14.4.9}$$

The *effective* concentration e_{PG}, of proteoglycans

$$e_{PG} = \frac{\text{algebraic nb. of moles of charges on proteoglycans}}{\text{volume of electrolyte}}\,, \tag{14.4.10}$$

plays a key role in the chemomechanical coupling. The fixed charge density FCD is equal to the absolute value of the effective concentration measured in mole of PGs per volume of water. The fluid phase, or electrolyte, is considered to include both intrafibrillar and extrafibrillar water, because this partition is not recognized by the Columbia group. If it was accounted for, only the extrafibrillar water should enter here since the proteoglycans belong to this compartment and are absent from the intrafibrillar compartment. In other words, the molar fractions, or the concentrations, are counted with respect to the tissue water and not to extrafibrillar water.

A *single* electroneutrality condition is enforced for the whole porous medium,

$$c_{Cl} = c_{Na} + e_{PG}\,. \tag{14.4.11}$$

For low ionic concentrations,

$$x_k \simeq \frac{c_k}{c_w}, \quad k = \mathrm{Na},\,\mathrm{Cl}; \quad x_w \simeq 1 - \frac{c_{Cl}}{c_w} - \frac{c_{Na}}{c_w}\,, \tag{14.4.12}$$

and, expanded to first order, the chemical potential of water is affine with respect to the ionic concentrations,

$$g_w = \widehat{m}_w\,\mu_w \simeq \widehat{v}_w\,p_F - RT\,\big(\frac{c_{Na}}{c_w} + \frac{c_{Cl}}{c_w}\big)\,, \tag{14.4.13}$$

while the chemical potential of salt involves the product of the ionic concentrations,

$$g_s = \widehat{m}_s\,\mu_s \simeq \widehat{v}_s\,p_F + RT\,\mathrm{Ln}\;\frac{c_{Na}}{c_w}\,\frac{c_{Cl}}{c_w}\,. \tag{14.4.14}$$

Assuming an incompressible solid matrix, the fixed charged density is modified by the volume change of the porous medium, as detailed in Exercise 14.3,

$$\frac{V_F^0}{V_F} = \frac{n_0^F}{n_0^F + \det\mathbf{F} - 1} \simeq 1 - \frac{\mathrm{tr}\,\boldsymbol{\epsilon}}{n_0^F}\,, \tag{14.4.15}$$

with n^F the volume fraction of the fluid, $\mathbf{F}$ the gradient of deformation and $\boldsymbol{\epsilon}$ the infinitesimal strain of the solid skeleton (or porous medium), and the index 0 denoting the reference configuration. As expected, the concentrations of all species and fixed charge decrease if the porous medium expands by pumping water in, and increase if the porous medium contracts by expelling water,

$$c_k = \frac{N_k}{V_{F0}}\frac{V_F^0}{V_F}, \quad \frac{c_{PG}}{c_{PG}^0} = \frac{e_{PG}}{e_{PG}^0} = \frac{V_F^0}{V_F}\,. \tag{14.4.16}$$

In fact, the model exposed in Lai et al. [1991] differs slightly with respect to the above exposition: 1. The fluid pressure is neglected in the electrochemical potentials of ions; 2. the chemical contribution to the latter is introduced via concentrations, rather than molar fractions; 3. these concentrations come into picture multiplied by chemical activities. The latter are not quantified and actually the ratios of their values in the bath and in the cartilage are set equal to one in applications.

14.4.4 The quadriphasic model of the Eindhoven University group

Here, cations and all anions are gathered in two separate phases, Frijns et al. [1997]. This approach seems more appropriate from an electrokinetic point of view than the triphasic model. Nevertheless, it treats all ionic species of each of the two phases on the same foothold. The partition between intra- and extrafibrillar waters is not envisaged either. A single electroneutrality condition is applied to the whole porous medium.

Once again, the notion of phase is not mechanically nor kinematically motivated in these models but rather serves to gather species based on their nature.

14.4.5 The experiments of the MIT group

Compression tests: shielding effects and chemical stress, Eisenberg and Grodzinsky [1985]

Eisenberg and Grodzinsky [1985] perform experiments on bovine articular cartilage and corneal stroma of 1- to 2-week-old calves. Cartilage samples are cylindrical, 9 mm in diameter and about 600 µm in thickness. Samples of corneal stroma have similar size, 6.4 mm in diameter and 750 to 850 µm in thickness. The epithelium and endothelium have been removed by scraping the corneal surfaces with a scalpel. The specimens are put in contact with a bath of controlled chemical composition. Mechanical loading is performed stepwise and, after each load increment, time to reach equilibrium is ensured: equilibrium requires about 15 mn for the tested specimens of articular cartilage and 60 mn for corneal stroma.

Their results highlight two effects:

- when the concentration of NaCl in the bath is increased at constant axial strain, the compressive axial stress decreases, their Fig. 5. The drop of the compressive stress is large for low NaCl concentrations, it diminishes as NaCl increases and it tends to a very small value at higher NaCl concentration: the stress decrease between 0.5 M and 1 M of NaCl is almost negligible. This effect is compatible with the chemical consolidation observed in clays, Loret et al. [2002];
- at given concentration of NaCl in the bath, the stress-strain relation is affine, their Fig. 9. The intercept with the unstrained state is viewed as a chemical stress. The stiffness (slope of the stress-strain curves) decreases with salt concentration, stabilization being reached between 0.5 M and 1 M of NaCl.

This increase of compressibility is attributed to an increased "electrical shielding" of PGs by cations. Eisenberg and Grodzinsky [1985] also note that this phenomenon has already been observed by others, e.g., Maroudas [1975], her Fig. 10. They model the stiffness and chemical stress as exponentially decaying with the concentration of NaCl in the bath.

The idea is also retained by Lai et al. [1991] who coin the additional stress *chemical expansion stress*. The latter is expressed as the product of the effective concentration of PGs times a function that decays with the bath concentration, their Eqn (82): this expression clearly displays the shielding effect due to NaCl.

At given bath concentration, the stress-strain relation is affine and approximately isotropic. Therefore, NaCl-dependent Lamé moduli are defined by Eisenberg and Grodzinsky [1985]. They also argue that this linear elasticity over a large range of compressive strains can not be explained by the action of PGs alone: the resulting strains would be isotropic, which is not verified experimentally. They explain their results by (a) either the fact that collagen tension is not completely released in confined compression, (b) or that the PGs form a gel-network that has solid-like properties and thus do not behave like in a solution.

Khalsa and Eisenberg [1997] find that the shear modulus μ of articular cartilage does not depend on bath composition. By contrast, Jin and Grodzinsky [2001] observe a dependence of the shear modulus with respect to ionic strength, their Figs. 6 and 9. These observations are not really in contradiction with the results of Eisenberg and Grodzinsky [1985] where only the apparent aggregate modulus $\lambda + 2\,\mu$ was measured.

Mechanoelectrical couplings, Frank and Grodzinsky [1987]

Frank and Grodzinsky [1987] have performed tests on adult bovine cartilage where the tissue is in chemical equilibrium with a reservoir of controlled composition. Their experiments are intended to reveal and quantify mechano-electrical and electro-mechanical couplings :

- "open circuit test": under a sinusoidal uniaxial compression, they measure the induced streaming potential, the circuit being electrically open;
- "short circuit test": the electrodes being shorted together (uniform electrical field), they measure the electrical current generated by a sinusoidal mechanical compression;
- a harmonic electric current density being applied to the specimen, they measure the generated stress.

Tension and compression, rate effects and anisotropy

As mentioned above, PGs are believed to contribute mainly to the compressive properties. Collagen has an effective role in compression as well where it is put in tension by PGs. However, tensile properties of collagen are mainly highlighted under tensile loadings. Accordingly, rate effects are expected to be revealed by tensile loadings rather than by compressive loadings, Myers et al. [1984], Huang et al. [2001], Lei and Szeri [2007].

Diffusion equations, Eisenberg and Grodzinsky [1987]

The above results are used as a basis to simulate transient loadings including pore pressure build up and dissipation. The diffusive flux of an ionic species involves the gradients of its own concentration and of the electrical potential but the effect of the pore pressure gradient is neglected, their Eqn (12). Several couplings are also neglected in the flux of water which reduces to the standard Darcy's law, their Eqn (4).

Diffusion properties: hydraulic conductivity and diffusivity

Hydraulic conductivity of articular cartilage is low, Maroudas [1975]. Effective diffusivity accounts for the tortuosity of the cartilage, that is, the longer path that ionic species have to follow with respect to diffusion in pure water. Eisenberg and Grodzinsky [1987], their Eqn (17), estimate the tortuosity factor via the Mackie-Meares expression (16.4.5). Section 16.4 provides ranges of values for the diffusion parameters.

14.4.6 Molecular and microstructural models

Nanometric models using Poisson-Boltzmann equation (13.E.6) aim at explaining the compressive behavior due to proteoglycans, Buschmann and Grodzinsky [1995]. Some features of the geometrical configuration of PGs at the nanometer scale are accounted for but adjustable parameters have to be introduced as well. Collagen plays no role in these models.

On the other hand, collagen is viewed to play an essential role in some microstructural models. Soulhat et al. [1999] consider cartilage as a composite material consisting of a matrix reinforced by fibrils. Bursac et al. [2000] idealize cartilage through a network of cables under pre-tension, representing collagen submitted to osmotic pressure. Under small external compression, the cables remain in tension, resulting in a high stiffness. As compression increases, the forces in the cables become compressive, the cables buckle and the overall stiffness drops significantly.

14.5 Interpretation of laboratory experiments

14.5.1 Difficulties of methodology

Most if not all mechanical models of articular cartilage present simultaneously elastic constitutive equations and diffusion equations. While there is nothing wrong in doing so, some confusion might arise as properties that hold at equilibrium only are not clearly delineated.

Another formal difficulty comes from the fact that derivation of constitutive equations is sometimes made in parallel with the presentation of typical experiments where a specimen of cartilage is brought in contact with a bath of known chemical composition: then the concentration of salt in the bath appears in the constitutive equations, while local constitutive equations should involve quantities defined at the point under consideration only. The issue can be resolved formally by introducing a fictitious compartment/bath, whose chemical composition is a function of that of the cartilage, Section 14.5.2. Of course, due to the presence of proteoglycans, salt concentration in cartilage is not expected to be equal to salt concentration in the bath even under equilibrium condition, Section 14.6.2. This discontinuity may easily lead to misinterpretation of experimental results and induce confusion in the identification of parameters, Section 16.3.3.2.

14.5.2 The fictitious bath: a tool for heterogeneous and transient processes

Standard formulations of chemomechanical constitutive equations consider a homogeneous piece of tissue surrounded by a bath of controlled chemical composition, pressure and electrical potential. Equilibrium is assumed between the bath and the cartilage. Some caution is required, especially concerning the use and interpretation of the associated osmotic pressure.

In fact, let us consider now a specimen of cartilage which is nonspatially uniform. One may also consider a point inside the cartilage during the transient period where the bath concentration is changed. In both cases, points

inside the specimen are not in equilibrium with the bath, either due to a transient loading or due to spatial non homogeneity. In addition, the bath might not be homogeneous, e.g., the case of a layer between two nonhomogeneous baths. In any case, the composition and properties of the bath are not constitutive: they should *not* be involved in the constitutive equations of the tissue.

Still one may use the above tissue-bath device, but with a different perspective. For that purpose, a *fictitious* bath is introduced which may vary in time and space.

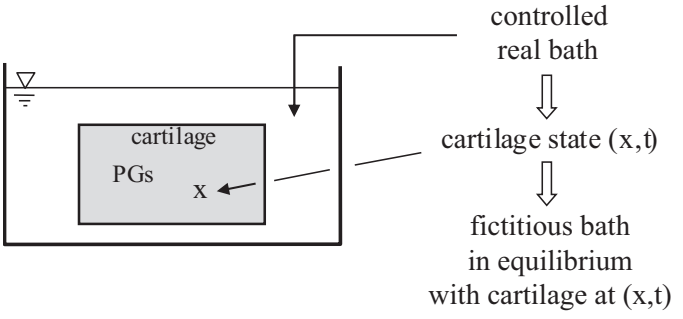

Fig. 14.5.1: The notion of a fictitious bath. Consider a cartilage specimen in contact with a bath of controlled and time varying chemical composition. Points inside the cartilage are not in instantaneous equilibrium with the bath. With each point is associated a time-varying fictitious bath. The properties of the fictitious bath are *deduced* from the properties of the extrafibrillar phase. If the specimen has spatially uniform physical properties and if equilibrium is homogeneous throughout the specimen, the local fictitious baths are identical to the real bath in contact with the specimen.

In fact, the properties of the fictitious bath (chemical composition, pressure and electrical potential) are *deduced* from the actual tissue at the point and time of interest, Fig. 14.5.1. Crucially, the fictitious bath contains the same species as the fluid phase of the cartilage, except PGs, it is electroneutral and in chemical equilibrium with the cartilage at the point and time of interest. Consider for example a single salt to be present, namely sodium chloride. Electroneutrality (one equation) and equilibrium of the electrochemical potentials (two equations) of the two ions yield the molar fractions and the electrical potential (three unknowns) in the fictitious bath in terms of the properties of the tissue. The consistency relation between molar fractions (they sum to one) yields the molar fraction of water, in terms of now known quantities. Equality of the chemical potentials of water of the cartilage and fictitious bath provides an osmotic pressure $\pi_{\rm osm}$, in terms of quantities which are functions of the thermodynamic state of the cartilage. This osmotic pressure and the pressure $p_{\rm E}$ of the tissue fluid are used to define the pressure $\tilde{p}_{\rm E}$ of the fictitious bath,

$$\tilde{p}_{\rm E} = p_{\rm E} - \pi_{\rm osm}\,. \tag{14.5.1}$$

To illustrate further the concept of a fictitious bath, let us assume that the constitutive equation is given through an effective stress format, namely

$$\boldsymbol{\sigma} + \overbrace{(p_{\rm E} + p_{\rm ch})}^{p_{\rm eff}}\,\mathbf{I} = \sum_k \boldsymbol{\sigma}^k_{\rm ch-mech}\,, \tag{14.5.2}$$

where $p_{\rm ch}$ is a term of chemical origin, and the rhs represents the apparent chemomechanical contributions of the structural components (collagen, PGs $\cdots$).

Use of this concept depends on the application:

- for example, to develop chemomechanical constitutive equations, we will consider a homogeneous specimen surrounded by a bath of known and controlled properties. The cartilage is in continuing equilibrium with the fictitious bath and with the real bath. Therefore fictitious and real baths are just one and the same in this circumstance. The above procedure still holds but is not used as such. Rather, the chemical composition and properties of the cartilage are *obtained* from those of the bath, which are controlled, e.g., now $\tilde{p}_{\rm E}$ is equal to the pressure $p_{\rm B}$ of the real bath, and

$$p_{\rm E} = \tilde{p}_{\rm E} + \pi_{\rm osm}\,. \tag{14.5.3}$$

The constitutive equations (14.5.2) may be rewritten in the form,

$$\boldsymbol{\sigma} + \tilde{p}_{\mathrm{E}}\,\mathbf{I} + (\pi_{\mathrm{osm}} + p_{\mathrm{ch}})\,\mathbf{I} = \sum_k \boldsymbol{\sigma}^k_{\mathrm{ch-mech}}\,. \tag{14.5.4}$$

- the notion of a fictitious bath is fully exploited during transient states and in the context of boundary value problems through, e.g., the finite element method. The chemical composition of the fictitious bath is deduced from that of cartilage as indicated above. The pressure p_{E} should be specified through some means, e.g., boundary conditions as for an incompressibility constraint. In other words, it is thought as a primary unknown, or at least, easily deducible from primary unknowns. Then, the pressure $\tilde{p}_{\mathrm{E}}$ is obtained as in (14.5.1). Similar comments hold for the electrical potentials. The real bath comes into picture but like in a boundary value problem and not pointwise.

  The constitutive equations (14.5.2) may be recast as,

$$\boldsymbol{\sigma} + p_{\mathrm{E}}\,\mathbf{I} + p_{\mathrm{ch}}\,\mathbf{I} = \sum_k \boldsymbol{\sigma}^k_{\mathrm{ch-mech}}, \quad p_{\mathrm{ch}} = p_{\mathrm{eff}} - \pi_{\mathrm{osm}} - \tilde{p}_{\mathrm{E}}\,. \tag{14.5.5}$$

  The standard formulation of porous media without chemical effects, namely $p_{\mathrm{ch}} = 0$, is recovered by interpreting p_{E} as the fluid pressure.

14.6 Partition of the tissue into phases

This section and the subsequent ones present a constitutive model with emphasis on chemomechanical couplings, Loret and Simões [2004] [2005]a. Transient aspects, including time dependent mass transfer and generalized diffusion, are addressed in Chapters 16 to 18.

In fact, several continuum theories have been proposed to model deformation and transport and to describe macroscopic couplings in articular cartilages, e.g., Lai et al. [1991], Gu et al. [1998], Huyghe and Janssen [1999]. However, their structure is different, as far as the intrafibrillar phase is usually not recognized. The intra/extrafibrillar split is considered in Huyghe [1999] and Huyghe et al. [2003], but only the mechanical aspects of cartilages bathed in a binary electrolyte are addressed.

14.6.1 Definition of the phases: a measure of spatial organization

The definition of the phases is mechanically motivated. A kinematical criterion on the other hand would sort species according to their velocities. Here, cartilage is viewed as a three-phase, multi-species, porous medium, Fig. 14.6.1.

The *solid phase* S contains the collagen fibers denoted by the symbol *c*. The *intrafibrillar fluid phase* I contains intrafibrillar water w, sodium ions Na^+, calcium ions Ca^{2+} and chloride ions Cl^-. The *extrafibrillar fluid phase* E contains proteoglycans, extrafibrillar water, sodium and calcium cations, and chloride anions. The sets of species of the solid, intrafibrillar and extrafibrillar phases can be defined in explicit form,

$$\mathrm{S} = \{\mathrm{c}\}, \quad \mathrm{I} = \{\mathrm{w},\,\mathrm{Na},\,\mathrm{Ca},\,\mathrm{Cl}\}, \quad \mathrm{E} = \{\mathrm{w},\mathrm{PG},\,\mathrm{Na},\,\mathrm{Ca},\,\mathrm{Cl}\}\,. \tag{14.6.1}$$

Exchanges of water and ions occur between the fluid phases but only the extrafibrillar phase communicates with the surroundings.

Due to the presence of proteoglycans a minimum number of cations is required to ensure electroneutrality of the extrafibrillar phase. Therefore, mobile cations are endowed with a velocity independent of that of their non mobile counterparts which, like the proteoglycans, move with the velocity of the solid phase. Thus cations in the extrafibrillar space are partitioned into a mobile mo part and a non mobile nm part. The set E_{mo} of extrafibrillar mobile species contains all extrafibrillar species but proteoglycans. Non mobile ions sodium do not bind to PGs. If this distinction between mobile and non mobile ions is not adopted, all ions are able to diffuse through the extrafibrillar fluid phase. The two options are left open in the model of generalized diffusion developed in Chapter 16. Unlike sodium ions, calcium ions may bind to proteoglycans. The issue is addressed in relation with the effects of pH in Chapter 17.

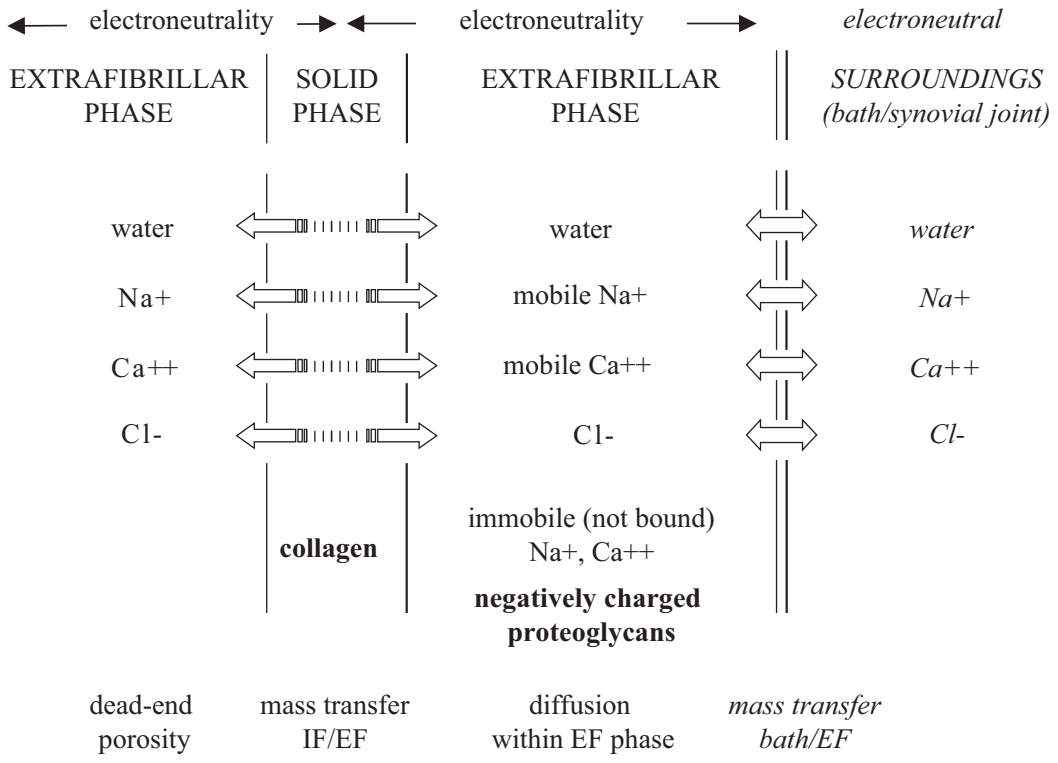

Fig. 14.6.1: Articular cartilage is partitioned in three phases, a solid phase and two fluid phases, Loret and Simões [2005]a. Each fluid phase contains several species. Some of these species are mobile, at least partially: water and ions can enter and leave the intrafibrillar space crossing the collagen fibrils. Proteoglycans which are macromolecules are too large to be admitted into that space. Water and ions of the extrafibrillar phase diffuse within their phase. For points at the surface of the tissue, only the extrafibrillar phase is in contact with the surroundings: species of the intrafibrillar phase should transit through the extrafibrillar fluid to access the synovial joint.

14.6.2 The fictitious membrane surrounding a cartilage specimen

When defining the partition of the species into phases, the fixed charge is of primary concern: should it reside in the solid phase with the collagen fibers, or in the fluid phases, where their effects are of primary importance for the electro-chemomechanical couplings?

According to a kinematic criterion, it would be part of the solid phase. On the other hand, its mechanical effects are related to its concentration with respect to the volume of extrafibrillar water. Some key differences between the two options are listed below:

1. Fixed charge in the solid phase.
   This option has been adopted in a model of expansive geomaterials in Loret et al. [2004]a [2004]b. Let us consider the chemomechanical equilibrium of a tissue with an external reservoir: pore pressure, concentration and electrical potential are continuous at the boundary between the water phase and the reservoir. Moreover, the electrical conductivity vanishes when the external reservoir is quasi-distilled water. In addition, the electroosmotic coefficient k_e and the osmotic coefficient ω are not constrained by compatibility conditions. Thus they have to be provided by additional constitutive equations.

2. Fixed charge in the fluid phase.
   The presence of the fixed charge in the extrafibrillar phase has two main consequences.
   First, pore pressure, concentrations and electrical potential undergo a jump across the interface that separates the cartilage and a bath, even at equilibrium, Fig. 14.6.2. This observation is of primary importance in the interpretation of laboratory experiments and in the identification procedure of material constants. In the finite element context addressed in Chapter 18, it strongly guides the choice of the primary variables. In fact, the

equilibrium condition is phrased in terms of the electrochemical potentials and not in terms of concentrations, pressures or electrical potentials.

Second, the electroosmotic coefficient k_e and the osmotic coefficient ω are constrained by compatibility conditions : in fact, they are shown in Chapter 16 *to result from the formulation*, in explicit or implicit form.

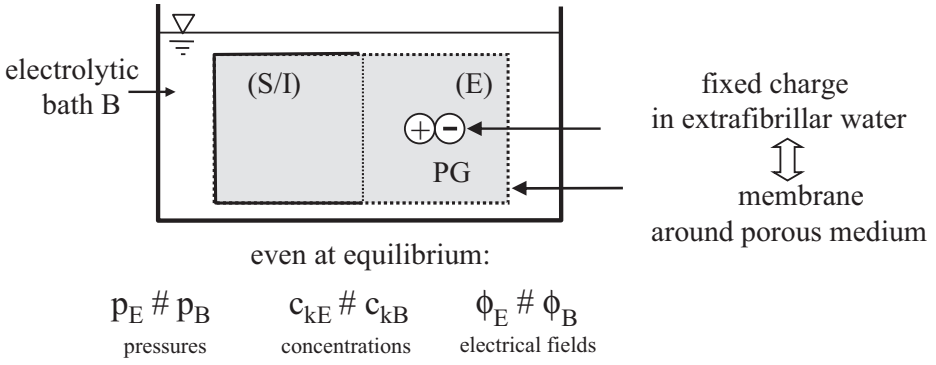

Fig. 14.6.2: The presence of the electrically charged proteoglycans in the extrafibrillar water implies a number of physical entities to be discontinuous across the specimen boundary, as if the specimen was surrounded by a semi-permeable membrane. The sketch displays a delocalized partition of cartilage, isolating the extrafibrillar compartment from the intrafibrillar compartment and solid phase.

14.6.3 A strongly interacting model

The main assumptions which underly the three-phase multi-species model follow a *strongly interacting* model. They have been listed in Loret and Simões [2004] in a purely mechanical perspective. Since deformation, mass transfer and generalized diffusion are accounted for, they need to be re-stated in this more general context, namely,

(H1) Mass balance is required for each species in each phase.

(H2) Momentum balance is required for the mixture as a whole. Water and mobile ions in the extrafibrillar phase are endowed with their own velocities so as to allow water to flow through the solid skeleton and ions to diffuse in their phase and satisfy their own balance of momentum.

(H3) The velocity of any species in the intrafibrillar phase is that of the solid phase, i.e., of collagen, $\mathbf{v}_{k\mathrm{I}} = \mathbf{v}_{\mathrm{S}}$, $\forall k \in \mathrm{I}$. The velocities of the proteoglycans, and of non mobile cations of the extrafibrillar phase, which do not diffuse through the cartilage are also equal to $\mathbf{v}_{\mathrm{S}}$. Thus, the balance of momentum of the above species is not required explicitly, but accounted for by the balance of momentum of the mixture as a whole. Exchange of species between the two fluid phases is viewed as a *mass transfer* and not as a diffusion process.

(H4) Incompressibility of all the constituents gives rise to a Lagrange multiplier interpreted as the intrafibrillar pressure p_{I}. However, in both the intrafibrillar and extrafibrillar phases, each constituent is endowed, by constitutive equations, with its own "generalized pressure" that contains specific contributions in addition to p_{I}.

(H5) Electroneutrality is required for the extrafibrillar fluid phase and for intrafibrillar fluid phase independently. Collagen fibers are charged at non physiological pH. Because collagen is in contact with both fluid phases, its charge is partitioned in the two phases: the charge partition is addressed in Chapter 17.

Although the point is seldom mentioned, the definition of phases in articular cartilages is not unambiguous because the mechanical, chemical and electrical roles of proteoglycans dictate contradictory choices. The consequences of two options are commented further in Section 14.6.2. In particular, proteoglycans move with the solid but their electrical charge plays a key role in the extrafibrillar phase. One way to go around this issue is to consider a single (fluid) phase and a single electroneutrality condition, as in Lai et al. [1991]. However, topological considerations dictate electroneutrality separately for the two fluid phases. Indeed, when electroneutrality is disturbed, typical times to recover equilibrium are expected to be much smaller than transfer times, so that electroneutrality gets established independently in the two fluid compartments, Section 13.6.3. As a direct consequence of the two electroneutrality conditions, the electrical potentials in the two fluid phases are distinct.

14.6.4 Measures of the chemical composition

Various macroscopic measures of mass and volume are used to formulate the constitutive equations. They are defined below. Since a species can be present in more than a single phase, it is endowed with two indices, one referring to the species itself, the other to the phase, e.g., $V_{k\mathrm{K}}$ denotes the volume of species k in phase K. The only exceptions to this convention are proteoglycans and collagen which unambiguously belong to a single phase. Entities at the phase level are referred by the index of the phase, e.g., V_{K} is the volume of phase K.

The current number of moles, volume and mass of the species k in phase K are denoted by $N_{k\mathrm{K}}$, $V_{k\mathrm{K}}$ and $M_{k\mathrm{K}}$. Let the initial volume of the porous medium be V_0 and let $V = V(t) = V_0 \det \mathbf{F}$ be its current volume, $\mathbf{F}$ denoting the deformation gradient, and M its current mass.

Various entities are attached to species:

- some are intrinsic, like the intrinsic density ρ_k, the molar volume $\widehat{v}_k$ and the molar mass $\widehat{m}_k$ linked by $\widehat{m}_k = \rho_k\, \widehat{v}_k$[14.12]. The molar mass is a constant, while the molar volume of compressible species depends on strain and the molar volume of dissolved ions is varying with the ionic strength of the electrolyte;
- some refer to the current volume, like the *volume fraction* $n^{k\mathrm{K}}$ of a species, and n^{K} of a phase,

$$n^{k\mathrm{K}} = \frac{V_{k\mathrm{K}}}{V}, \quad n^{\mathrm{K}} = \sum_{k\in\mathrm{K}} n^{k\mathrm{K}}, \quad \sum_{\mathrm{K=S,I,E}} n^{\mathrm{K}} = 1\,, \tag{14.6.2}$$

and the *apparent* density $\rho^{k\mathrm{K}}$,

$$\rho^{k\mathrm{K}} = \frac{M_{k\mathrm{K}}}{V} = n^{k\mathrm{K}}\,\rho_k \text{ (no sum on k)}, \quad \rho^{\mathrm{K}} = \frac{M_{\mathrm{K}}}{V} = \sum_{k\in\mathrm{K}} \rho^{k\mathrm{K}}, \quad \rho = \frac{M}{V} = \sum_{\mathrm{K=S,I,E}} \rho^{\mathrm{K}}\,; \tag{14.6.3}$$

- some refer to the initial volume like the *volume content* $v^{k\mathrm{K}}$,

$$v^{k\mathrm{K}} = \frac{V_{k\mathrm{K}}}{V_0}, \quad v^{\mathrm{K}} = \frac{V_{\mathrm{K}}}{V_0} = \sum_{k\in\mathrm{K}} v^{k\mathrm{K}}, \quad \sum_{\mathrm{K=S,I,E}} v^{\mathrm{K}} = \frac{V}{V_0} = \det \mathbf{F}\,, \tag{14.6.4}$$

the *mass content* $m^{k\mathrm{K}}$,

$$m^{k\mathrm{K}} = \frac{M_{k\mathrm{K}}}{V_0} = \frac{N_{k\mathrm{K}}\,\widehat{m}_k}{V_0} = \rho_k\, v^{k\mathrm{K}}, \quad m^{\mathrm{K}} = \frac{M_{\mathrm{K}}}{V_0} = \sum_{k\in\mathrm{K}} m^{k\mathrm{K}}, \quad m = \frac{M}{V_0} = \sum_{\mathrm{K=S,I,E}} m^{\mathrm{K}}\,, \tag{14.6.5}$$

and the *mole content*,

$$\mathcal{N}_{k\mathrm{K}} = \frac{N_{k\mathrm{K}}}{V_0}\,. \tag{14.6.6}$$

From $(14.6.4)_3$ follow the incremental and rate relations,

$$\sum_{\mathrm{K=S,I,E}} dv^{\mathrm{K}} = \frac{dV}{V_0} = d\det \mathbf{F}, \quad \sum_{\mathrm{K=S,I,E}} \frac{dv^{\mathrm{K}}}{dt} = \frac{d(\det \mathbf{F})}{dt} = \det \mathbf{F}\, \mathrm{div}\, \mathbf{v}_{\mathrm{S}}\,. \tag{14.6.7}$$

The above entities are *intensive*: as indicated, their phase counterparts are defined by algebraic summation of individual contributions. In turn, the phase entities themselves contribute additively at the level of the porous medium.

Other entities live in their phase, e.g., the molar fractions and the concentrations. The *molar fraction* $x_{k\mathrm{K}}$ of the species k in phase K is defined by the ratio of the mole number $N_{k\mathrm{K}}$ of that species over the total number of moles N_{K} within the phase,

$$x_{k\mathrm{K}} = \frac{N_{k\mathrm{K}}}{N_{\mathrm{K}}}, \quad \sum_{k\in\mathrm{K}} x_{k\mathrm{K}} = 1, \quad \mathrm{K} = \mathrm{S,I,E}\,. \tag{14.6.8}$$

[14.12] As just stated, the same species is usually endowed with distinct properties in the intra- and extrafibrillar phases. Therefore, any property should be referred to by the indices of both the species and the phase. However, because we have in mind incompressible species, the intrinsic mass density might dispense of the phase index. The notation is ambiguous for compressible species. Now, even for incompressible species, *apparent* properties have to refer to both the species and the phase because the volume fractions are certainly distinct in the two phases.

Mole content, mole number and mass content are equivalent variables,

$$\mathcal{N}_{k\mathrm{K}} = \frac{N_{k\mathrm{K}}}{V_0} = \frac{m^{k\mathrm{K}}}{\widehat{m}_k}, \quad k \in \mathrm{K}, \quad \mathrm{K} = \mathrm{S}, \mathrm{I}, \mathrm{E}\,, \tag{14.6.9}$$

and therefore the molar fractions can also be expressed in terms of mass contents,

$$x_{k\mathrm{K}} = \frac{m^{k\mathrm{K}}/\widehat{m}_k}{\sum_{l\in\mathrm{K}} m^{l\mathrm{K}}/\widehat{m}_l}, \quad k \in \mathrm{K}, \quad \mathrm{K} = \mathrm{S}, \mathrm{I}, \mathrm{E}\,. \tag{14.6.10}$$

The *concentration* of an extrafibrillar species is equal to its number of moles referred to the volume of extrafibrillar phase,

$$c_{k\mathrm{E}} = \frac{N_{k\mathrm{E}}}{V_\mathrm{E}} = \frac{N_{k\mathrm{E}}}{N_\mathrm{E}\widehat{v}_\mathrm{E}} = \frac{1}{\widehat{v}_k}\frac{V_{k\mathrm{E}}}{V_\mathrm{E}} = \frac{1}{\widehat{v}_k}\frac{n^{k\mathrm{E}}}{n^\mathrm{E}} = \frac{1}{\widehat{v}_k}\frac{v^{k\mathrm{E}}}{n^\mathrm{E}}\frac{V_0}{V} = \frac{x_{k\mathrm{E}}}{\widehat{v}_\mathrm{E}}\,, \quad k \in \mathrm{E}\,, \tag{14.6.11}$$

with $\widehat{v}_\mathrm{E} = \sum_{k\in\mathrm{E}} x_{k\mathrm{E}}\,\widehat{v}_k \sim \widehat{v}_\mathrm{w}$ the molar volume of the extrafibrillar fluid phase.

Collagen and proteoglycans are macromolecules with a large molar mass, 0.285×10^6 gm for collagen and 2×10^6 gm for PGs. The molar fraction $x_{\mathrm{PG}} = N_{\mathrm{PG}}/N_\mathrm{E}$ and concentration $c_{\mathrm{PG}} = N_{\mathrm{PG}}/V_\mathrm{E}$ of proteoglycans are thus quite small with respect to the other species of the extrafibrillar phase. On the other hand, the valence ζ_{PG} of proteoglycans is large at neutral pH. The *effective* molar fraction y_{PG} and *effective* concentration e_{PG} are commensurable with molar fractions and concentrations of other species, and they are key parameters of the biochemical and biomechanical responses of PGs. To stress this issue, the intrinsic and effective measures used for PGs are listed below,

$$\underbrace{x_{\mathrm{PG}} = N_{\mathrm{PG}}/N_\mathrm{E}}_{\substack{\text{molar}\\\text{fraction}}}, \quad \underbrace{c_{\mathrm{PG}} = N_{\mathrm{PG}}/V_\mathrm{E}}_{\text{concentration}}, \quad \underbrace{y_{\mathrm{PG}} = \zeta_{\mathrm{PG}}\,x_{\mathrm{PG}}}_{\substack{\text{effective}\\\text{molar fraction}}}, \quad \underbrace{e_{\mathrm{PG}} = \zeta_{\mathrm{PG}}\,c_{\mathrm{PG}}}_{\substack{\text{effective}\\\text{concentration}}}\,. \tag{14.6.12}$$

The definitions relative to PGs purposely refer to the extrafibrillar phase : indeed, according to Maroudas, the effects of PGs is primarily felt in that compartment. However, unlike in the formula (14.6.12), the effective concentration reported in the literature usually refers to the total volume or mass of the fluid and, with an opposite sign, it is referred to as fixed charge density FCD, Eqn (14.4.1). Maroudas [1975] reports values of FCD between 0.05 and 0.20 mole per liter of *total* water. According to Gu et al. [1997], the typical value of FCD is about 0.15 M for sound articular cartilage and 0.05 M for osteoarthritic cartilage.

For different zones of the human hip cartilage, Maroudas et al. [1991] indicate values ranging from 0.109 to 0.210 and 0.228 mole per liter of *total* water, equivalent to 0.14, 0.28 and 0.32 mole per liter of EF water. Basser et al. [1998] report a mean FCD of 0.37 mole per liter of EF water for normal hip cartilage. This value drops to 0.167 for osteoarthritic cartilage.

14.6.5 Work and electrochemical potentials

14.6.5.1 Incremental work

The incremental work done per unit initial volume by the total stress $\mathbf{T}$ in the incremental strain $d\mathbf{E}$ of the porous medium and by the *electrochemical potentials* $\mu^{\mathrm{ec}}_{k\mathrm{K}}$ during the addition of mass $dm^{k\mathrm{K}}$ of the species k to the phase K is obtained by summation as,

$$\begin{aligned} d\underline{E} &= \mathbf{T} : d\mathbf{E} + \sum_{k,\mathrm{K}} \mu^{\mathrm{ec}}_{k\mathrm{K}}\, dm^{k\mathrm{K}} \\ &= \mathbf{T} : d\mathbf{E} + \sum_{k,\mathrm{K}} g^{\mathrm{ec}}_{k\mathrm{K}}\, d\mathcal{N}_{k\mathrm{K}}\,. \end{aligned} \tag{14.6.13}$$

Here the electrochemical potentials $\mu^{\mathrm{ec}}_{k\mathrm{K}}$ [unit : $\mathrm{m}^2/\mathrm{s}^2$] are mass based and the fluid mass contents per unit initial volume of the porous medium $m^{k\mathrm{K}}$ are measured in kg/m^3. On the other hand, the electrochemical potentials $g^{\mathrm{ec}}_{k\mathrm{K}} = \widehat{m}_k\,\mu^{\mathrm{ec}}_{k\mathrm{K}}$ [unit : $\mathrm{kg}\times\mathrm{m}^2/\mathrm{s}^2/\mathrm{mole}$] are mole based and the mole contents per unit initial volume of the porous medium $\mathcal{N}_{k\mathrm{K}}$'s are measured in $\mathrm{mole}/\mathrm{m}^3$.

The sum in (14.6.13) involves all species but in practice only the species that change mass contribute and need to be endowed with an electrochemical potential. Collagen and proteoglycans are assumed to maintain their mass and therefore do not contribute to work.

The chemical potential $\mu_{k\mathrm{K}}$ of a species k in phase K identifies a generalized pressure $p_{k\mathrm{K}}$ and a chemical contribution which accounts for the molar fraction $x_{k\mathrm{K}}$. For a charged species in presence of the electrical potential ϕ_{K} [unit volt V=kg×m^2/s^3/A], the electrochemical potential involves in addition an electrical contribution.

For compressible species, the algebraic expression involves an integration which is performed from a reference state to the current state,

$$g^{\mathrm{ec}}_{k\mathrm{K}} = \widehat{m}_k\, \mu^{\mathrm{ec}}_{k\mathrm{K}} = \int \widehat{v}_k\, dp_{k\mathrm{K}} + RT\,\mathrm{Ln}\; x_{k\mathrm{K}} + \zeta_k\,\mathrm{F}\,\phi_{\mathrm{K}}\,, \quad k \in \mathrm{K}\,. \tag{14.6.14}$$

For incompressible species, the expression simplifies to,

$$g^{\mathrm{ec}}_{k\mathrm{K}} = \widehat{m}_k\, \mu^{\mathrm{ec}}_{k\mathrm{K}} = \widehat{v}_k\, p_{k\mathrm{K}} + RT\,\mathrm{Ln}\; x_{k\mathrm{K}} + \zeta_k\,\mathrm{F}\,\phi_{\mathrm{K}}\,, \quad k \in \mathrm{K}\,. \tag{14.6.15}$$

In this formula, $R = 8.31451\,\mathrm{J/mole/K}$ is the universal gas constant, T [unit : K] the absolute temperature, and $\mathrm{F} = 96\,485\,\mathrm{coulomb/mole}$ is Faraday's equivalent charge. The ζ's are the valences.

The extrafibrillar generalized pressures $p_{k\mathrm{E}}$ require constitutive equations: they include in particular

- a purely mechanical contribution p_{I};
- a term aimed at satisfying the chemomechanical equilibrium between the EF and IF compartments in the hypertonic state, and
- a term representing the enthalpy of formation, or dissolution into water, of ionic species and their affinity to PGs.

The intrafibrillar species are subjected to the pressure p_{I}. In addition, an adhesion mechanism tends to oppose the osmotic flow of intrafibrillar water towards the extrafibrillar compartment where the PGs reside.

Clearly, since the valences of electrically neutral species vanish, the chemical and electrochemical potentials of these species are one and the same. The electrochemical potentials are detailed in the subsequent sections and in Section 18.2.2.

14.6.5.2 Chemical affinity, enthalpy of formation, and equilibrium constant

Chemical and physico-chemical reactions involve a linear combination of chemical potentials termed chemical affinity defined by (3.1.17). Its vanishing means equilibrium of the reaction. Chemical affinity includes, besides mechanical, chemical and electrical terms, a constant referred to as equilibrium constant. For example, for the reaction

$$A \rightleftharpoons B\,, \tag{14.6.16}$$

the variations of the numbers of moles of species involved are linked,

$$-\,dN_{\mathrm{A}} = dN_{\mathrm{B}}\,. \tag{14.6.17}$$

Consequently, if the reaction does not give rise to deformation, the incremental work done during this reaction is defined by the chemical affinity $\mathcal{G}$,

$$g_{\mathrm{A}}\, dN_{\mathrm{A}} + g_{\mathrm{B}}\, dN_{\mathrm{B}} \;=\; \Big(\mathcal{G}^0 + RT\,\mathrm{Ln}\,\frac{x_{\mathrm{B}}}{x_{\mathrm{A}}} + \mathrm{F}\,(\zeta_{\mathrm{B}}\phi_{\mathrm{B}} - \zeta_{\mathrm{A}}\phi_{\mathrm{A}})\Big)\, dN_{\mathrm{B}} = \mathcal{G}\, dN_{\mathrm{B}}\,. \tag{14.6.18}$$

The equilibrium of the reaction is defined via the enthalpy $\mathcal{G}^0 = -RT\,\mathrm{Ln}\; K^{\mathrm{eq}}$, which is expressed through a dimensionless equilibrium constant K^{eq}, or conversely $K^{\mathrm{eq}} = \exp(-\mathcal{G}^0/RT)$. At 25°C, a change of K^{eq} of an order of magnitude corresponds to a change of affinity of $5.7\,\mathrm{kJ/mole}$. For acid-base reactions, the equilibrium constant is replaced by a pK, easily interpreted in a pH-scale,

$$\mathcal{G}^0 = -RT\,\mathrm{Ln}\; K^{\mathrm{eq}}, \quad K^{\mathrm{eq}} = \frac{10^{-\mathrm{pK}}}{\widehat{v}_{\mathrm{w}}}\,. \tag{14.6.19}$$

In biochemistry, the standard thermodynamic state corresponds to atmospheric pressure and a temperature of 25°C. The standard enthalpy of formation of substances is the energy required to obtain the substance from its elements, under standard conditions. Therefore the affinity $\mathcal{G}^0$ associated with the reaction (14.6.16) can be obtained from the enthalpies of formation of its reactant and product.

The concentration of water, about 55.55 mole/liter, or its molar volume, $\widehat{v}_{\rm w} = 18\,{\rm cm}^3/{\rm mole}$, are often included in the equilibrium constants. The dimension of these constants helps to decipher whether it is the case or not.

In summary, vanishing of the chemical affinity,

$$\mathcal{G} = RT\,{\rm Ln}\left(\frac{1}{K^{\rm eq}}\,\frac{x_{\rm B}}{x_{\rm A}}\right) + {\rm F}\,(\zeta_{\rm B}\phi_{\rm B} - \zeta_{\rm A}\phi_{\rm A})\,, \tag{14.6.20}$$

defines chemical equilibrium. If the electrical potentials ϕ are known, the ratio of molar fractions results. Conversely, if the concentrations are known, the difference of electrical potentials required to imply equilibrium follows. When $\zeta_{\rm A} = \zeta_{\rm B} = \zeta$, this difference is referred to as Nernst potential,

$$\text{Nernst potential} \quad \phi_{\rm B} - \phi_{\rm A} = -\frac{RT}{\zeta\,{\rm F}}\,{\rm Ln}\left(\frac{1}{K^{\rm eq}}\,\frac{x_{\rm B}}{x_{\rm A}}\right). \tag{14.6.21}$$

If the reactant and product are electrically neutral, equilibrium simplifies to $x_{\rm B}/x_{\rm A} = K^{\rm eq}$. Formally, the reaction has been assumed to be reversible. Still, if $K^{\rm eq}$ is small, then it is actually essentially from right to left, and conversely from left to right if $K^{\rm eq}$ is large.

14.6.5.3 Phasewise electroneutrality

In phase K, the *electrical density* $I_{\rm eK}$ [unit : coulomb/m^3] is defined as the number of moles in the volume V weighted by their charges,

$$I_{\rm eK} = \frac{\rm F}{V}\sum_{k\in{\rm K}}\zeta_k\,N_{k{\rm K}}\;\left[=\,{\rm F}\,n^{\rm E}\sum_{k\in{\rm E}}\zeta_k\,c_{k{\rm E}}\;\text{for K = E}\right]. \tag{14.6.22}$$

According to Assumption (H5), both the intrafibrillar and extrafibrillar fluid phases are electrically neutral,

$$I_{\rm eI} = 0; \quad I_{\rm eE} = 0. \tag{14.6.23}$$

For pH close to 7, the collagen can be considered neutral, Li and Katz [1976]. Given that the PGs are negatively charged at any pH, electroneutrality requires a minimal number of extrafibrillar cations, that we refer to as *non mobile* cations : the charge of these cations balances the large negative charge of the proteoglycans. Let us reiterate that the non mobile sodium cations *do not bind* to the PGs. The situation is more complex for calcium cations, as indicated in Section 16.1.2.6.

Pointwise electroneutrality in each phase has far-reaching consequences which are cast in two propositions:

Proposition 14.1 on dependent and independent chemical variables.

As a further consequence of electroneutrality, the number of moles of chloride anions is no longer an independent variable and it can be eliminated in favor of the numbers of moles of the cations,

$$dN_{\rm ClK} = \sum_{i\in{\rm K_{in}}}\zeta_i\,dN_{i{\rm K}}, \quad dm^{\rm ClK} = \sum_{i\in{\rm K_{in}}}\zeta_i\,\frac{\widehat{m}_{\rm Cl}}{\widehat{m}_i}\,dm^{i{\rm K}}, \quad {\rm K = I,\,E}\,, \tag{14.6.24}$$

with $\rm K_{in}$ the set of independent variables.

The relation holds only in incremental form in the extrafibrillar phase due to the presence of PGs. However it does in total form in the intrafibrillar phase,

$$N_{\rm ClI} = \sum_{i\in{\rm I_{in}}}\zeta_i\,N_{i{\rm I}}, \quad m^{\rm ClI} = \sum_{i\in{\rm I_{in}}}\zeta_i\,\frac{\widehat{m}_{\rm Cl}}{\widehat{m}_i}\,m^{i{\rm I}}\,. \tag{14.6.25}$$

The incremental relations between the molar fractions and the independent variables can now be made explicit, Exercise 14.5. First, let us note the differential form of (14.6.10),

$$\frac{dx_{k{\rm K}}}{x_{k{\rm K}}} = \sum_{l\in{\rm K}}\frac{dm^{l{\rm K}}}{m^{l{\rm K}}}\,(I_{kl} - x_{l{\rm K}})\,, \quad k\in{\rm K}\,. \tag{14.6.26}$$

As another consequence of electroneutrality, the partial derivatives of the molar fractions with respect to the independent mass contents take the form,

$$\frac{m^{i{\rm K}}}{x_{k{\rm K}}}\,\frac{\partial x_{k{\rm K}}}{\partial m^{i{\rm K}}} = I_{ki} - x_{i{\rm K}}\,(1+\zeta_i) + \zeta_i\,\frac{x_{i{\rm K}}}{x_{\rm ClK}}\,I_{k{\rm Cl}}, \quad k\in{\rm K},\; i\in{\rm K_{in}}\,. \tag{14.6.27}$$

In explicit form, with K = I or E, $\mathrm{K_{in}} = \{\mathrm{w}, \mathrm{Na}, \mathrm{Ca}\}$,

$$\begin{aligned}
dx_{\mathrm{wK}} &= (1-x_{\mathrm{wK}})\,\frac{x_{\mathrm{wK}}}{m^{\mathrm{wK}}}\,dm^{\mathrm{wK}} - 2\,x_{\mathrm{wK}}\,\frac{x_{\mathrm{NaK}}}{m^{\mathrm{NaK}}}\,dm^{\mathrm{NaK}} - 3\,x_{\mathrm{wK}}\,\frac{x_{\mathrm{CaK}}}{m^{\mathrm{CaK}}}\,dm^{\mathrm{CaK}},\\
dx_{\mathrm{NaK}} &= -x_{\mathrm{NaK}}\,\frac{x_{\mathrm{wK}}}{m^{\mathrm{wK}}}\,dm^{\mathrm{wK}} + (1-2\,x_{\mathrm{NaK}})\,\frac{x_{\mathrm{NaK}}}{m^{\mathrm{NaK}}}\,dm^{\mathrm{NaK}} - 3\,x_{\mathrm{NaK}}\,\frac{x_{\mathrm{CaK}}}{m^{\mathrm{CaK}}}\,dm^{\mathrm{CaK}},\\
dx_{\mathrm{CaK}} &= -x_{\mathrm{CaK}}\,\frac{x_{\mathrm{wK}}}{m^{\mathrm{wK}}}\,dm^{\mathrm{wK}} - 2\,x_{\mathrm{CaK}}\,\frac{x_{\mathrm{NaK}}}{m^{\mathrm{NaK}}}\,dm^{\mathrm{NaK}} + (1-3\,x_{\mathrm{CaK}})\,\frac{x_{\mathrm{CaK}}}{m^{\mathrm{CaK}}}\,dm^{\mathrm{CaK}},\\
dx_{\mathrm{ClK}} &= -x_{\mathrm{ClK}}\,\frac{x_{\mathrm{wK}}}{m^{\mathrm{wK}}}\,dm^{\mathrm{wK}} + (1-2\,x_{\mathrm{ClK}})\,\frac{x_{\mathrm{NaK}}}{m^{\mathrm{NaK}}}\,dm^{\mathrm{NaK}} + (2-3\,x_{\mathrm{ClK}})\,\frac{x_{\mathrm{CaK}}}{m^{\mathrm{CaK}}}\,dm^{\mathrm{CaK}}.
\end{aligned} \tag{14.6.28}$$

The second proposition follows:

Proposition 14.2 The incremental work expresses in terms of the independent variables.

The electrical potential does not enter the elastic constitutive equations, that can be phrased in terms of chemical potentials rather than *electro*chemical potentials: indeed the electrical potential does no work due to electroneutrality. In fact, the incremental energy (14.6.13) can be recast in terms of the chemical potentials of water w and salts s_1=NaCl and s_2=$CaCl_2$ conjugated to the mass contents of water and (mobile) sodium and calcium cations, Exercise 14.6,

$$\begin{aligned}
d\underline{E} &= \mathbf{T} : d\mathbf{E} + \sum_{k,\mathrm{K}} \mu^{\mathrm{ec}}_{k\mathrm{K}}\, dm^{k\mathrm{K}}\\
&= \mathbf{T} : d\mathbf{E} + \sum_{k,\mathrm{K}} \mu_{k\mathrm{K}}\, dm^{k\mathrm{K}}\\
&= \mathbf{T} : d\mathbf{E} + \sum_{\mathrm{K=I,E}} \sum_{(i,n)\in(\mathrm{K_{in}},\mathrm{K_{ne}})} \mu_{n\mathrm{K}}\, dm^{i\mathrm{K}},
\end{aligned} \tag{14.6.29}$$

with $\mathrm{K_{in}}$ the set of *independent* variables, and $\mathrm{K_{ne}}$ the set of neutral species in phase K = I, E,

$$\underbrace{\mathrm{K_{in}} = \{\mathrm{w}, \mathrm{Na}, \mathrm{Ca}\}}_{\substack{\text{set of}\\ \text{independent variables}}}, \quad \underbrace{\mathrm{K_{ne}} = \{\mathrm{w}, \mathrm{s}_1 = \mathrm{NaCl}, \mathrm{s}_2 = \mathrm{CaCl_2}\}}_{\text{set of neutral species}}. \tag{14.6.30}$$

The entities $\mu_{n\mathrm{K}}$, $n = \mathrm{s}_1, \mathrm{s}_2$, can be viewed as the chemical potentials of the dissociated salts in phase K, namely in accordance with (14.6.15),

$$\widehat{m}_i\,\mu_{n\mathrm{K}} = \begin{cases} \widehat{m}_i\,\mu^{\mathrm{ec}}_{i\mathrm{K}} + \zeta_i\,\widehat{m}_{\mathrm{Cl}}\,\mu^{\mathrm{ec}}_{\mathrm{ClK}}, \\ \\ \widehat{v}_n\,p_{n\mathrm{K}} + RT\,\mathrm{Ln}\;x_{i\mathrm{K}}\,(x_{\mathrm{ClK}})^{\zeta_i}. \end{cases} \tag{14.6.31}$$

The molar volumes $\widehat{v}_n$ and densities ρ_n are defined by the relations,

$$\widehat{v}_n = \rho_n^{-1}\,\widehat{m}_i = \widehat{v}_i + \zeta_i\,\widehat{v}_{\mathrm{Cl}}, \quad (i,n) \in (\mathrm{K_{in}}, \mathrm{K_{ne}}). \tag{14.6.32}$$

It should be stressed that the electrochemical potentials of ions involve the molar fractions of all ions. The molar fraction of chloride ion deduces from the electroneutrality condition, which indicates that it might not be equal to the molar fraction of sodium cations,

- either due to the presence of the fixed charge in the extrafibrillar phase, for example for the sodium electrolyte, $x_{\mathrm{ClE}} = x_{\mathrm{NaE}} + y_{\mathrm{PG}}$;
- or in the presence of a ternary electrolyte, e.g., sodium chloride and calcium chloride: then in the intrafibrillar phase and bath, $x_{\mathrm{ClK}} = x_{\mathrm{NaK}} + 2\,x_{\mathrm{CaK}}$, K = I, B;
- or if water is considered to dissociate into hydrogen and hydroxyl ions.

14.6.5.4 Absolute fluxes, diffusive fluxes and electrical current density

Balance and constitutive equations are phrased in terms of several fluxes, namely mass and volume fluxes, absolute and diffusive fluxes. Due to the incompressibility of the species, mass fluxes and volume fluxes can be viewed as entities that differ only by their units.

The *absolute mass flux* through the solid skeleton $\mathbf{M}_{k\mathrm{K}}$ [unit : $\mathrm{kg/m^2/s}$] and the associated *volume flux* $\mathbf{J}_{k\mathrm{K}}$ [unit : m/s] of the species k in phase K involve a velocity relative to the solid skeleton,

$$\rho_k^{-1}\,\mathbf{M}_{k\mathrm{K}} = \mathbf{J}_{k\mathrm{K}} = n^{k\mathrm{K}}\,(\mathbf{v}_{k\mathrm{K}} - \mathbf{v}_{\mathrm{S}}), \quad k \in \mathrm{K}. \tag{14.6.33}$$

Therefore the fluxes of the species in the solid phase and intrafibrillar phase vanish, since these species move with the solid velocity as a consequence of Assumption (H3),

$$\rho_k^{-1}\,\mathbf{M}_{k\mathrm{K}} = \mathbf{J}_{k\mathrm{K}} = \mathbf{0}, \quad k \in \mathrm{K} = \mathrm{S}, \mathrm{I}\,. \tag{14.6.34}$$

The sum of the fluxes $\mathbf{J}_{k\mathrm{K}}$, $k \in \mathrm{K}$, defines the volume averaged flux $\mathbf{J}_{\mathrm{K}}$ of phase K through the solid skeleton,

$$\mathbf{J}_{\mathrm{S}} = \mathbf{0}, \quad \mathbf{J}_{\mathrm{I}} = \mathbf{0}, \quad \mathbf{J}_{\mathrm{E}} = \sum_{k\in\mathrm{E}} n^{k\mathrm{E}}\,(\mathbf{v}_{k\mathrm{E}} - \mathbf{v}_{\mathrm{S}})\,. \tag{14.6.35}$$

The *diffusive flux* with respect to extrafibrillar water is denoted by $\mathbf{J}^d_{k\mathrm{E}}$,

$$\mathbf{J}^d_{k\mathrm{E}} = n^{k\mathrm{E}}\,(\mathbf{v}_{k\mathrm{E}} - \mathbf{v}_{\mathrm{wE}}), \quad k \in \mathrm{E}\,. \tag{14.6.36}$$

The absolute flux of PGs is zero as a consequence of Assumption (H3), but their diffusive flux does *not* vanish,

$$\mathbf{J}_{\mathrm{PG}} = \mathbf{0}, \quad \mathbf{J}^d_{\mathrm{PG}} = n^{\mathrm{PG}}\,(\mathbf{v}_{\mathrm{S}} - \mathbf{v}_{\mathrm{wE}}) = -\frac{n^{\mathrm{PG}}}{n^{\mathrm{wE}}}\,\mathbf{J}_{\mathrm{wE}}\,. \tag{14.6.37}$$

Conversely the diffusive flux of water vanishes while its absolute flux $\mathbf{J}_{\mathrm{wE}}$ does not. Relations between the different fluxes are detailed in Exercise 14.1.

The *electrical current density* $\mathbf{I}_{\mathrm{eK}}$ in phase K [unit : $\mathrm{A/m^2}$] is defined as the sum of the constituent velocities weighted by their valences and molar densities,

$$\mathbf{I}_{\mathrm{eK}} = \mathrm{F}\sum_{k\in\mathrm{K}} \zeta_k\,\frac{N_{k\mathrm{K}}}{V}\,\mathbf{v}_{k\mathrm{K}}\,. \tag{14.6.38}$$

A uniform velocity for all species of a phase satisfying electroneutrality is seen to be a sufficient condition for the electrical current density to vanish in that phase. Therefore, the electrical current density vanishes in the intrafibrillar phase,

$$\mathbf{I}_{\mathrm{eI}} = \mathbf{0}\,. \tag{14.6.39}$$

Due to electroneutrality, the electrical current density in the extrafibrillar phase $\mathbf{I}_{\mathrm{eE}}$ may be viewed as a sum of either interphase or diffusive fluxes, namely

$$\mathbf{I}_{\mathrm{eE}} = \mathrm{F}\sum_{k\in\mathrm{E}} \zeta_k\,\frac{\mathbf{J}_{k\mathrm{E}}}{\widehat{v}_k} = \mathrm{F}\sum_{k\in\mathrm{E}} \zeta_k\,\frac{\mathbf{J}^d_{k\mathrm{E}}}{\widehat{v}_k}\,. \tag{14.6.40}$$

14.6.6 Balance equations

In line with a strongly interacting multi-species continuum, rules governing the balance equations may be stated :

- the balances of mass are required for all mobile species in the fluid phases but extrafibrillar water, and for the extrafibrillar fluid phase as a whole;
- the balances of mass for the intrafibrillar species are accounted for by the transfer relations;
- the balances of momentum of mobile species of the extrafibrillar phase are accounted for indirectly through the generalized diffusion relations, as explained in a poroelastic context in Section 7.3.2;
- the balance of momentum for the mixture as a whole is required in a standard format.

The balances of momentum of species whose velocities are equal to the solid velocity, namely intrafibrillar species, collagen and PGs, are not required individually. Instead they are included in the balance of momentum of the whole mixture.

14.6.6.1 Balance of mass

A change of mass of the species k of phase K is due a priori to both *transfer*, i.e., a physico-chemical reaction, and *diffusion* within its phase, see Exercise 14.4,

$$\frac{1}{\det \mathbf{F}} \frac{dm^{k\mathrm{K}}}{dt} = \underbrace{\hat{\rho}^{k\mathrm{K}}}_{\substack{\text{mass}\\ \text{transfer}}} - \underbrace{\operatorname{div} \mathbf{M}_{k\mathrm{K}}}_{\text{diffusion}}, \ k \in \mathrm{K}\,. \tag{14.6.41}$$

The symbol div denotes the divergence operator, and d/dt represents the derivative following the solid phase whose velocity is $\mathbf{v}_{\mathrm{S}}$.

The mass changes in the species of the intrafibrillar fluid phase are purely reactive and they are due to transfer, between the fluid phases, of water and ionic species, Fig. 14.6.1,

$$\frac{1}{\det \mathbf{F}} \frac{dm^{k\mathrm{I}}}{dt} = \underbrace{\hat{\rho}^{k\mathrm{I}}}_{\text{mass transfer}}, \ k \in \mathrm{I}\,. \tag{14.6.42}$$

These transfers are governed by the constitutive equations which are developed in Section 10.2.

On the other hand, the extrafibrillar compartment is in contact with both the intrafibrillar phase and the surroundings,

$$\frac{1}{\det \mathbf{F}} \frac{dm^{k\mathrm{E}}}{dt} = \underbrace{\hat{\rho}^{k\mathrm{E}}}_{\text{mass transfer}} - \underbrace{\operatorname{div} \mathbf{M}_{k\mathrm{E}}}_{\text{diffusion}}, \ k \in \mathrm{E}\,. \tag{14.6.43}$$

In the present context, a transfer concerns the same species in both compartments,

$$\hat{\rho}^{k\mathrm{I}} + \hat{\rho}^{k\mathrm{E}} = 0\,, \ k \in \mathrm{I}\,. \tag{14.6.44}$$

For a species that does not transfer we simply set formally its rate of mass transfer to zero. Therefore,

$$\frac{1}{\det \mathbf{F}} \frac{dm^{k\mathrm{E}}}{dt} = -\underbrace{\frac{1}{\det \mathbf{F}} \frac{dm^{k\mathrm{I}}}{dt}}_{\text{mass transfer}} - \underbrace{\operatorname{div} \mathbf{M}_{k\mathrm{E}}}_{\text{diffusion}}, \ k \in \mathrm{E}\,. \tag{14.6.45}$$

A detailed derivation is provided in Exercise 14.4.

As a consequence of (14.6.45) and of the electroneutrality in the two fluid phases, the electrical current density $\mathbf{I}_{\mathrm{eE}}$ defined by (14.6.38) or (14.6.40), may be shown to be divergence free, Exercise 14.2,

$$\operatorname{div} \mathbf{I}_{\mathrm{eE}} = 0\,. \tag{14.6.46}$$

14.6.6.2 Equilibrium, continuing equilibrium and time scale granularity

A number of time scales are involved in laboratory tests on articular cartilages, namely

- external time scales which are representative of loadings of mechanical, chemical and electrical natures;
- internal time scales characterizing the material response.

The material response embeds

- the time dependent mechanical behavior;
- the time dependence of mass transfer;
- the time dependence of diffusion processes, including seepage of water through the extrafibrillar phase and ionic diffusion;
- departure from electroneutrality.

The notion of equilibrium is linked to some time scale. To explore the issue, let us consider chemical equilibrium of a species k at the interface between the two fluid compartments. Chemical equilibrium corresponds to equal chemical potentials. The term "chemical" should be understood as "electrochemical" for a charged species.

The mass transfers are not instantaneous, with respect to the other representative physical phenomena of interest listed above, and the constitutive equations of mass transfer involve specific transfer times. The mass transfers will be shown to be driven by the out-of-balance $\mu_{k\mathrm{I}} - \mu_{k\mathrm{E}}$ in electrochemical potentials across the IF-EF interface.

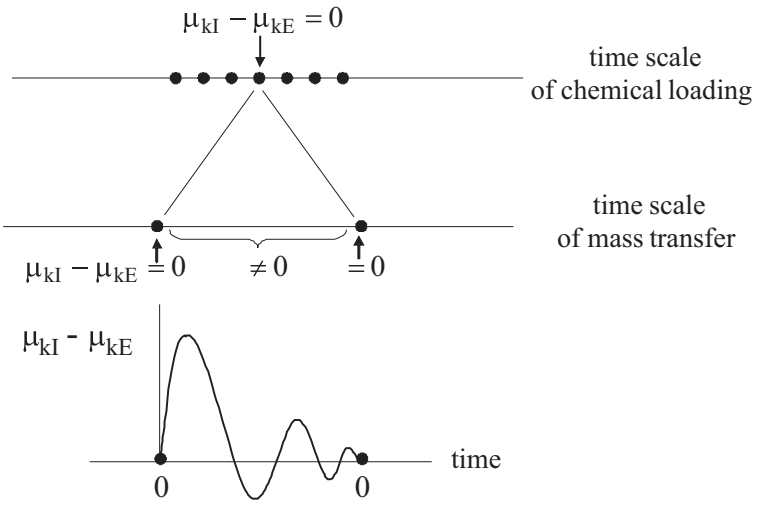

Fig. 14.6.3: Time scale granularity. Time scales may differ by orders of magnitude, depending on the associated physical phenomena. If the time scale of loading is much larger than the transfer time, continuing equilibrium applies at the time scale of the experimentalist: chemical potentials are equal but mass transfer is nevertheless possible.

Continuing equilibrium should be contrasted with equilibrium. Let us consider a chemical laboratory experiment in which the specimen is in contact with a bath whose chemical composition is changed according to a controlled process while the mechanical loading is kept fixed. In the context of continuing equilibrium, mass can transfer even if the chemical potentials $\mu_{k\mathrm{I}}$ and $\mu_{k\mathrm{E}}$ in the two fluid phases adopt a common time profile. This point can be realized by considering that the transfer times are infinitesimally small with respect to the time scale, of granularity Δt, along which the chemical potentials are considered to be equal, Fig. 14.6.3. Indeed, let us assume the latter to be equal at time t_1 and $t_2 = t_1 + \Delta t$. Experimentally they are certainly not equal *within* this interval: this departure allows the transfer to take place, as far as the transfer times are assumed to be smaller than Δt.

As an immediate consequence, transfer equations will not be needed in this chapter where only continuing equilibria are considered: the exchanged masses are then obtained by constraining the material to adapt to the mechanical and chemical loading path. Alternatively, transfer equations should be used if the granularity of the loading path is of the same order of magnitude as, or smaller than, the transfer times. The issue is considered in Section 10.2.

14.6.6.3 Balance of momentum

In absence of external supplies the balance of momentum of the porous medium as a whole reduces to the standard format,

$$\mathrm{div}\ \boldsymbol{\sigma} + \rho\,\mathbf{b} = \mathbf{0}, \tag{14.6.47}$$

where $\rho\,\mathbf{b} = \sum_{k,\mathrm{K}} \rho^{k\mathrm{K}}\,\mathbf{b}_{k\mathrm{K}}$ is the sum of the body forces and acceleration terms. Under quasi-static loading and with the sole gravity $\mathbf{g}$ of intensity g as body force, then $\rho = \sum_{k,\mathrm{K}} \rho^{k\mathrm{K}} = \sum_{\mathrm{K}} \rho^{\mathrm{K}}$ is identified as the mass density of the porous medium as a whole.

For most laboratory tests, inertia has negligible effects on stress and strain with respect to the mechanical and chemical loadings. Since specimens are of small size, the effects of gravity can be neglected in mechanical and chemical tests.

14.6.7 Incompressibility of species

The incompressibility of all individual species is commonly accepted, even if the loads to which soft tissues are subjected may be high. In algebraic form,

$$d\rho_k = 0, \quad \forall k \in \{\mathrm{I},\,\mathrm{E}\}\,. \tag{14.6.48}$$

If all species are incompressible, the change of volume of the solid skeleton, which is the same as that of porous medium, is equal to the change of volume of the extrafibrillar fluid phase due to diffusion,

$$\text{div}\ \mathbf{v}_{\mathrm{S}} + \text{div}\ \mathbf{J}_{\mathrm{E}} = 0\,. \tag{14.6.49}$$

The above relation is self-explanatory (see, however, Exercise 14.4 for a detailed proof). Incompressibility leads also to

Proposition 14.3 the volume change of the mixture expresses in terms of the independent chemical variables.

The volume change of the whole porous medium dV/V_0 is equal to the sum of volume changes due to addition/subtraction of individual species, Eqn (14.6.7). It can be expressed in terms of independent variables, Loret and Simões [2005]a,

$$\begin{aligned} \det\mathbf{F}\ \mathrm{tr}\,(d\mathbf{F}\cdot\mathbf{F}^{-1}) &= \sum_{\mathrm{K=I,E}}\ \sum_{k\in\mathrm{K}} dv^{k\mathrm{K}} \\ &= \sum_{\mathrm{K=I,E}}\ \sum_{k\in\mathrm{K}} \rho_k^{-1}\, dm^{k\mathrm{K}} \\ &= \sum_{\mathrm{K=I,E}}\ \sum_{(i,n)\in(\mathrm{K_{in}},\mathrm{K_{ne}})} \rho_n{}^{-1}\, dm^{i\mathrm{K}}\,, \end{aligned} \tag{14.6.50}$$

where ρ_n is the mass density of the neutral species $n \in \mathrm{K_{ne}}$ defined by (14.6.32). The second relation assumes incompressible species, and the last one is a consequence of phasewise electroneutrality, Exercise 14.6.

14.7 The constitutive structure: deformation, mass transfer, diffusion

The constitutive equations are developed in a thermodynamic framework *à la Biot* where the solid skeleton is taken as reference. Such an approach has been derived in Chapter 4 in a more general context including in addition the growth phenomenon. It is specialized in the current context where the tissue has been partitioned into phases.

A single inequality for the internal entropy production is required for the porous medium as a whole,

$$T\hat{\underline{S}}_{(\mathrm{i})} = -\frac{d\underline{E}}{dt} + \mathbf{T} : \frac{d\mathbf{E}}{dt} - \sum_{k,\mathrm{K}} \underline{\text{div}}\ (\mu^{\mathrm{ec}}_{k\mathrm{K}}\, \underline{\mathbf{M}}_{k\mathrm{K}}) - \mathbf{F}\cdot\underline{\mathbf{M}}_{k\mathrm{K}}\cdot\mathbf{b}_{k\mathrm{E}} \geq 0\,. \tag{14.7.1}$$

With help of the balance of mass (14.6.41), the dissipation $T\hat{\underline{S}}_{(\mathrm{i})}$ may advantageously be recast in a form that highlights the contributions due to deformation, mass transfer and diffusion, namely,

$$T\hat{\underline{S}}_{(\mathrm{i})} = -\frac{d\underline{E}}{dt} + \mathbf{T} : \frac{d\mathbf{E}}{dt} + \sum_{k,\mathrm{K}} \mu^{\mathrm{ec}}_{k\mathrm{K}}\,(\frac{dm^{k\mathrm{K}}}{dt} - \det\mathbf{F}\,\hat{\rho}^{k\mathrm{K}}) - \sum_{k,\mathrm{K}} \underline{\boldsymbol{\nabla}}\mu^{\mathrm{ec}}_{k\mathrm{K}}\cdot\underline{\mathbf{M}}_{k\mathrm{K}} - \mathbf{F}\cdot\underline{\mathbf{M}}_{k\mathrm{K}}\cdot\mathbf{b}_{k\mathrm{E}} \geq 0\,. \tag{14.7.2}$$

The inequality is viewed/partitioned as the sum of three terms of distinct natures, and which consequently are required to be positive separately,
